ORAL PRESENTATIONS

SUNDAY, DECEMBER 4

Symposium 1: Molecular Mechanisms

1

Dicing and Beyond: Regulatory RNA in Humans and Bacteria.

J. Doudna[1]; [1]Department of Molecular and Cell Biology, Univ California-Berkeley/HHMI, Berkeley, CA

In eukaryotic cells, small RNA molecules regulate the expression of many genes. The enzyme Dicer plays a central role in producing these RNAs and ensuring that they assemble with other proteins into effector complexes. Recent findings show that Dicer and its partner RNA binding proteins can alter miRNA processing to change the set of mRNAs targeted for silencing. Although Dicer homologs do not occur in prokaryotic cells, bacteria possess distinct sets of enzymes that produce short RNA molecules to block the propagation of viral and plasmid sequences. In bacteria, these regulatory RNAs are produced from clustered regularly interspaced short palindromic repeats (CRISPRs). I will discuss our recent work to uncover the molecular basis for small RNA production and targeting. Molecular structures of the CRISPR machinery for targeting nucleic acids will be presented, revealing how the RNA is used to identify foreign sequences for destruction. Based on these structures and related biochemical studies, we find interesting similarities in target recognition mechanisms between RNAi-type and CRISPR-type systems.

2

Molecular Origami: chaperone-asisted protein folding and misfolding in health and disease.

J. Frydman[1]; [1]Department of Biological Sciences and BioX Program, Stanford Univ, Stanford, CA

Achieving correct protein folding and quality control is essential for normal cellular function. The accumulation of misfolded proteins is emerging as central to a wide range of disease states, including many neurodegenerative disorders such as Huntington's and Prion Disease. Molecular chaperones are a diverse family of enzymes that assists the folding of newly translated and stress-denatured proteins, as well as affects protein quality control. The role of chaperones in these diverse functions will be discussed.
Biochemical analyses together with systems approaches are used to define the chaperone networks and mechanisms in the eukaryotic cytosol. We find that a chaperone network linked to the protein synthesis apparatus assists protein biogenesis. The emergence of this translation-linked chaperone network likely underlies the elaborate co-translational folding process necessary for the evolution of larger multidomain proteins characteristic of eukaryotic cells. A stress-inducible chaperone network protects cells from environmental stress and assists quality control. These chaperones also communicate with the ubiquitin-proteasome pathway to clear misfolded proteins from the cell. We identify two intracellular compartments for the sequestration of misfolded cytosolic proteins and discuss how our findings provide a framework to understand the link between protein misfolding and human disease.

3

Quantitative Systems Biochemistry of Microtubule Cytoskeleton Organisation and Function.

T. Surrey[1]; [1]Cancer Research UK London Research Institute, London, England

The microtubule cytoskeleton performs essential mechano-chemical tasks in eukaryotic cells. It is crucial for the internal organisation of the cell, intracellular trafficking and for the separation of the genetic material during cell division. These complex processes require the coordinated activity of dynamic microtubules, molecular motors, their regulators, and other proteins linking microtubules to intracellular substructures. All these proteins form a dynamically interconnected microtubule cytoskeleton whose distinct biological function is intimately linked to its overall organisation and dynamic state. How this network operates as an integrative system and how its large-scale behaviour depends on the combinatorial action of its nano-scale biochemical constituents is a major open question. Biochemical reconstitutions of cytoskeletal subsystems mimicking in vivo behaviour, in combination with quantitative fluorescence microscopy and cryo-electron microscopy, have become a powerful approach to extract the underlying rules of how the microtubule cytoskeleton acts as a dynamic system. For example, through this approach the hierarchical functioning of a regulatory protein interaction network at growing microtubule ends, formed around so-called end binding (EB) proteins, can now be understood from the atomic to the micrometer scale. Similarly, the minimal mechanism for the establishment of distinct topological features of bipolar spindles, e.g. central anaphase microtubule overlaps mediated by PRC1 and a kinesin regulating microtubule dynamics, can now be understood from the knowledge of the biophysical properties of the interacting proteins. In the future, the challenge will be to reconstitute even more complex systems to be able to test directly our understanding of higher-order cytoskeletal functions.

Bruce Alberts Award for Excellence in Science Education

4

CourseSource, a New Partnership for Higher Education.

P. Bruns[1]; [1]HHMI, Chevy Chase, MD

High quality undergraduate science instruction is being challenged by a changing world. Knowledge is expanding at an increasing rate. Students are more diverse in age, background and place of instruction, and use technology to gather information in new ways. Education research is uncovering aspects of student learning that can advance the practice of teaching. And although the internet is a growing source of information, it is failing to enhance instruction; it is noisy, complex and unreliable. Faculty members want to respond but they do not want to reinvent the wheel every time they contemplate revising an existing course or creating a new one. The growing inclusion of educational issues in the organization and workings of scientific societies such as ASCB shows that the scientific community takes improved teaching seriously and recognizes the need for change, but professional society responses are independent efforts with few interconnections between disciplines and no uniformity in type of materials offered. Finally, a recent national effort organized by the American Association for the Advancement of Science (“Vision and Change in Undergraduate Biology Education”) strongly supports the adoption of student centered education strategies and decisively calls for a web tool that would be easy to use, address undergraduate teaching needs, and be reliably vetted.

I will describe a web portal, the CourseSource, designed to respond to these issues. The site will be organized by courses and will be based on highly successful design principles

recommended by Vision and Change and promoted by efforts such as the National Academy of Sciences Summer Institute for Undergraduate Education in Biology. Each course will be represented by a series of modules; each module will be anchored by a specific learning goal and contain appropriate assessment and learning materials. Initial collections of modules for specific courses will be made in partnership with appropriate scientific societies. Content will be included by references and links. CourseSource will include a navigation system that will enable users to follow learning goals and underlying concepts through multiple courses; faculty will be able to find and combine learning goals and associated materials from many different, sometimes seemingly unrelated courses. The primary audience for the portal will be faculty, ranging from those who want the basic design of a whole course ready for use, to people who want to enhance existing courses, to users who want to develop entirely new courses. Although the site will be in English, it will serve faculty from all sectors of higher education, anywhere in the world.

Symposium 2: Function of Multi-Molecular Machines

5

Single Molecule Microscopy of Macromolecular Machines: The Spliceosome.

M. Moore[1], A. Hoskins[1], L. Friedman[2], I. Shcherbakova[1], D. Crawford[2], E. Anderson[1], V. Cornish[3], J. Gelles[2]; [1]Biochemistry and Molecular Pharmacology, Univ Massachusetts Med Sch/HHMI, Worcester, MA, [2]Biochemistry, Brandeis University, [3]Chemistry, Columbia University, New York, New York

Excision of introns from pre-mRNAs is mediated by the spliceosome, a large, dynamic complex consisting of five small ribonucleoprotein particles (snRNPs) and scores of associated proteins. Our current understanding of spliceosome assembly is based largely on the procession of stable complexes that can be resolved from in vitro splicing reactions. Such ensemble experiments have suggested a highly ordered, linear assembly pathway in which initial binding of U1 snRNP to the 5' splice site is followed by stable U2 association with the branch site and subsequent U4/U5/U6 tri-snRNP and Nineteen Complex (NTC) addition to form the fully assembled spliceosome. Previously unknown, however, were the detailed forward and reverse kinetics of each assembly step, the extent to which branched and/or dead-end assembly pathways exist, and whether or not different introns utilize the same or alternate assembly pathway(s). We are now addressing these questions by combining yeast genetic engineering, chemical biology, and multi-wavelengthfluoresence microscopy to follow assembly of single spliceosomes in real time. Because no protein purification or reconstitution is required for such Colocalization Single Molecule Spectroscopy (CoSMoS), this experimental strategy should prove widely useful for mechanistic analysis of many other macromolecular machines in environments approaching the complexity of living cells.

6

Mechanisms and regulation of cullin-RING ubiquitin ligation machines.

