and V. A. Dogiel⁵

ABSTRACT

We have investigated the properties of a group of γ -ray emitting globular clusters (GCs) which have recently been uncovered in our Galaxy. By correlating the observed γ -ray luminosities L_γ with various cluster properties, we probe the origin of the high energy photons from these GCs. We report L_γ is positively correlated with the encounter rate Γ_c and the metallicity $[\text{Fe}/\text{H}]$ which place an intimate link between the gamma-ray emission and the millisecond pulsar population. We also find a tendency that L_γ increase with the energy densities of the soft photon at the cluster location. Furthermore, the two-dimensional regression analysis suggests that L_γ , soft photon densities, and $\Gamma_c/[\text{Fe}/\text{H}]$ possibly span fundamental planes which potentially provide better predictions for the γ -ray properties of GCs.

Subject headings: gamma rays: stars — globular clusters: general — pulsars: general

1. INTRODUCTION

Millisecond pulsars (MSPs) are generally believed as the descendents of the low-mass X-ray binaries (LMXBs) (Alpar et al. 1982). As the formation rate per unit mass of LMXBs is orders of magnitude greater in globular clusters (GCs) than in the Galactic field (Katz

1975; Clark 1975), it is not surprise that 80% of the detected MSPs are located in GCs⁶ (cf. Manchester et al. 2005). The relatively high formation rate of LMXBs and MSPs is a natural consequence of the frequent stellar encounters. With the X-ray populations in various GCs have been revealed by the *Chandra X-Ray Observatory*, Pooley et al. (2003) and Gendre et al. (2003) have found a positive correlation between the number of LMXBs in GCs and the stellar encounter rate, Γ_c . This provides evidence for the dynamical formation of LMXBs in GCs. As the descendents of the LMXBs, MSPs are also expected to have a dynamically origin.

Very recently, with the corrections of the observational effects in the radio pulsar surveys toward different GCs, Hui, Cheng & Taam (2010) have found a positive correlation between the MSP populations in GCs and Γ_c , which has long been predicted. Moreover, the authors have also found another positive correlation between the metallicity and the MSP population. This relation is not unexpected as the high metallicity in a GC can result in a more efficient orbital shrinkage by magnetic braking. Therefore, the parameter space for the successful Roche-lobe overflow is enhanced (Ivanova 2006) and subsequently lead to a higher formation rate of MSPs.

A brand new window for investigating the MSPs in GCs has been open by the launch of the *Fermi Gamma-ray Space Telescope*. Since MSPs are the only steady γ -ray emitters in GCs, observations with *Fermi* can provide an alternative channel for investigating MSP populations. Shortly after the commence of its operation, the Large Area Telescope (LAT) onboard the spacecraft has detected γ -rays from 47 Tucanae (hereafter 47 Tuc) (Abdo et al. 2009). Terzan 5, which hosts the largest known MSP population, has also been subsequently detected (Kong et al. 2010). As the sensitivity of LAT increases monotonically with the continuous all-sky survey, a total of 15 confirmed detections of γ -ray emitting GCs have very recently been reported by Abdo et al. (2010a; 2010b) and Tam et al. (2010). Using ~ 1.5 years of LAT data, Abdo et al. (2010a) have detected 6 new γ -ray GCs besides 47 Tuc and Terzan 5. On the other hand, Tam et al. (2010) have recently reported 7 other new detections with ~ 2 years data. Among all known γ -ray GCs, Liller 1, which has the highest metallicity in our Milky way, is also found to have the highest γ -ray luminosity (Tam et al. 2010). This discovery further suggests that the effects of metallicity cannot be neglected. Thanks to these surveys, we are able to study these clusters as a unique class for the first time.

To explain the γ -rays from GCs, there are two main streams. Venter & de Jager (2008) and Venter et al. (2009) suggest the γ -rays are originated from the curvature radiation of

⁶see also <http://www.naic.edu/~pfreire/GCpsr.html>

electrons in MSP magnetospheres. However, the frequent stellar interactions can lead to a complicated magnetic field structure (Cheng & Taam 2003), which can possibly explain the difference of the radio and X-ray properties of MSPs in GCs with respect to those located in the Galactic field (cf. Hui, Cheng & Taam 2009, 2010). One consequence of the complicated surface magnetic field is to turn off the accelerating region for producing high energy photons. Ruderman & Cheng (1988) argue that if the open field lines are curving upward due to the effect of local field then in this case e^-/e^+ pair production and outflow can occur on all open-field lines. As a result, the outer-magnetospheric gap is quenched by these pairs. This scenario is supported by the fact that the MSPs in 47 Tuc are essentially thermal X-ray emitters (Bogdanov et al. 2006). All these demonstrate the potential difficulties of the pulsar magnetospheric model in explaining the observed γ -rays from GCs, which motivate the exploration of additional / alternative emission mechanisms.