R. J. Deshaies[1]; [1]Division of Biology, California Inst Technol/HHMI, Pasadena, CA

The ubiquitin-proteasome system (UPS) comprises a set of macromolecular machines that recognize substrates with a high degree of specificity, catalyze the polymerization of chains of ubiquitin molecules on these substrates, extract them from the complexes in which they reside, and unfold them to enable their degradation. Although it is now appreciated that the protein machines of the UPS play critical roles in normal and diseased cells and are the targets of both disease-causing mutations and therapeutic drugs, we know relatively little about how these

machines operate. My talk will discuss our recent progress in understanding the mechanism of actions and regulation of cullin-RING ubiquitin ligase (CRL) enzymes and an ubiquitin-selective chaperone, p97, that acts downstream of CRLs. I will also touch on the prospect of developing drugs that target these enzymes as potential tools for the treatment of cancer.

7

Spatio-Dynamics of Clathrin-Mediated Endocytosis in Yeast and Mammals.

D. Drubin[1], J. Cheng[1], A. Grassart[1], A. Cheng[1]; [1]Department of Molecular and Cell Biology, Univ California-Berkeley, Berkeley, CA

Clathrin-mediated endocytosis (CME) is the best-studied pathway by which cells selectively internalize molecules from the plasma membrane and surrounding environment. We study this process by live-cell microscopy in yeast and mammalian cells. The yeast studies have revealed a regular sequence of events necessary for endocytic vesicle formation involving some 60 proteins, which induce a highly choreographed series of changes in membrane geometry, ultimately resulting in scission and vesicle release. To analyze endocytic dynamics in mammalian cells in which endogenous protein stoichiometry is preserved, we previously targeted zinc finger nucleases (ZFNs) to the clathrin light chain A and dynamin-2 genomic loci and generated cell lines expressing fluorescent protein fusions from each locus (1). The genome-edited cells exhibited enhanced endocytic function, dynamics and efficiency when compared with previously studied cells. The high regularity of CME dynamics in these genome-edited cells has now been exploited to interrogate by RNAi and chemical inhibition how endocytic proteins and the actin cytoskeleton contribute to endocytic vesicle formation and to the regulation and dynamics of the process. These studies demonstrate the importance of actin assembly for robust endocytic dynamics in mammalian cells.

Thymic Nurse Cell Function: The "Proto-Thymus"?

J. Guyden[1]; [1]Department of Biology, City Coll New York, New York, NY

MHC restriction is a selection process that removes potentially autoreactive thymocytes during T cell development. The thymocyte subset that participates in the process of MHC restriction expresses the ??TCR+CD4+CD8+ cell surface phenotype. Thymocytes that survive MHC restriction continue to develop into mature functional T cells. Over ninety-five percent of developing thymocytes do not survive this process and are induced to undergo apoptosis. Thymic nurse cells (TNCs) are specialized epithelial components of the thymic stroma that contain developing T cells completely enclosed within intra-cytoplasmic vacuoles. As many as 200 thymocytes are found within this unique multicellular complex. For twenty years after their discovery very little information about their function was reported due to the lack of pure TNC populations in quantities necessary for thorough analyses. Our laboratory was the first to immortalize TNCs and to make a TNC-specific monoclonal antibody (pH91). Cells from our TNC lines have been shown to internalize thymocytes in tissue culture. This was the first report of the

isolation of a cell able to internalize and maintain viable another cell. Since that time, we have shown that TNCs exclusively bind and internalize ??TCR+CD4+CD8+ cells (the thymocyte subset involved in MHC restriction). We captured the internalization process using video microscopy. A subset of internalized thymocytes dies through the process of apoptosis and is degraded through lysosomal fusion. The remaining thymocytes survive and are released back into the general microenvironment of the thymus. We propose that TNCs house thymocytes undergoing the process of MHC restriction.

Most recently we performed a literature search and discovered that thymic nurse cells exist in the thymus of all jawed vertebrates (Chondrichthyes). Even shark thymi (almost 500M years old) have TNCs. On the other hand Good and Finstad (1964) discovered that lampreys, jawless vertebrates (Agnatha) that are the most immediate extant ancestors to sharks, have no thymus. This precipitated the question of what provided thymic functions before a thymus existed. Using lamprey larvae, Good and Finstad described what they termed the “proto-thymus” as 5-25 lymphocytes in intimate contact with epithelial cells located in the pharyngeal gutter. This cellular complex was described as having no barriers between the lymphocytes and the epithelial cell. They propose these complexes to be the primitive forerunners of the lymphoepithelial thymus. In 1995, Zurbrigg and Beamish found a subset of lymphocytes to stain with anti-Thy-1 antibody in the typhlosole of larval lamprey. Recently, we stained the typhlosole with the TNC-specific monoclonal antibody pH91 and found pH91+ stromal cells in association with Thy-1 positive lymphocytes. We have now isolated structures with the morphology of thymic nurse cells from the typhlosole of lamprey larvae. Are thymic nurse cells evolutionary descendants of the proto-thymus? Or, do thymic nurse cells represent the evolutionary bridge from the lamprey VLR-based immune system to one involving the IgG superfamily?

Minisymposia 1: Actin Dynamics

9

The formin Cappuccino contains a C-terminal actin binding domain that is essential for nucleation and is regulated by Spire.

C. Vizcarra[1], B. Bor[2], E. Roth[2], C. Leettola[1], M. Quinlan[1,2]; [1]Department of Chemistry & Biochemistry, University of California Los Angeles, Los Angeles, CA, [2]Molecular Biology Institute, University of California Los Angeles

The *Drosophila* formin Cappuccino (Capu) is essential for body axis establishment during oogenesis. Capu interacts directly with the WH2-based actin nucleator Spire via a short (~30 aa) sequence at the C-terminus of Capu and the N-terminal kinase non-catalytic C-lobe domain of Spire (Vizcarra, 2011), analogous to the interaction described in their mammalian orthologs (Pechlivanis, 2009). This interaction potently inhibits Capu’s actin nucleation activity (Quinlan, 2007), which lead us to further investigate the role of Capu’s C-terminal tail in actin assembly. We found that truncation of the tail markedly reduced Capu’s ability to stimulate polymerization in pyrene-actin assays. Additionally, substitution of the tail with the DAD domains from the more potent nucleators mDia1 and mDia2 increased the actin assembly activity of Capu, while substitution with the DAD domain from the less active FRL1 suppressed its activity. Monomer binding was recently reported for the DAD domains of Diaphanous-related formins. The Capu tail also binds actin monomers as well as actin filaments. Interestingly, the interaction between the Capu tail and actin monomers was observed for actin purified from *Acanthamoeba castellanii* and rabbit skeletal muscle but not for actin purified from *Saccharomyces cerevisiae*. However, a single point mutation in *S. cerevisiae* actin, A167E, was sufficient to recover actin

binding by the Capu tail to affinities comparable to those measured for other actins. The fact that the Capu tail is able to bind to the A167E mutant of yeast actin leads us to hypothesize that the tail binds in or near the hydrophobic cleft of actin. Consistent with this, WH2 domains compete with the Capu tail for actin binding. Taken together, our data indicate that the Capu tail is an actin binding domain that coordinates with the FH1 and FH2 domain to assemble actin filaments. The fact that actin binding by the Capu tail is essential for nucleation provides a mechanistic explanation for regulation of Capu by Spir. Moreover, we propose that the C-termini of most or all formins help determine the nucleation rates of their respective FH2 domains.

10

Actin network architecture determines myosin motor activity.

A-C. Reymann[1], R. Boujemaa-Paterski[1], J-L. Martiel[1], W. Cao[2], H. Chin[2], E. De La Cruz[2], M. Théry[1], L. Blanchoin[1]; [1]Institut de Recherches en Technologies et Sciences pour le Vivant, CNRS/CEA/INRA/UJF, Grenoble, France, [2]Department of Molecular Biophysics and Biochemistry,Yale University, New Haven, CT

The organization of actin filaments into higher-ordered networks governs overall eukaryotic cell shape, mechanical integrity and directed movement. The global architecture of the actin cytoskeleton is determined by coordinated actions of a large number of actin regulatory proteins that modulate filament assembly and disassembly dynamics. Myosin motors also plays a critical role in these processes and reorganize filament structures through sliding (e.g. contractility) and/ or depolymerization. Understanding the molecular mechanism of such complex spatiotemporal orchestration is extremely challenging in cells, where hundreds of different proteins act simultaneously on overlapping actin sub-structures. Here, we use geometrically controlled and polarized in vitro actin networks to evaluate how myosin motors influences filament architecture. Direct visualization of filaments indicates that myosins selectively disassemble randomly-oriented and anti-parallel actin filament structures while parallel actin filament bundles are unaffected by myosin contractility. This “orientation selection” reveals how the overall organization and dynamics of the actin cytoskeleton is controlled by actomyosin contractility. General principles governing the spatial organization of actin filaments in cells emerge from this work.

11

Bar-coding of the actin track and myosin-II motor activity by tropomyosins.

J. Clayton[1], G. Hoeprich[1], L. Pollard[1], M. Lord[1]; [1]Molecular Physiology & Biophysics, University of Vermont, Burlington, VT

How alternative assemblies self-organize represents a key problem in cell biology. With respect to the different actomyosin structures found in cells, it remains unclear how the distinct classes and isoforms of myosin motors are specified to their relevant structures. Given the number of different actin structures in cells, properties of the actin track likely contribute to spatial regulation of myosin motor activity.

Using the relatively simple and tractable fission yeast model, we found that the actin filament-binding protein tropomyosin plays a central role in the differential regulation of myosins at distinct actin structures. The presence of fission yeast tropomyosin on the actin track stabilizes

certain actomyosin interactions, favoring myosin-II (Myo2p) and myosin-V (Myo52p) motility in vitro. Tropomyosin in turn promotes Myo2p-driven contractile ring assembly and Myo52p intracellular transport along actin cables in vivo. In contrast, tropomyosin inhibits myosin-I (Myo1p) activity, thereby restricting Myo1p motor function to the endocytic actin patches (which unlike rings and cables are devoid of tropomyosin).

Ultimately we wish to test how well this actin track-based regulation outlined in fission yeast extends into mammalian cells, where there are many more myosins and tropomyosins in play. We are currently taking a global approach using actin-activated ATPase and motility assays to survey and compare the ability of yeast and mammalian tropomyosins to regulate yeast and mammalian (non-muscle and muscle) myosin-II motors. Our analysis is uncovering distinct patterns of regulation that depend on both the tropomyosin and myosin isoform. For example, while fission yeast tropomyosin and two mammalian tropomyosins (Tm4 and Tm5NM1) significantly increase the activity of fission yeast Myo2p, they potently inhibit skeletal muscle myosin-II; on the other hand another mammalian tropomyosin (TmBr3) is passive toward myosin-IIs. We predict that certain tropomyosins can differentially regulate myosin-II isoforms. Such ‘bar-coding’ of the actin track by tropomyosins offers a way of sorting the activity of myosin-II isoforms to specific actin structures in the complex environment of the cytoplasm. This represents a major divergence from current thinking regarding steric regulation of myosin-II, where tropomyosin dictates an ‘open’ or ‘closed’ state. Our studies indicate one state can mediate different outputs depending on the myosin-II isoform.

12

Quantifying the Dynamic Interactions of the Actin Cytoskeleton with T-Cell Receptor Clusters.

A. Smoligovets[1], A. Smith[1], H-J. Wu[1], R. Petit[1], J. Groves[1]; [1]University of California, Berkeley, Berkeley, CA

Actin's effects on cell surface receptors have recently received significant attention, and it is becoming clear that virtually every property of receptors can be influenced by the cytoskeleton, including spatial organization, receptor-ligand interactions, and signaling thresholds. Somewhat less characterized are the reciprocal effects of the receptors on the local actin environment. We have studied the behavior of actin as it interacts with microclusters of T-cell receptors (TCRs), which form in response to antigen presentation on an apposing membrane and converge into a micrometer-scale central domain in an actin-dependent manner. Using the hybrid live cell-nanopatterned supported lipid bilayer system, we find that the cytoskeleton shows characteristic responses to TCR clusters that are specifically limited in their ability to laterally diffuse. These responses are spatially and temporally dynamic, and we have developed a quantitative analysis method based on time-autocorrelation to describe them. Such a method may prove useful for identifying and quantifying similar actin behavior during cytoskeleton interactions with other cell surface receptors and in other cell systems, and it should be broadly applicable to any dynamically fluctuating protein-protein interaction that can be observed in real-time.

13

Dual roles of Arp2/3 complex in maintenance of the asymmetric position of meiotic II spindle in mammalian oocytes.

K. Yi[1], J. Unruh[1], M. Deng[2], S. Brian[1], R. Boris[1], R. Li[1]; [1]Stowers Institute for Medical Research, Kansas City, MO, [2]Brigham and Women’s Hospital, Harvard Medical School, Boston, MA

Mammalian female meiosis is highly asymmetric in that it generates one large-volume mature oocyte and three tiny polar bodies through two consecutive meiotic divisions. Cell division apparatus, the spindle, is formed in the center of the cell and then trans-located to the cortical

region in meiosis I, whereas in meiosis II, the spindle is formed de novo near the cortex. It was clear meiotic I spindle migration is an actin dependant process; however, how the spindle is positioned in meiosis II oocyte remains mysterious. Here, we show that the Arp2/3 complex plays dual roles in the maintenance of asymmetric spindle positioning in meiosis II oocyte. The Arp2/3 complex is localized to the cortical cap through a Ran-dependant mechanism, where it nucleates the assembly of a continuous actin flow. With the assistance of high resolution live imaging, spatiotemporal image correlation spectroscopy (STICS) and mathematic simulation, we show that this actin flow then powers a cytoplasmic streaming that exerts a net pushing force to the spindle toward the cortical cap. Inhibition of the Arp2/3 complex-nucleated actin assembly completely abolished the actin flow and the cytoplasmic streaming. Under this condition, it was further revealed the myosin based contractile force in actomyosin-rich cortical region could be active even before cytokinesis onset. When Arp2/3 nucleated actin assembly is inhibited, this contractile force facilitates a cytoplasmic streaming in reverse direction, resulting in spindle movement away from the cortex. Therefore, our results indicate that, in meiotic II oocyte, the role of Arp2/3 nucleated actin assembly is two-fold: initiating continuous actin flow from the cortical cap and preventing premature actomyosin contraction of the same cortical domain. The asymmetric positioning of MII spindle is maintained dynamically through the balance of these actin-based forces.

14

Regulation of stereocilia length by myosin XVa and whirlin depends on the actin-regulatory protein Eps8.

U. Manor[1], A. Disanza[2], M. Grati[1], L. Andrade[1], H. Lin[3], P. Di Fiore[2], G. Scita[2], B. Kachar[1];
[1]Laboratory of Cell Structure and Dynamics, National Institute on Deafness and Other Communication Disorders, Bethesda, MD, [2]The FIRC Institute of Molecular Oncology, Fondazione IFOM, Milan, Italy, [3]Department of Otolaryngology, Head and Neck Surgery, Massachusetts Eye and Ear Infirmary