On the other hand, Bednarek & Sitarek (2007) have proposed that the inverse Compton scattering (ICS) could be a possible mechanism to produce γ -rays from GCs. In their model they predict that GCs could be sources of GeV-TeV photons. Unfortunately they have ignored the contribution from the Galactic background photons. Very recently, through generalizing the ICS model by including various soft photon fields, Cheng et al. (2010) have found that the observed γ -ray spectra of all 8 γ -ray GCs reported by Abdo et al. (2010a) can be well-modeled by the ICS between relativistic electrons/positrons in the pulsar wind of MSPs in the GCs and the background Galactic soft photons. This provides another possible explanation for the origin of the γ -rays.

In this paper, we report the results from exploring the γ -ray emission properties by comparing with various cluster properties, which provides us with insight on the origin of the γ -rays from this class of GCs. In §2, we report the method and the results from the correlation and the regression analysis. We subsequently discuss the implication of these results in §3.

2. CORRELATION & REGRESSION ANALYSIS

Abdo et al. (2010a) and Tam et al. (2010) have reported 15 GCs with firm detections. This sample size is somewhat larger than that adopted by Pooley et al. (2003) for investigating the relations between the X-ray point source populations in GCs and various cluster parameters. The sensitivity limit of the current sample is $\sim 6 \times 10^{-12}$ erg cm $^{-2}$ s $^{-1}$ (0.1-100 GeV). The properties of 15 confirmed γ -ray GCs are summarized in Table 1 and the entries are explained in the following.

^f γ -ray luminosities adopted from in Abdo et al. (2010a) and Tam et al. (2010)

For choosing the cluster parameters for the correlation analysis, we have considered two-body encounter rate Γ_c , metallicity $[\text{Fe}/\text{H}]$, absolute visual magnitude M_V , as well as Galactic background optical / infrared photon densities at the locations of the GCs $u_{\text{optical}} / u_{\text{IR}}$.

Γ_c is the most obvious parameter related to the binary formation rate and hence the number of MSP in a GC. This parameter can be estimated as $\rho_0^2 r_c^3 \sigma_0^{-1}$ where ρ_0 is the central luminosity density, r_c is the core radius and σ_0 is the velocity dispersion at the cluster center. σ_0 are adopted from Gnedin et al. (2002). For ρ_0 and r_c , the values are taken from Harris (1996; 2003 version) and modified for the distances adopted for this analysis (cf. Tab. 1). Besides Γ_c , Hui et al. (2010) have shown that $[\text{Fe}/\text{H}]$ are also a key parameter in determining the size of the MSP population in a GC. The values of $[\text{Fe}/\text{H}]$ are taken from Harris (1996). On the other hand, if stellar encounters were not the major channel of the binary formation, one would expect the binary population to be correlated with the cluster mass M_{GC} for a primordial binary origin (Lu et al. 2009; Lan et al. 2010). Pooley et al. (2003) have estimated the cluster mass by integrating the King’s profiles of the GCs. And therefore, their mass estimates are naturally correlated with Γ_c . On the other hand, assuming a constant mass-to-light ratio, M_{GC} can also be estimated from the absolute visual magnitude M_V : $M_{\text{GC}} = 10^{-0.4M_V}$ (cf. Hui et al. 2010; Lu et al. 2009). Different from the estimates adopted by Pooley et al. (2003), the correlations between our mass estimates with Γ_c is only confident at the level less than 53% (see Figure 1a). Also, the correlation between M_V and $[\text{Fe}/\text{H}]$ only attains a confidence level $\lesssim 56\%$. The values of M_V are also taken from Harris (1996) and modified for the adopted distances as presented in Table 1.

Apart from the number of MSPs, in the context of ICS model, the γ -ray luminosity of a GC also depends on the energy density of the soft photon field (see Cheng et al. 2010). There are three components of background photons in the Galaxy which can interact with the relativistic leptons: they are relic, infrared and optical photons. As the energy density of the relic photons is uniform and does not vary from cluster to cluster, we ignore it in our analysis. We obtain the estimates of Galactic optical and infrared photon density, u_{optical} and u_{IR} with the GALPROP code (Strong & Moskalenko 1998).

Without a priori knowledge of the distributions of the tested quantities, we follow Pooley et al. (2003) to adopt a nonparametric correlation analysis. The computed Spearman rank correlation coefficients between L_γ and various tested quantities are tabulated in Table 2. We have also computed the linear correlation coefficients (i.e. Pearson’s r) for an intuitive account for the data scattering, though they are less robust than the Spearman ranks in quantifying the correlations. We have also performed the 1-dimensional regression analysis. The best-fit parameters are also given in Table 2. All the quoted uncertainties are 95%

confidence intervals. The best-fit relations of these quantities with L_γ are plotted as solid straight lines in Figure 1b and Figure 2. We have also plotted the upper and lower 95% confidence bands for a visual comparison for the data scattering in each panel.

Among all these parameters, the weakest correlation is found for the $\log L_\gamma - M_V$ relation which is only significant at $\sim 15\%$ confidence level. Therefore, there is no convincing correlation between these two quantities (see Figure 1b). On the other hand, the correlations of L_γ with Γ_c and $[\text{Fe}/\text{H}]$ are confident at a level over 99% (see Figure 2). All these findings are fully consistent with the results from analysing the radio MSP population (Hui et al. 2010).