Proper hearing and balance depend on the staircase shaped bundle of inner ear hair cell stereocilia, which are the actin-based protrusions or “hairs” inside our cochlear and vestibular organs which move in response to sound vibrations and head movement. In comparison to other actin protrusions (e.g. microvilli), stereocilia are extraordinary in at least 2 ways: 1) Differential regulation - in each hair cell there are rows of stereocilia with lengths that increase in height by several micrometers, but stereocilia within the same row vary in height by no more than several nanometers. 2) Length – normal epithelial microvilli are ~500 nanometers long, while stereocilia are up to 120 micrometers long. A large number of mutations that cause deafness affect proteins involved in regulating stereocilia length. Our recent work has revealed that stereocilia are dynamic structures undergoing constant renewal and regulation via the activities of numerous myosin motor proteins and their actin-regulatory cargoes. Myosin XVa (MyoXVa) and its cargo whirlin are implicated in deafness (DFNB3 and DFNB31, respectively) and have been shown to localize at stereocilia tips and to be essential for stereocilia elongation. Given that whirlin is a scaffolding protein with no actin-regulatory activity, it remains unclear how these proteins work together to elongate stereocilia. Here we show that the actin-regulatory protein Eps8 interacts with MyoXVa and whirlin, and that mice lacking Eps8 have very short stereocilia similar to MyoXVa- and whirlin-deficient mice. We also show that Eps8 localizes to stereocilia tips in concentrations directly proportional to length, showing for the first time a relationship between the amounts of an actin-regulatory protein and stereocilia length, revealing a biochemical mechanism for differential stereocilia elongation. We show that Eps8 fails to accumulate at the tips of stereocilia in the absence of MyoXVa, that overexpression of MyoXVa results in both elongation of stereocilia and increased accumulation of Eps8 at stereocilia tips, and that the exogenous expression of MyoXVa in MyoXVa-deficient hair cells rescues Eps8 tip

localization. We also found that both MyoXVa and Eps8 appear in reduced amounts at the tips of whirlin-deficient stereocilia, which suggests that whirlin plays an integral role in the efficient accumulation of the MyoXVa:Eps8 complex at stereocilia tips, perhaps via its scaffolding activity. Our data demonstrates that MyoXVa, whirlin, and Eps8 are integral components of a stereocilia tip complex, where Eps8 is a central actin-regulatory element transported by MyoXVa to stereocilia tips for elongation of the stereocilia actin core. This work provides insight towards DFNB3 and DFNB31 pathologies, and identifies EPS8 as a candidate deafness gene.

Minisymposium 2: Cell-Cell and Cell-Matrix Interactions

15

The differential recruitment of vinculin to adherens junctions and focal adhesions dictates biological response.

X. Peng[1], A. Angell[1], K. DeMali[1]; [1]Department of Biochemistry, University of Iowa, Iowa City, IA

Integrin and cadherin adhesion complexes exhibit an antagonistic relationship that determines whether cells maintain contact with their neighbors or uncouple and migrate. Signal events that regulate this antagonism have received considerable attention, but how these signal pathways differentially maintain cell adhesion at one site while promoting its loss at another are not known. Here we demonstrate that vinculin is tyrosine phosphorylated by Abelson tyrosine kinase in cell-cell, but not cell-matrix, adhesions. Phosphorylation at tyrosine 822 is required for adherens junction assembly and integrity and collective cell migration. Substitution of tyrosine 822 with phenylalanine prohibited vinculin recruitment and function in adherens junctions. Furthermore, preventing vinculin tyrosine phosphorylation, either by substitution with phenylalanine or by induction of an epithelial to mesenchymal transition, resulted in elevated integrin-mediated cell adhesion and cell spreading and single cell migration. Taken together these data provide a mechanism for determining if a cell maintains contact with their neighbors or uncouples and migrates. This work provides insight into how antagonism between integrins and cadherins is achieved.

16

A novel proteolytic processing of talin is associated with cadherin-mediated cell-cell adhesion.

F. Zhang[1], A. Kashina[1]; [1]Animal Biology, University of Pennsylvania, Philadelphia, PA

Talin is an essential cell adhesion molecule that plays a key role in integrin-mediated cell adhesion to the extracellular matrix, but has never been found to be involved in cadherin-mediarted cell-cell adhesions. Talin is a large rod-like molecule that scaffolds multiple components of the actin cytoskeleton. It is regulated by limited calpain-mediated proteolysis with a release of its N-terminal regulatory domain during integrin adhesion maturation and turnover. Other types of cleavages in vivo with functional significance have not been reported. Here we studied talin regulatory proteolysis in response to changes in cell density and found that the formation of cell-cell adhesions in a dense culture is accompanied by calpain-dependent generation of a novel 70 kDa talin fragment, which partially co-localizes with cadherin and accumulates in a dose-dependent manner in cells establishing cell-cell adhesions. Analysis of arginyltransferase (Ate1) knockout cells deficient in cell-cell adhesions revealed that these cells have little or no 70 kDa talin fragment, suggesting that arginylation knockout inhibits this fragment's generation, which in turn may be responsible for the adhesion defects in these cells. Phentype rescue experiments showed that reintroduction of the 70 kDa talin fragment into Ate1

knockout cells rescues their cell-cell adhesion defects, and that arginylation of this fragment further enhances the rescue effect in addition to regulating its turnover. Thus, we have discovered a novel proteolytic cleavage of talin that participates in its novel function in cadherin-mediated cell-cell adhesion and is regulated by a multi-level mechanism that involved cell density, calpain, and arginylation.

17

Myosin-X is required for proper junction assembly and epithelial morphogenesis.

K. C. Liu[1], D. T. Jacobs[2], B. D. Dunn[1], A. S. Fanning[1], R. E. Cheney[1]; [1]Cell & Molecular Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS

Myosin-X (Myo10) is an unconventional myosin that localizes to the tips of actin-rich protrusions such as filopodia and invadopodia and is necessary for filopodia formation. Although Myo10 has been studied primarily in fibroblast-like cells, little is known about its functions in polarized epithelial cells and junction formation. Here we use MDCK cells as a model system to investigate the functions of Myo10 in polarized epithelial cells and junction formation.

In MDCK cells triggered to form junctions using a calcium switch assay, TIRF imaging shows that GFP-Myo10 localizes to the tips of dynamic, filopodia-like protrusions. As cells contact one another and junctions begin to assemble, GFP-Myo10 transiently localizes to lateral membranes labeled by E-cadherin. In fully polarized cells, GFP-Myo10 exhibits little localization to apical microvilli and instead localizes to puncta on the basolateral surface that appear to represent the tips of basolateral filopodia. Deletion mapping studies indicate that the basolateral localization of Myo10 is dependent on its FERM and PH domains, which are known to bind to integrin and PIP3, respectively.

Knockdown of Myo10 resulted in a delay in the recruitment of junctional proteins, E-cadherin and ZO-1, as well as a delay in the development of peak transepithelial resistance (TER). Importantly, knockdown of Myo10 does not perturb apicobasal polarity or steady state TER. In three-dimensional cyst culture, knockdown of Myo10 resulted in a multiple lumen phenotype, indicating that Myo10 is required for normal lumen formation during epithelial morphogenesis. Together, this work reveals unexpected functions for Myo10 in junction formation and epithelial morphogenesis. The localization of Myo10 to basolateral puncta also raises intriguing questions about the functions of basolateral filopodia in cell-cell and cell-substrate interactions.

18

Invasive adhesion refines inductive signaling in the Ciona heart progenitor lineage.

J. Norton[1], J. Cooley[2], S. Ilchena[2], S. Sweeney[2], S. Fraser[3], B. Davidson[2]; [1]CMM, University of Arizona, [2]MCB, University of Arizona, Tucson, AZ, [3]California Institute of Technology, Pasadena, CA

Discrete populations of progenitor cells give rise to the heart and other organs. To ensure proper organ size and function, inductive signals that pattern these progenitor fields must be tightly regulated. We are exploring the role of extrinsic, micro-environmental cues in refining inductive signaling. In the basal chordate, *Ciona intestinalis*, fibroblast growth factor (FGF) drives induction of the heart progenitor lineage. Cardiac founder cells are exposed to a uniform FGF inductive gradient. However, founder cells respond differentially to this inductive signal, dividing to produce one heart progenitor daughter and one tail muscle progenitor. Differential induction is associated with a highly polarized invasion of adjacent epithelia. Through targeted transgenic manipulations, we have found that localized Cdc42 activity and actin polymerization

associated with invasive protrusions restrict inductive signaling. We are now investigating the precise mechanism by which invasive protrusions localize induction. Our initial results indicate that invasion leads to regional changes in cell-matrix adhesion that potentiate localized FGF signaling. We are currently investigating the precise in-vivo role of adhesion in the sub-cellular localization of FGF signaling components.

19

Syndecan-4 in breast carcinoma cells is an invadopodia component that regulates invasive behavior.