While the correlation between L_γ and Γ_c was reported by Abdo et al. (2010a) with 8 GCs, the effect of metallicity was ignored in their work. From the 95% confidence bands shown in Figure 2, the degree of data scattering of the $\log L_\gamma - [\text{Fe}/\text{H}]$ relations is found to be the smallest among all the tested single parameters. This can be also reflected by the fact that its corresponding linear correlation attains the confidence levels over 99.9%.

For the tested soft photon fields, Figure 2 shows that L_γ also tends to increase with their energy densities. For u_{optical} and u_{IR} , the confidence levels for the correlations are $> 96\%$ and $> 99\%$ respectively.

In comparison to the $\log L_\gamma - \log \Gamma_c$ and $\log L_\gamma - [\text{Fe}/\text{H}]$ relations, the relatively large scattering of the data points in the plots of $\log L_\gamma - \log u_{\text{optical}}$ and $\log L_\gamma - \log u_{\text{IR}}$ can be due to the fact that the GALPROP code is a simplification of the real situation in the Galaxy, which assumes an axisymmetric distribution of all parameters of the program (cf. Strong & Moskalenko 1998). Although it provides reliable average density of background photons in the Galaxy, the real photon densities at the locations of the GCs can differ by a factor of a few, in particular for those close to the disk.

Despite the scattering, the correlation analysis strongly suggests L_γ is likely related to the soft photon energy density estimates. This inference is consistent with the ICS modeling the γ -ray spectra of GCs (Cheng et al. 2010) which indicates neither the number of MSPs nor the soft photon energy density is the sole factor in determining L_γ . With this consideration, we investigate if L_γ , $\Gamma_c/[\text{Fe}/\text{H}]$, and $u_{\text{optical}}/u_{\text{IR}}$ span a fundamental plane by a 2-dimensional regression analysis. We have examined the sample with the following relations:

$$\log L_\gamma = a_1 + a_2 \log \Gamma_c + a_3 \log u_{\text{optical}} \quad (1)$$

$$\log L_\gamma = a_4 + a_5 \log \Gamma_c + a_6 \log u_{\text{IR}} \quad (2)$$

$$\log L_\gamma = a_7 + a_8 [\text{Fe}/\text{H}] + a_9 \log u_{\text{optical}} \quad (3)$$

$$\log L_\gamma = a_{10} + a_{11} [\text{Fe}/\text{H}] + a_{12} \log u_{\text{IR}}. \quad (4)$$

The best-fit parameters are tabulated in Table 3. We have shown the edge-on view of these best-fit fundamental plane relations in Figure 3. In comparison with Figure 2, the data scatter in these plots are somewhat reduced which suggest these fundamental plane relations can possibly provide us with better γ -ray luminosity predictors than the single parameter relations. To better constrain the uncertainties of these parameters, we have further computed the 1σ , 2σ and 3σ confidence contours for various parametric spaces which are shown in Figure 4.

3. DISCUSSION

We have examined the γ -ray emission properties of a group of GCs. By investigating the possible correlations between the γ -ray power and a number of cluster properties, we shed light on the origin of the γ -rays from these GCs. First of all, the correlation between L_γ and Γ_c suggests the high energy radiation are intimately related to the population of dynamically-formed objects, which are presumably MSPs, confirming Abdo et al. (2010a) who used 8 GCs in their study. Together with the lack of any correlation with M_V and hence the cluster mass, this is fully consistent with the inference suggested by Hui et al. (2010) and consolidates the dynamical formation scenario of MSPs in GCs.

Apart from Γ_c , we have found that L_γ is also positively correlated with $[\text{Fe}/\text{H}]$. This is well-consistent with the tendency deduced from studying the radio MSP population in GCs (Hui et al. 2010) and the fact that the GC possesses the highest $[\text{Fe}/\text{H}]$ also has the highest L_γ (Tam et al. 2010). Ivanova (2006) proposes that the absence of the outer convective zone in metal-poor main sequence donor stars in the mass range of $0.85M_\odot - 1.25M_\odot$, in comparison to their metal rich counterparts can be responsible, since the absence of magnetic braking in such stars precludes orbital shrinkage, thereby, significantly reducing the binary parameter space for the production of bright LMXBs. For a conventional scenario, MSPs are the old pulsars that have passed through the death-line in $P - \dot{P}$ diagram which are

subsequently spun-up in the binaries. As the metallicity determines the parameter space for successful Roche-lobe overflow, it is also a key parameter in determining the intrinsic number of MSPs in a GC (Hui et al. 2010; Ivanova 2006).

We note that the link between the LMXBs in extragalactic GCs and the metallicity is somewhat weaker than with the cluster mass (e.g. Sivakoff et al. 2007; Kim et al. 2006; Kundu et al. 2002), which is different from the inference drawn from our investigation of the Galactic MSP-hosting or γ -ray selected clusters. However, a direct comparison between these two populations has to be cautious. As the MSPs are long-lived and are produced by the previous generations of LMXBs, their dynamical properties might be different from that of the LMXB population currently observed. Since the relaxation time at the cluster core is generally longer than the lifetime of LMXBs, the cluster is continuously evolved with mass segregation at the cluster center which can result in a varying formation rate of compact binaries (cf. the discussion in Hui et al. 2010). Also, while a large number of LMXB-hosting GCs in Virgo cluster early-type galaxies have relaxation times > 2.5 Gyr, there is no single GC in our Galaxy with a relaxation timescale larger than this value contains an active LMXB (cf. Sivakoff et al. 2007). Although the reason is still unclear, this suggests possible different properties between the Milky Way GCs and the extragalactic ones. Further investigations are required to understand the difference.

It is instructive to compare the fundamental plane relations of the γ -ray population with the best-fits inferred from the radio MSP population in GCs. Hui et al. (2010) have found that the slopes of $\log \Gamma_c$ and $[\text{Fe}/\text{H}]$ inferred from the radio GC MSPs population are 0.69 ± 0.11 and 0.72 ± 0.11 respectively. Within these quoted uncertainties, the slope of the $[\text{Fe}/\text{H}]$ relation for the radio population is found to intersect with the 2σ error contours for the corresponding parameters of the γ -ray fundamental plane relations (i.e. a_8 and a_{11}). On the other hand, the logarithmic slope of the Γ_c relation for the radio population is only marginally overlapped with the rims of the 3σ error contours for the corresponding parameters inferred from the γ -ray population (i.e. a_2 and a_5).

We have also identified possible positive correlations with various soft photon fields which have significances compatible with those for the encounter rate and the metallicity. These correlations are not expected from the magnetospheric model. Together with the uncertainty of the sustainability of the outergaps in the MSPs in GCs (see §1), our finding further motivate the exploration of alternative explanations for the origin of the observed γ -ray from GCs.

Abdo et al. (2010a) have argued that the γ -ray emission is magnetospheric in nature because of the hard photon indices and the cutoff energies inferred from the phenomenological model is consistent with the values expected from the magnetospheric model. On the

other hand, Cheng et al. (2010) have recently found that the ICS model can also describe the observed γ -ray spectra of all the GCs discovered by Abdo et al. (2010a) very well. Simply based on the model fitting, we were not able to discriminate these two scenarios unambiguously. However, different from the case of the magnetospheric model, positive correlation between the energy density of the soft photon fields are expected in a ICS scenario as the ICS power is directly proportional to soft photon energy density.

The energy density of the background soft photon field depends on the location of the cluster. We notice these γ -ray GCs are possibly resided in the Galactic bulge and therefore they are also metal-rich clusters. This results in a natural correlation between the metallicity and the soft photon energy density with a significance $> 95\%$. Therefore, it is non-trivial to disentangle the effects of these two parameters.

In any case, our investigation strongly suggests that either the metallicity or the soft photon energy density has to be the new parameter, in addition to Γ_c , in determining the observed γ -ray luminosities. This inference is supported by comparing the results reported by Abdo et al. (2010a) and Tam et al. (2010). Apart from the 8 confirmed cases, Abdo et al. (2010a) have also reported 5 non-detections which include three upper-limits and two other cases with the γ -ray emission slightly offset from the respective GC cores. With the LAT data of a longer exposure, Tam et al. (2010) have found a larger number of γ -ray GCs including 4 previously non-detected cases in Abdo et al. (2010a). This leaves M 15 to be the only non-detected GC in Abdo et al. (2010a). This is not unexpected from trends of metallicity and background soft photon energy density. Although the encounter rate of M 15 ($\Gamma_c = 53.9$) is even higher than M 62, its metallicity ($[\text{Fe}/\text{H}] = -2.26$) and the background soft energy densities at its location ($u_{\text{optical}} = 0.44 \text{ eV cm}^{-3}$; $u_{\text{IR}} = 0.11 \text{ eV cm}^{-3}$) are much lower than those of all 15 confirmed γ -ray GCs.

In view of the aforementioned complication, it is not possible to discriminate the ICS and the magnetospheric scenarios unambiguously simply based on the currently available information. Also, there is still a degeneracy within the context of ICS model. Cheng et al. (2010) show that the γ -ray spectrum from 47 Tuc can be explained equally well by upward scattering of either the relic photons, the Galactic infrared photons or the Galactic optical photons whereas the γ -ray spectra from the other seven GCs reported by Abdo et al. (2010a) are best fitted by the upward scattering of either the Galactic infrared photons or the Galactic optical photons. This has prompted us also to discriminate which source provides the predominant soft photon field for ICS.

Since the IC radiation power is directly proportional to the energy density of the soft photon field, a logarithmic slope of unity is thus expected for the fundamental plane parameters a_3 , a_6 , a_9 and a_{12} . For the corresponding parameters of u_{IR} (i.e. a_6 and a_{12}), the line of

unity is found to cut through the centers of the 1σ error contours for both Γ_c and $[\text{Fe}/\text{H}]$ fundamental plane relations. On the other hand, for the parameters correspond to u_{optical} (i.e. a_3 and a_9), the expected value is only marginally intersected with their 3σ error contours. Although an unambiguous conclusion cannot be drawn from the current population yet, the comparison between the theoretical expectation and the fundamental plane parameters does favor the scenario involving the background infrared emission as the soft photon field for IC upscattering.