H. Lim[1], M. Lendorf[1], H. Multhaupt[1], J. Couchman[1]; [1]Biomedical Sciences, University of Copenhagen, Copenhagen, Denmark

Syndecan-4, a transmembrane heparan sulfate proteoglycan, has roles in integrin-mediated adhesion. It signals to the actin-associated cytoskeleton, and directly interacts with alpha-actinin. However, not much is understood of its roles in tumor cells. We have demonstrated that syndecan-4, in MDA-MB231 cells has a punctate distribution, shown by confocal microscopy to co-localize with invadopodia components, including matrix metalloproteinase 14 (MT1-MMP). However, experiments with siRNA or over-expression showed that syndecan-4 opposes both cell migration and collagen matrix invasion. These properties were dependent on the heparan sulfate chains, but not, surprisingly, on its cytoplasmic domain. Moreover, addition of heparin or heparan sulfate, but not chondroitin or dermatan sulfate to the breast carcinoma cells, led to decreased migration, with increased spreading, microfilament bundle formation, and cadherin 11-containing adherens junctions. These effects were independent of integrin or MMP14 status on the cell surface, although collagen gel invasion was a MMP14-dependent process. Recent experiments suggest that syndecan-4 and its heparan sulfate chains may inhibit thrombin on the cell surface, with downstream effects on the cytoskeleton.

20

L-lectin Domain-dependent Associations Mediate Extracellular Matrix Incorporation of Thrombospondins: a Novel Process in Matrix Organisation.

J. Adams[1], E. Christofidou[1], D. Kim[2], D. Keene[3]; [1]School of Biochemistry, University of Bristol, Bristol, United Kingdom, [2]Department of Medical Pharmacology and Physiology, University of Missouri-Columbia, Columbia, MO, [3]Micro-Imaging Center, Shriner's Research Center, Portland, OR

The extracellular matrix is a key mediator of multi-cellularity in the metazoa. Comparative genomics indicate that a core set of ECM components and associated proteases arose on the metazoan stem lineage and have been highly conserved subsequently (Ozbek et al., (2010) Mol. Biol. Cell 21:4300-4306). Within this core ECM set are the Thrombospondins (TSPs), a family of multi-domain, calcium-binding glycoproteins. The 5 TSPs of mammals have multiple roles in tissue organisation, and disorganisation of collagen fibrils is a phenotype shared by several *Thbs* gene knockout mice. Despite many extracellular matrix (ECM)-associated roles, mechanisms by which TSPs incorporate into and impact on ECM organisation are poorly understood. Through a model assay for isolation of insoluble ECM we identified that the C-terminal region of TSP1 in trimeric form is sufficient to mediate its ECM incorporation. Mechanistically, a novel, conserved site on the outer face of the TSP L-lectin like domain is the major mediator of ECM incorporation of TSP-1 and controls ECM deposition of TSP-5/COMP. The site acts in trans to mediate homophilic (eg, TSP1-TSP1) and heterophilic (eg, TSP1-TSP5) recruitment of trimeric or pentameric TSPs into insoluble ECM. This specificity is not replicated in conditioned media, indicating additional cell-surface and/or ECM-based steps in the process. Considering the many physiological and pathological contexts that involve modulation of levels

of extracellular TSPs, we propose the novel concept that concentration-dependent "matrix-trapping" of TSPs is a fundamental mechanism for ECM incorporation of TSPs, and modulates collagenous ECM organisation.

Minisymposium 3: Chemical Biology : Probes and Therapeutics

21

Optical recording of action potentials in mammalian neurons with a voltage indicating protein.

D. Hochbaum[1], J. Kralj[2], A. Douglass[3], A. Cohen[2]; [1]Applied Physics, Harvard University, Cambridge, MA, [2]Chemistry and Chemical Biology, Harvard University, Cambridge, MA, [3]Molecular Cell Biology, Harvard University, Cambridge, MA

Reliable optical detection of single action potentials in mammalian neurons has been one of the longest-standing open challenges in neuroscience. Here we achieve this goal in cultured neurons using a new voltage indicating protein (VIP1) which has approximately 10-fold improvements in sensitivity and speed over other genetically encoded voltage indicators. The endogenous fluorescence of our microbial rhodopsin-based VIP1 showed 2-fold variation in brightness over physiological voltage range, with a sub-millisecond response time. Single action potentials yielded bursts of fluorescence with optical signal-to-noise ratio > 10. The mutant VIP2 showed 50% greater sensitivity than VIP1 and lacked endogenous proton pumping, but had a slower response (41 ms). VIP2 was still capable of resolving individual action potentials. Microbial rhodopsin-based voltage indicators promise to enable optical interrogation of complex neural circuits, and electrophysiology in systems for which electrode-based techniques are challenging.

22

Chemical tools for probing protein function with spatial and temporal resolution in living cells.

A. Ting[1]; [1]Department of Chemistry, MIT, Cambridge, MA

I will describe new methods from our lab to (1) image specific protein function in living cells, and (2) determine the proteomic composition of subcellular compartments of living cells.

23

Expanding the scope of bioluminescence imaging: synthetic luciferins and mutant luciferases.

S. Miller[1], K. Harwood[1], R. Reddy[1], D. Mofford[1]; [1]Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA

Firefly luciferase-catalyzed light emission from D-luciferin is widely used as a reporter of gene expression and enzymatic activity both in vitro and in vivo. Despite the power of bioluminescence for non-invasive tumor imaging and anti-cancer drug discovery, light emission from luciferase is fundamentally limited by the photochemistry of the luciferin substrate and its ability to access the luciferase (modulated by affinity, cell permeability, and cellular efflux). We have recently described synthetic aminoluciferin derivatives such as CycLuc1 and CycLuc2 which exhibit light emission at longer wavelengths than D-luciferin (> 600 nm) and have increased affinity for luciferase. However, these desirable properties come with the caveat that aminoluciferin substrates exhibit marked burst kinetics with wild-type firefly luciferase due to

product inhibition. To help overcome this limitation, we have screened for and identified mutant luciferases that can efficiently emit light with aminoluciferins, both in vitro and in live mammalian cells. We have also synthesized new aminoluciferins that are substrates for these mutant luciferases and yield bioluminescent light emission at even longer wavelengths that are more suitable for whole animal imaging (> 630 nm). Together, these synthetic luciferin substrates and mutant luciferases have the potential to expand the scope of bioluminescent detection, allowing bioluminescence at wavelengths where tissue is more transparent to light, and the construction of orthogonal luciferase-luciferin pairs for multiplexed bioluminescent imaging.

24

Drugging the Undruggable: Small-Molecule Inhibition of the Ras Oncoprotein.

T. Maurer[1], L. Garrenton[1], A. Oh[1], K. Pitts[1], N. Skelton[1], B. Fauber[1], B. Pan[1], S. Malek[1], D. Stokoe[1], K. Bowman[1], J. Wu[1], A. Giannetti[1], M. Starovasnik[1], I. Mellman[1], P. Jackson[1], J. Rudolph[1], W. Wang[1], G. Fang[1]; [1]Genentech, Inc., South San Francisco, CA

The Ras protein is the most frequently mutated oncogene and has been considered by the scientific community one of the most important oncology drug targets. Despite the enormous interest and extensive exploratory efforts in industry and academia, small molecules that bind to Ras in a well-defined manner and exert inhibitory effects have not been uncovered to date.

To explore a new means of directly targeting Ras, we took a fragment-based lead discovery approach in an NMR-based screen. We identified a group of small molecules that bind to a unique site adjacent to the switch I/II regions in the Ras protein. X-ray crystallography studies of three compound-Ras complexes indicate that the binding site can be expanded upon ligand binding. Nucleotide exchange factors, notably SOS, are required to convert inactive RasGDP to active RasGTP. We determined that the compound binding site is located at the interface of Ras and SOS. A subset of our Ras-binding molecules indeed inhibited SOS-mediated nucleotide exchange. Further mechanistic studies revealed that the compounds block the formation of the Ras-SOS complex, a key intermediate of the exchange reaction. At the cellular level, our compounds inhibit the formation of active RasGTP and prevent Ras signaling to downstream effectors. We conclude that the compounds act as competitive inhibitors of nucleotide exchange to prevent the activation of Ras. The discovery of a binding pocket on Ras with functional significance represents a breakthrough finding that will offer a new direction for therapeutic intervention of the Ras oncoprotein. Our findings provide new opportunities to target the “undruggable” Ras oncoprotein.