We would like to point out that the predicted spectral shape in energy regime much larger than 10 GeV is significantly different for different soft photon fields (cf. Fig. 2 in Cheng et al. 2010). Therefore, observations with TeV facilities, such as MAGIC, HESS and VERITAS, can be feasible to lift up this degeneracy. Furthermore, as the ICS model and the magnetospheric model predict a rather different TeV spectrum for GCs (Cheng et al. 2010; Venter et al. 2009), TeV observations in the future can possibly better discriminate these two possible contributions of soft photons.

Constraints for the emission model can also be derived from the other energy bands. With the diffusion of the relativistic pulsar wind particles, it has been shown that extended radio and X-ray emission from the GCs can also be produced by synchrotron radiation and ICS respectively (Cheng et al. 2010). This is consistent with the recent discovery of the diffuse X-rays around Terzan 5 which extended up ~ 10 pc (Eger, Domainko & Clapson 2010). Although a clear scenario cannot be identified yet, these diffuse X-rays are more likely to have a non-thermal origin (Eger, Domainko & Clapson 2010). Assuming these X-rays are originated from the tail of ICS, the corresponding γ -ray spectrum can be calculated (Cheng et al. 2010). Therefore, a systematic search for the extended X-ray and radio feature outside the half-mass radii of the other γ -ray GCs can provide us independent constraints.

In exploring the fundamental plane relations, our analysis suggests that by combining the soft photon energy densities with $\Gamma_c/[\text{Fe}/\text{H}]$ the data scattering can be reduced. These best-fit relations can provide the indicators in identifying what kind of GCs are potential γ -ray sources for a further search. And the other way round, any deeper γ -ray search from the GCs can result in an enlarged sample size and a lower sensitivity limit than the current value (i.e. 6×10^{-12} erg cm $^{-2}$ s $^{-1}$), which will certainly enable a further test for all these reported relations.

The authors would like to thank Kinwah Wu and anonymous referee for the useful discussion and providing comments for improving the quality of this manuscript. CYH is supported by research fund of Chungnam National University in 2010. KSC is supported by a GRF grant of Hong Kong Government under HKU700908P. DOC and VAD are supported

by the RFBR grant 08-02-00170-a, the NSC-RFBR Joint Research Project RP09N04 and 09-02-92000-HHC-a. And AKHK is supported partly by the National Science Council of the Republic of China (Taiwan) through grant NSC96-2112-M007-037-MY3 and a Kenda Foundation Golden Jade Fellowship.

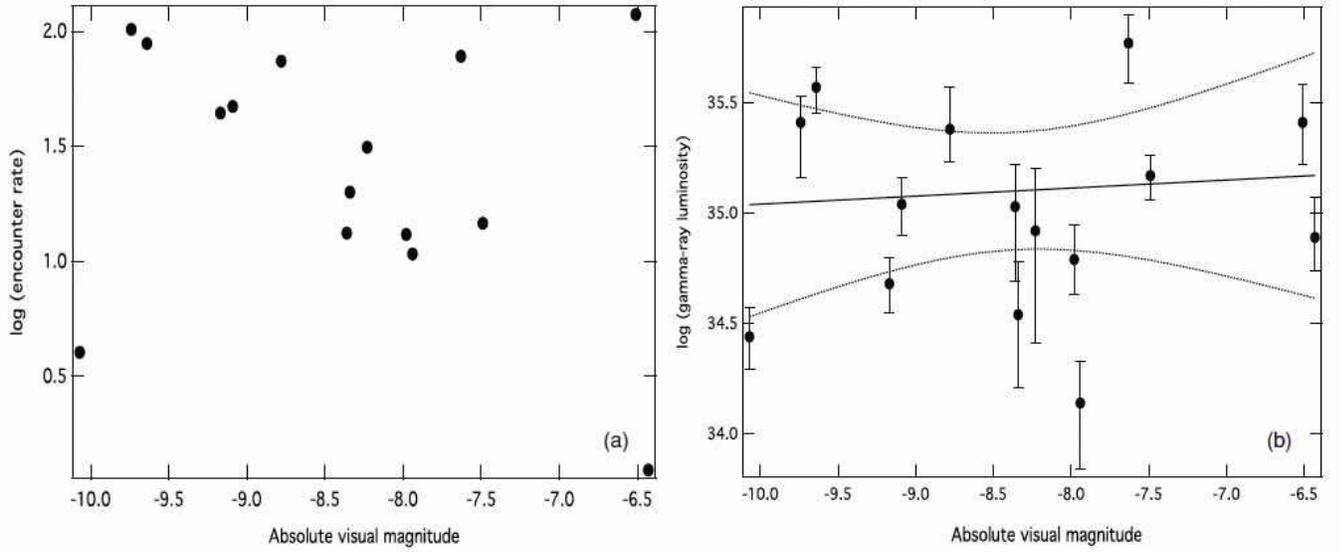

Fig. 1.— **a.** Two-body encounter rate Γ_c vs. absolute visual magnitude M_V . **b.** The γ -ray luminosity L_γ vs. M_V . The straight line represents the best-fit straight line with the errors of the data points fully taken into account. The dotted lines represent the upper and the lower 95% confidence bands.

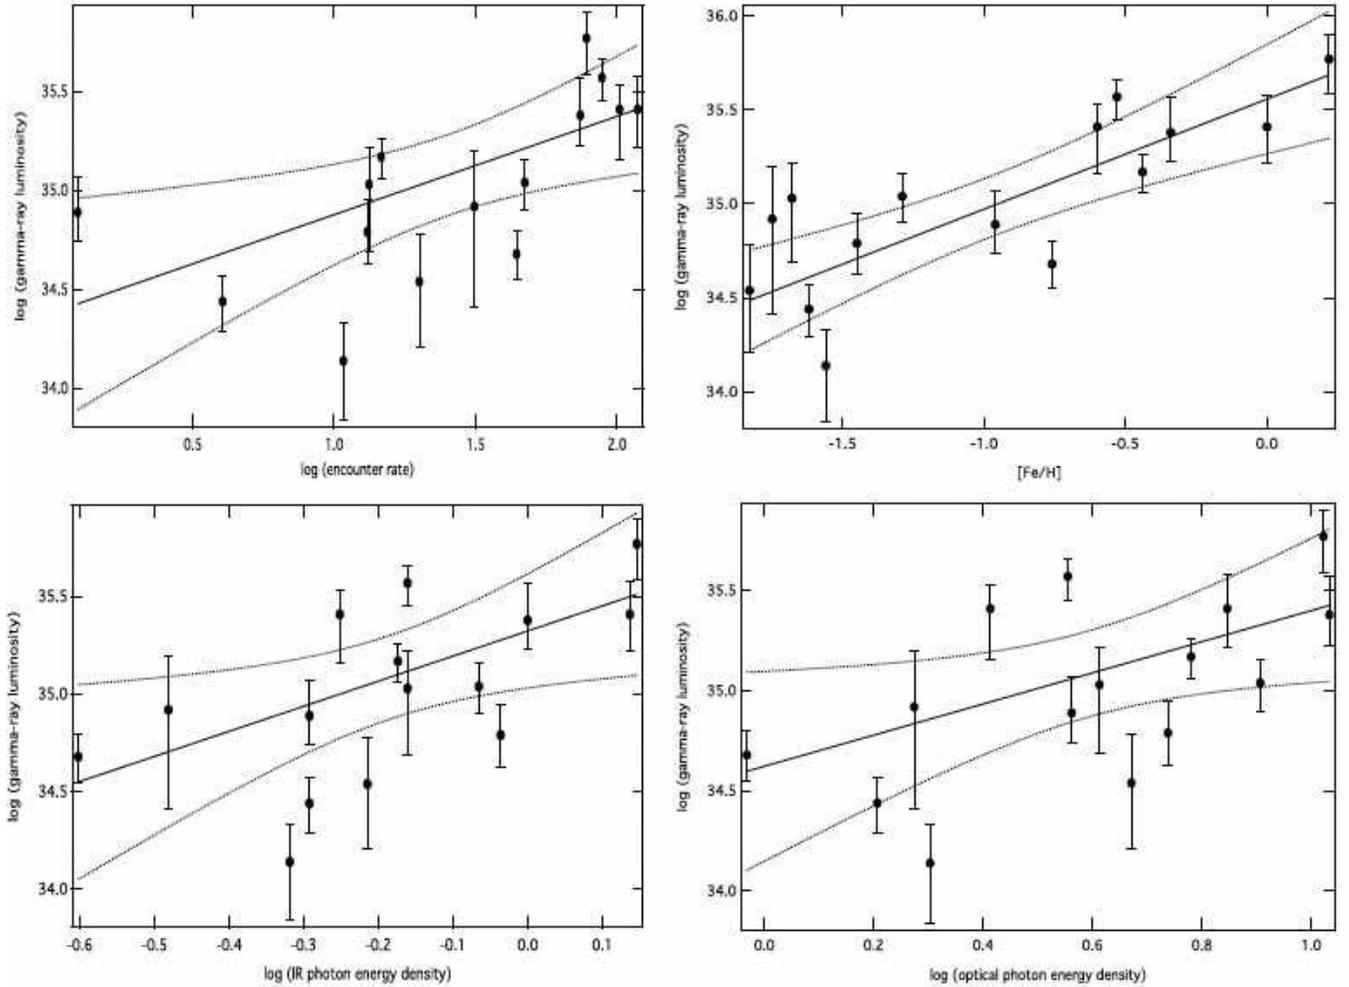

Fig. 2.— L_γ vs. various individual cluster properties. The straight lines in the plots represent the best-fits from the linear regression with the errors of the data points fully taken into account. The dotted lines represent the upper and the lower 95% confidence bands.