25

3000 chemogenomic screens reveal novel targets and inhibitors: compound prioritization for academic chemical biologists.

C. Nislow[1], M. Urbanus[2], L. Heisler[2], R. St. Onge[3], G. Giaever[2]; [1]Donnelly Centre and Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada, [2]Donnelly Centre, University of Toronto, Toronto, ON, Canada, [3]Biochemistry, Stanford University, Stanford, CA

Our lab has pioneered the use of genome-wide pooled screens for drug target and target pathway identification by employing two validated assays; HaploInsufficiency Profiling (HIP) and Homozygote Profiling (HOP) using the barcoded yeast deletion collections. One of the most vexing challenges has become the selection of compounds for screening in a manner that is both cost-effective and which explores maximal chemical diversity. We describe how pre-selection of compounds that are more likely to induce a phenotype can increase the efficiency and reduce the costs for model organism screening. To identify such molecules, we screened

~81,000 compounds in *S. cerevisiae* and identified ~7,500 that inhibit cell growth. Screening these growth-inhibitory molecules across a diverse panel of model organisms resulted in an increased phenotypic hit-rate. This data was used to build a model to predict compounds that inhibit yeast growth. Empirical and *in silico* application of the model enriched the discovery of bioactive compounds in diverse model organisms. To demonstrate the potential of these molecules as lead chemical probes we used chemogenomic profiling in yeast and identified several dozen novel protein targets and their cognate inhibitors from over 3000 full genome-screens. This library of growth-inhibitory molecules has been made commercially available and the computational model and filter used are available as a chemical biology resource.

26

Predicting Synergy: Drug combination screening to identify predictive biomarkers for combination drug therapy.

L. Belmont[1], N. Tan[1], M. Wong[1], P. Yue[2]; [1]Molecular Diagnostics & Cancer Cell Biology, Genentech, Inc., South San Francisco, CA, [2]Bio-informatics, Genentech, Inc., South San Francisco, CA

Navitoclax (formerly ABT-263) is a potent, selective inhibitor of Bcl-2 and Bcl-xL that has shown clinical activity in chronic lymphocytic leukemia (CLL), a disease with frequent high expression of Bcl-2. Although there is little evidence of single agent navitoclax activity in pre-clinical models of epithelial solid tumors, data suggest that Bcl-xL protects against chemotherapy induced cellular stress in many cancer cells. To determine if Bcl-xL inhibitors synergize with chemotherapy or targeted anti-cancer agents, we performed drug combination screens of navitoclax and gemcitabine, paclitaxel, carboplatin, erlotinib, as well as experimental agents that inhibit MEK, and phosphatidylinositol-3-kinase in a panel of cell lines derived from NSCLC, breast, ovarian and pancreatic cancer. We find that navitoclax is broadly synergistic with most of the agents tested. However, there were significant differences in the level of synergy among cell lines, suggesting it may be critical to identify biomarkers to identify the cancers that are more likely to exhibit strong synergy in response to drug combinations. We performed correlative marker analysis of mutations, gene expression and protein levels of relevant pathways to identify predictive biomarkers of drug synergy and found that cell lines with a high ratio of Bcl-xL/Mcl-1 exhibit a stronger synergistic response to the combination of paclitaxel and navitoclax. Single cell analysis of time-lapse microscopy revealed a significant decrease in the time from mitotic entry to cell death in cells exposed to paclitaxel plus navitoclax compared to paclitaxel alone, resulting in more cell killing and a reduction in clonogenic survival. In contrast, the best correlative markers for the MEK inhibitor navitoclax combination were activating mutations of EGFR or KRAS. However, we observed variable degrees of synergy even with the KRAS mutant cell lines, suggesting additional contributing factors. We find variation in the regulation of Mcl-1, Bad and Bim in response to MEK inhibition that could account for the differences in synergy. In conclusion, we find 1) it is possible to identity predictive markers for synergy through drug combination screening and correlative marker analysis, and 2) the predictive markers depend upon the mechanism of action of the combining agent.

Minisymposia 4: Innovations in Cell Biology Graduate Education

27

The role of graduate education in bridging the gap between basic sciences and human health.

I. Arias[1]; [1]NICHD/Cell Biology and Metabolism, NIH, Bethesda, MD

Since the 70's, progressive decline in physician-scientists and increased technology created a gap between basic science and medicine which delays application of basic science to human health. Interest surveys and outcome data support the effectiveness of teaching pathobiology to PhD students/fellows. Since an initial proposal (NEJM,'89), the number and variety of successful programs have increased. Programs vary in duration, frequency and degree relatedness, and are supported by NIH, foundations and institutions worldwide. Teaching pathobiology to PhDs has become a global concern. Because there are more than 4000 PhD students/fellows at NIH, a different format was required. A weekly one semester course entitled "Demystifying Medicine for PhDs" was established 10 yrs ago. Attendance exceeds ~900 per year. The format includes a specific disease,live patient(s), discussion by "translational" investigator followed by basic scientist who presents state-of-the-art research and challenges. All materials are available on a NIH website (Demystifying Medicine) and videoarchive. Over 1200 Course DVDs have been distributed worldwide. The basic concept has been replicated in basic science departments in many American institutions and 16 countries. Particularly in the present era of cell, molecular and genetic biology, teaching pathobiology to undergraduates and PhD students/fellows is timely,challenging,supported by outcomes data,and,for some, preparatory for academic positions in clinical departments. The goal is to enable basic scientists to share ideas with clinical investigators and other basic scientists. These programs contribute to bridging advances in biological and engineering sciences and human health, challenge longstanding educational paradigms and offer exciting, productive and novel research careers.

28

The Mechanisms of Disease & Translational Science Track at UT Southwestern.

H. Yin[1], M. McPhaul[1]; [1]Univ Texas Southwestern Med Ctr, Dallas, TX

“Mechanisms of Disease & Translational Science “(MoDTS) is a PhD enrichment track that provides students with new opportunities to study human diseases at the interface between basic and clinical sciences. MoDTS students will be empowered to spearhead the bidirectional translation of discoveries between the bench and bedside to harness the explosion of scientific knowledge to improve human health. MoDTS was launched in 2008 with institutional seed money. It obtained a 5-year grant from the Texas Innovative Graduate Program Initiative in 2009 and a 4-year grant from the HHMI Med into Grad Initiative in 2010. Matriculated students apply for admission in the spring of graduate year 1 (G1). MoDTS now admits 8 students per year. There has been a large increase in the number of applicants and selectivity. In 2001, the rate of acceptance was 50% and 7 of the 8 admitted students graduated from top-tier national research universities. The MoDTS curriculum is overlain on the traditional graduate school curriculum, and involves the following: (1) Summer Immersion in Clinical and Translational research in G1/G2. It provides first hand clinical research experience, observations in hospital ward teaching rounds and Institutional Review Board sessions; (2) new mini-medical school style courses on Human Physiology and Pathology, new Introduction to Biostatistics, and an existing Human Biology and Disease course; (3) a Bench to Bedside elective in G3 spring, in which the student designs a program of independent study with a team of clinical experts to obtain an individualized, in-depth experience about the diseases directly aligned with his/her

dissertation research topic. The dissertation research topic must have relevance to human biology and diseases, although there is no absolute requirement for actual translational research. However, the qualifying exam, which is based on the student's thesis research, must propose a translation aim using primary human derived samples. In spite of the increase in coursework, the 4 initial students will graduate with a time to degree of 3.9 years, compared with the graduate school average of 5.1 years. There are opportunities for PhD student interactions with MD/PhD and Doris Duke medical students through the monthly joint Grand Rounds, and small group discussions. We have forged an alliance with the Clinical and Translational Science Award (CTSA) and increased the number of clinicians participating for the first time in PhD graduate education.

29

IICCBB - Building an International Network for Student Training and Research Collaboration in the Biological Sciences.

A. Bassini[1], L-C. Cameron[1], E. De La Cruz[2], S. Esteves[1], R. Luzes[1], J. Mercer[3], J. Sotelo[4], M. Titus[5]; [1]Laboratory of Biochemistry of Proteins, Univ Fed Estado Rio De Janeiro, Rio De Janeiro, Brazil, [2]Molecular Biophysics & Biochemistry Department, Yale University, New Haven, Brazil, [3]Department of Biochemistry Stanford School of Medicine, McLaughlin Research Institute, Great Falls, MT, [4]Dept. of Proteins & Nucleic Acids, Instituto de Investigaciones Biológicas Clemente Estable, Uruguay, [5]Department of Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN

Students, academic scientists, and private sector scientists in South America have historically had limited opportunities to present and discuss their work in an international setting, thereby diminishing the broader impact of their work and training. For nearly two decades, a team of South and North American scientists have joined efforts to establish an international "school" - International Institute for Collaborative Cell Biology and Biochemistry (IICCBB) - an organization without borders or physical location. Our mission is to inspire future scientists in biochemistry and cell biology. IICCBB offers annual interdisciplinary courses in biochemistry, cell biology, and molecular biology to international students in the biosciences. With a history of over twenty organized courses and symposia, more than 1500 students from 28 countries, and over 100 faculties from over 15 countries, we have succeeded in establishing a stable consortium of scientists dedicated to training the next generation of scientists and promoting research collaboration at an international level. We will provide information on the diversity of talks and interests, new collaborations, and other interactions, students exchange and postdoctoral positions that have resulted from our courses.

30

Innovations in Graduate Education: the Professional Science Master's Degree.

C. Lynch[1]; [1]Council of Graduate Schools, Washington, DC

The Professional Science Master's (PSM) is an innovative, graduate degree designed to allow students to pursue advanced training in science or mathematics, while simultaneously developing workplace skills highly valued by employers. PSM programs consist of academic training in an emerging or interdisciplinary area, along with a professional component that may include internships and "cross-training" in workplace skills, such as business, ethics, communications, and regulatory affairs. Programs are developed in concert with employers and are designed to dovetail into present and future professional career opportunities. PSM degrees date from 1997, when the Sloan Foundation began funding research universities to develop clusters of such programs, and the Keck Foundation endowed the Keck Graduate Institute to offer degrees in applied biomedical sciences following the PSM model. In 2001 the Council of

Graduate Schools (CGS) partnered with the Sloan Foundation to expand PSMs to select “master’s focused” institutions, and in 2006 CGS assumed primary responsibility for the promotion of the PSM degree. PSM programs now number about 250 at about 115 institutions. They attract students who are not likely to pursue a doctorate, but want a degree that leads to a science-based career in innovative organizations and that prepares them for advancement into leadership positions. PSM graduates experience almost 100% employment and many programs – especially in biology – report more demand for graduates than they can supply. Examples will be given from specific PSM programs in biology of student experiences in the program and employment of graduates.

31

Crossing Silos: Graduate Training in Cell Analysis and Modeling.

R. M. Holmes[1,2]; [1]Center for Cell Analysis and Modeling, U. Conn. Health Center, Farmington, CT, [2]Center for Computational Science, Boston University, Boston, MA

Modern cell biology draws on multiple areas of expertise including biology, mathematics, physics and computational sciences. Developing researchers capable of working in this increasingly interdisciplinary field requires strategies to support communication, collaboration and innovation among current and future researchers. At the Center for Cell Analysis and Modeling (CCAM), home to the newly established Cell Analysis and Modeling (CAM) area of concentration with the Biomedical Sciences graduate program, we have implemented both structural components that are common to interdisciplinary research and training programs, as well as activities to address the qualitative and creative characteristics of collaborative, interdisciplinary research. The CAM graduate program is geared to students who are interested in understanding the biophysical and biochemical mechanisms that underlie cell function. Our faculty research is broadly multi-disciplinary, which allows students to work closely and concurrently with experimentalists and modelers with existing collaborations, and on projects that incorporate both types of approaches. CCAM faculty are from diverse disciplines, are physically co-located and collaborate on jointly funded multi-disciplinary projects. Combined with multi-disciplinary seminars these features are important structures for a rich interdisciplinary environment. Students and postdocs joining the research environment typically come from traditional biology backgrounds that require training that incorporates physics, math, and computer science, or from physics, engineering, math, and computer science backgrounds that lack sufficient training in biology. Individually-tailored short courses are used to address each student’s needs, while a minimal set of core classes cover a breadth of topics in modern cell biology. We take a sociocultural approach (Vygotsky, 1976; Newman and Holzman, 1993; Lobman and Lundquist, 2007; Alon, 2009) to developing students’ abilities to collaborate, communicate and organize their scientific careers. Along side our academic courses, we have held improvisational theater workshops for scientists, which support active listening, risk taking, and the breaking down of barriers due to language, culture, or disciplines. Meetings are held by directors of the program with students to invite suggestions to improve their training. The CAM Student Association, initiated and organized by students, produces a CAM Newsletter which provides science highlights, “reports from the lab” and invitations to social events to foster rapport among colleagues. The combination of a rigorous scientific environment with rich social interactions creates a context for students to develop as innovative, collaborative researchers in cell analysis and modeling. Variations of the improvisation workshop sessions have been incorporated into graduate student orientations, postdoctoral trainings at UCHC and are active components of national programs building inclusive scientific communities.

32

Professional Training Experiences of Science Faculty with Education Specialties (SFES) in the US.

K. Tanner[1], S. Bush[2], N. Pelaez[3], J. Rudd[4], M. Stevens[5], K. Williams[6]; [1]Biology, San Francisco State University, San Francisco, CA, [2]Chemistry and Biochemistry, California Polytechnic State Univ, San Luis Obispo, CA, [3]Biological Sciences, Purdue University, West Lafayette, IN, [4]Chemistry and Biochemistry, California State University, Los Angeles, CA, [5]Biology, Utah Valley University, Orem, UT, [6]Biology, San Diego State University, San Diego, CA

Efforts to improve K-16+ science education in the U.S. have included the hiring of Science Faculty with Education Specialties (SFES) – scientists who take on specialized roles in science education within their departments, including biology departments (Bush, 2006). Though SFES occupy a potentially pivotal role in reform efforts, there has been little systematic investigation of these positions. In the first cross-disciplinary research study of SFES in the U.S. – conducted in the nation's largest university system, the California State University (CSU), we previously demonstrated that SFES populations reported more formal training in basic science than in science education (Bush, 2008, Bush, 2010). Most CSU SFES (88%) across all science disciplines had earned science PhDs, whereas many had completed science postdocs (37%) and/or science master's degrees (48%). In contrast, only 32% of CSU SFES reported having any type of formal post-baccalaureate training in science education. In the CSU, Chemistry SFES had the greatest (43%) proportion of faculty with any formal science education training; proportions for Biology (30%), Geoscience (25%), and Physics (27%) were lower. Patterns of the types of formal training in science education varied among disciplines. For example, 20% of Biology CSU SFES had earned teaching credentials, 10% had conducted postdoctoral work in science education, and only 5% had earned science education doctorates. More recently, preliminary analyses of data collected in a National Study of SFES in the U.S. suggest similar trends nationwide. Nearly all of US SFES report formal training in science through MS, PhD, and/or postdoctoral training. However, only about a third of US SFES reported formal training in science education. Many fewer Biology and Geosciences SFES reported formal training in science education compared to SFES in Physics and Chemistry. These research findings can inform aspiring SFES of potential training pathways and biology departments considering SFES faculty hires, as well as policymakers and grant agencies that aspire to establish training pathways for future SFES.

Minisymposium 5: Membrane Fission and Fusion

33

Regulation of COPII recruitment to ER exit sites.