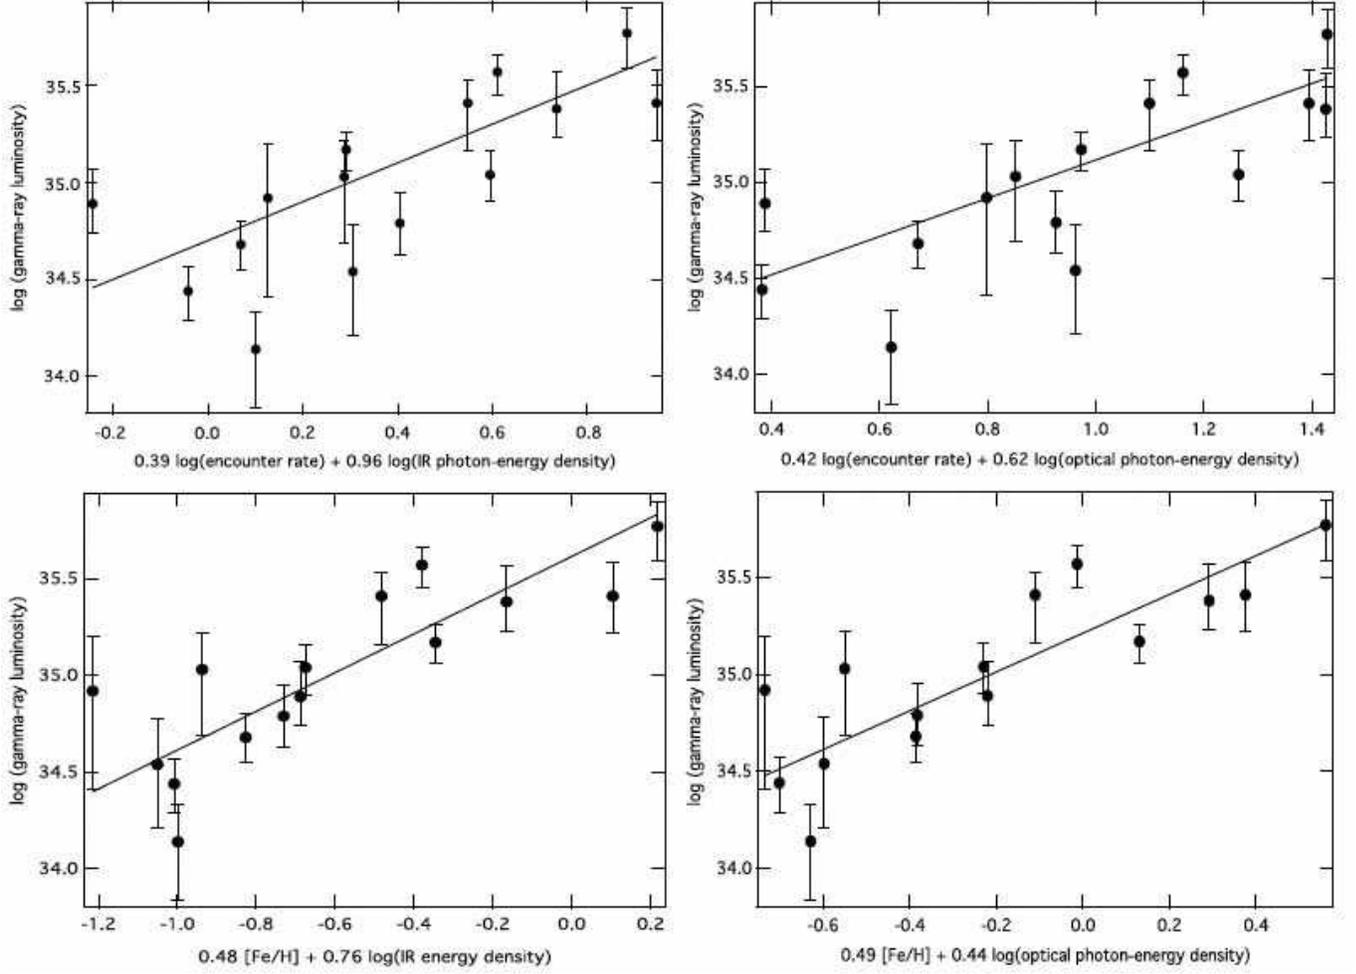

Fig. 3.— The edge-on views of the fundamental plane relations of γ -ray GCs. The straight lines in the plots represent the projected best-fits given in Table 3.

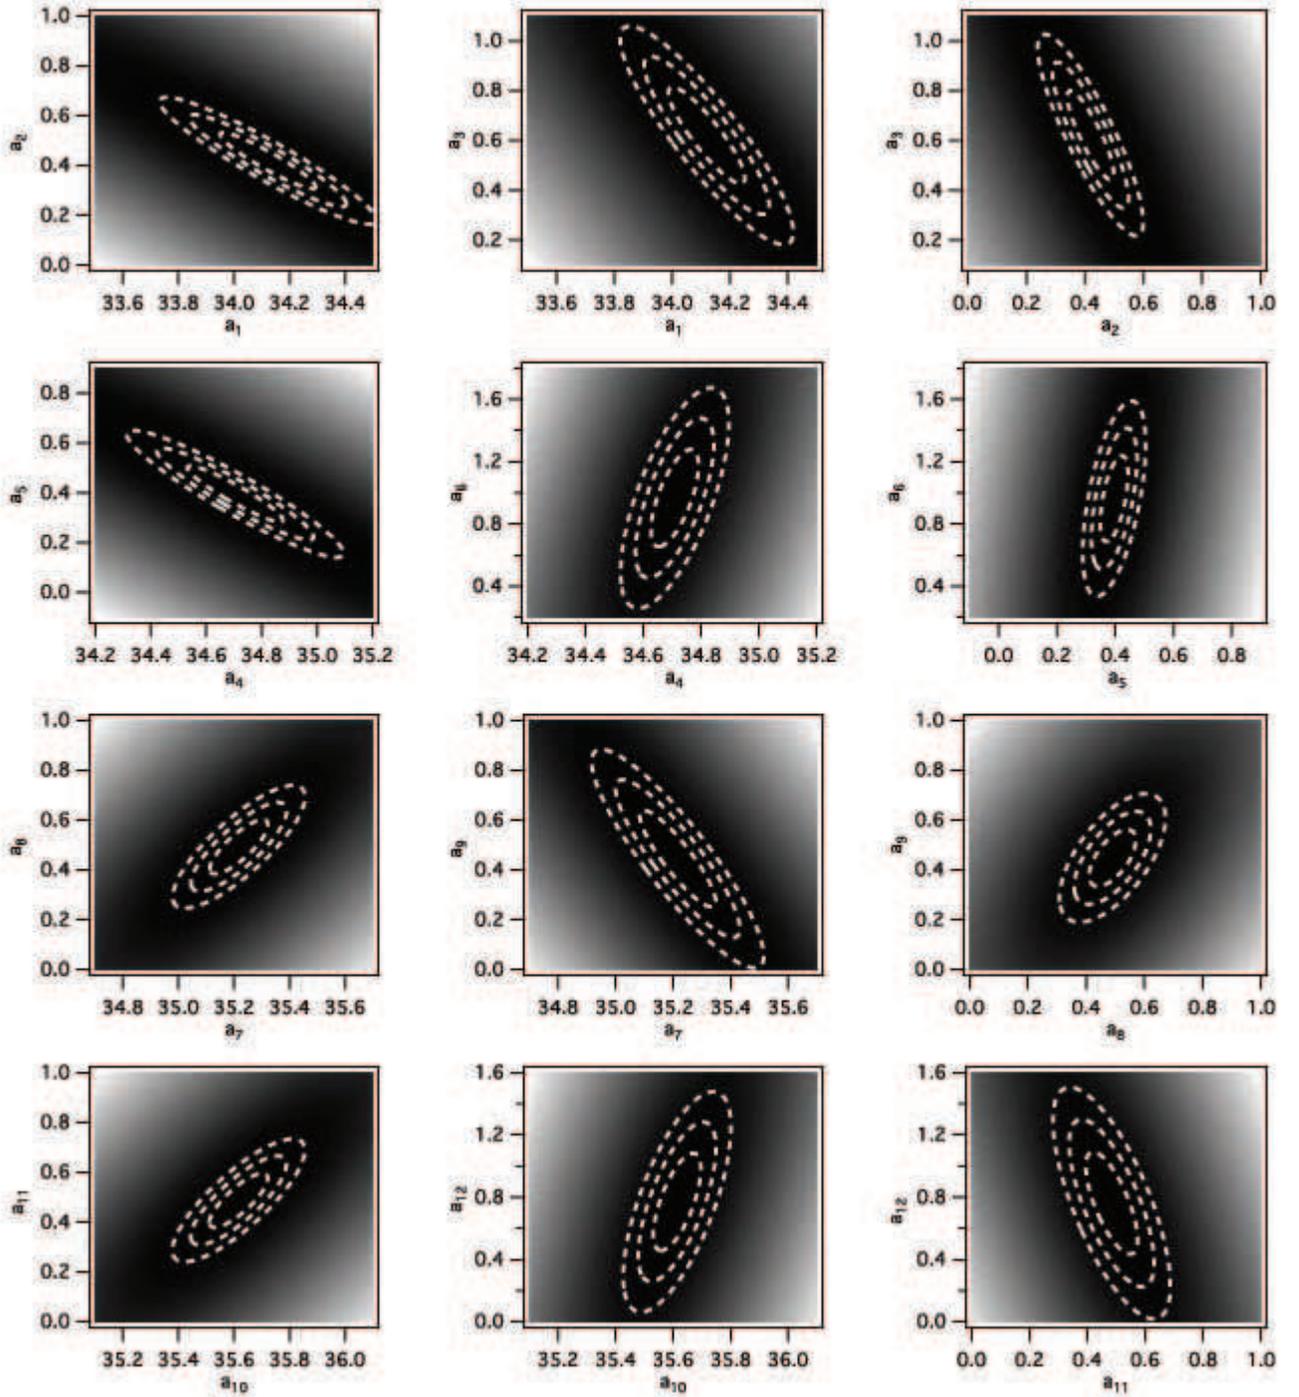

Fig. 4.— The χ^2 maps for various parametric spaces of the fundamental plane relations. The dashed lines illustrate the 1σ , 2σ and 3σ confidence contours for two parameters of interest which encircle the best-fit values (i.e. the positions with the lowest χ^2).