K. Witte[1], A. Schuh[1], J. Hegermann[2], A. Sarkeshik[3], J. Mayers[1], J. Yates[3], S. Eimer[2], A. Audhya[1]; [1]Biomolecular Chemistry, University of Wisconsin-Madison, Madison, WI, [2]European Neuroscience Institute (ENI) Göttingen, Germany, [3]The Scripps Research Institute, La Jolla, CA

Export of proteins from the endoplasmic reticulum (ER) in COPII-coated vesicles occurs at defined sites, which contain the scaffolding protein Sec16. Although Sec16 has been shown to interact with multiple COPII subunits to mediate vesicle biogenesis at the ER, mechanisms by which COPII recruitment is regulated remain poorly defined. Using both functional genomics and biochemical approaches, we identify a new, conserved Sec16-interacting protein named TFG that is required for COPII subunit accumulation at ER exit sites. Consistent with this finding, depletion of TFG inhibits secretion of multiple cargoes from the ER. Furthermore, using immuno-gold EM techniques, we demonstrate that TFG localizes to a matrix between ER exit

sites and the Golgi. We hypothesize that a TFG matrix may serve as a molecular sink, which helps to retain COPII components locally and facilitate efficient vesicle egress from the ER.

34

Regulating AP-2 interactions to control vesicle size and number during clathrin-mediated endocytosis.

B. Ritter[1], S. Murphy[2], M. Halin[1], J. Philie[1], K. Gehring[2], P. S. McPherson[1]; [1]Neurology and Neurosurgery, McGill University, Montreal, PQ, Canada, [2]Biochemistry, McGill University, Montreal, PQ, Canada

The clathrin adaptor protein AP-2 is the core organizing element in clathrin-mediated endocytosis; it concentrates cargo and clathrin at the site of vesicle formation and it orchestrates a myriad of endocytic accessory proteins to control aspects of vesicle formation ranging from membrane deformation to vesicle fission. Thus, clathrin and accessory proteins need to interact with AP-2 in a temporally and spatially controlled manner, yet it remains elusive as to how access of these binding partners to AP-2 is regulated. Using knock down and functional rescue studies, we now demonstrate that the AP-2-binding protein NECAP 1 is a critical regulator of AP-2 interactions. In fact, NECAP 1 needs to be present in a complex with AP-2 to enhance the stability of FCHo2-marked vesicle nucleation sites, thereby controlling the number of clathrin-coated vesicles that form. During vesicle formation, NECAP 1 and AP-2 function cooperatively in the efficient recruitment of other accessory proteins that in turn control vesicle size. Moreover, we use binding assays and nuclear magnetic resonance studies to reveal NECAP 1 as the first known factor that competes with clathrin for access to the AP-2 beta2-linker, positioning NECAP 1 to regulate the ability of AP-2 to recruit and polymerize clathrin. Thus, our data demonstrate that NECAP 1 is a key modulator of the AP-2 interactome needed for productive vesicle formation and reveal a new layer of organizational control within the endocytic protein machinery.

35

Coupling the membrane to the actin cytoskeleton during clathrin-mediated endocytosis.

M. Skruzny[1], T. Brach[1], R. Ciuffa[1], S. Rybina[1], M. Wachsmuth[1], M. Kaksonen[1];
[1]Cell Biology and Biophysics Unit, EMBL, Heidelberg, Germany

Polymerization of actin filaments at the site of clathrin-mediated endocytosis is thought to provide force for the membrane shape changes that take place during vesicle formation. However, the molecular mechanism by which the force from the actin cytoskeleton is transmitted to the membrane has not been known. We show that in budding yeast, Saccharomyces cerevisiae, Ent1 (epsin) and Sla2 (homolog of mammalian HIP1R) proteins couple the membrane to the actin cytoskeleton during endocytic vesicle formation. Deficiency of either Sla2 or the redundant pair of two endocytic epsins Ent1/Ent2 leads to an uncoupling phenotype where actin is still polymerizing at the endocytic site, but the membrane does not invaginate. In vivo and in vitro experiments revealed that the N-terminal lipid-binding domains of Sla2 and Ent1 interact with the membrane in a cooperative manner. Furthermore, the C-terminal parts of both Sla2 and Ent1 interact with the actin cytoskeleton. Sla2 binds actin filaments through a well-characterized THATCH domain, and Ent1 by a novel actin-binding domain in its natively unfolded C-terminal region. One of these actin-binding domains is sufficient for endocytosis, while deletion of both domains uncouples actin and prevents membrane invagination. The actin-binding domains of Sla2 and Ent1 can be functionally replaced with a heterologous actin-binding domain fused to Ent1. By their synergistic binding to the membrane and redundant interaction with the actin cytoskeleton, Ent1 and Sla2 form a unique molecular

linker that transmits the force generated by the actin cytoskeleton to the invaginating membrane.

36

Curvature and tension control of dynamin fission reaction.

A. Roux[1]; [1]Biochemistry, University of Geneva, Geneva, Switzerland

Dynamin is a GTPase that polymerizes into helical collars at the neck of endocytic buds, and constricts upon GTP hydrolysis in order to release free vesicles. Several hypotheses are currently being debated to understand how this polymerization and conformational change are promoting membrane fission in a controlled manner.
I'll show recent results where we have investigated the lipid membrane parameters influencing the fate of dynamin reaction. By using templates consisting of thin lipid tubules extracted by optical tweezers from Giant Liposomes maintained in micropipettes, we studied the mechanical parameters controlling membrane fission. We showed that if the curvature of the tube triggers polymerization of dynamin (spontaneous nucleation is observed at radii below 20nm), the saddle-like shape of endocytic buds strongly favors the dynamin reaction. As well, high membrane tension intensively reduces both the stochasticity and the average time it takes for fission. Accordingly, when membrane tension is changed in cells by osmotic changes, dynamin is blocked when tension decreases but not when it increases. Our findings support the idea that the high curvature of the neck and its saddle-like shape are respectively triggering the nucleation of the polymer and the membrane break. Also, as expected from our previous findings, membrane tension is a primordial parameter of fission efficiency.

37

Cdc42 Controls the Balance between Kiss-and-run and Full Fusion of Secretory Vesicles by Regulating Membrane Tension.

M. Bretou[1,2], O. Jouannot[1], C. Desnos[1], P. Pierobon[2], I. Fanget[1], N. Larochette[1], M. Guillon[3], S. Gasman[4], A-M. Lennon-Duménil[2], F. Darchen[1]; [1]CNRS-Univ Paris Descartes, Paris, France, [2]Inserm - Institut Curie, Paris, France, [3]Inserm - CNRS - Univ Paris Descartes, Paris, France, [4]CNRS - Univ Strasbourg, Strasbourg, France

Membrane fusion underlies several physiological processes including exocytosis of hormones and neurotransmitters. Fusion pore dynamics controls the release of vesicle content but is poorly understood. Here we show that the small GTPase Cdc42 controls the dilation of the fusion pore during exocytosis. We found that Cdc42 silencing in neuroendocrine cells had no effect on the probability of vesicle exocytosis but compromised the enlargement of the fusion pore, as measured by carbon fiber amperometry and evanescent wave microscopy. As a consequence, the mode of vesicle exocytosis was shifted from full-collapse fusion to kiss-and-run in Cdc42 knockdown cells. Remarkably, using the tether pulling technique, we found that Cdc42 silencing reduced the membrane tension. Finally, the artificial increase of membrane tension restored fusion pore enlargement in these cells. We conclude that membrane tension is the driving force for fusion pore dilation and that Cdc42 is a key regulator of this force.

38

Dynamics of SNARE assembly in homotypic and heterotypic vacuole fusion.

A. J. Merz[1], B. T. Lobingier[1], M. L. Schwartz[1], C. G. Angers[1]; [1]Department of Biochemistry, University of Washington School of Medicine, Seattle, WA

Our laboratory has used a combination of genetic analyses, cell-free reconstitution approaches, and protein biochemistry to dissect the pathway of SNARE zippering during the docking and

fusion of intact yeast vacuoles. We find that SNARE assembly relies on SNARE interactions with multiple components of the HOPS tethering complex, including the SM protein Vps33. We also show that a single α-helix between layers +4 and +5 of the SNARE core complex defines the transition between the efficient formation of a stable but non- fusogenic trans-SNARE complex, and a complex that is almost fully fusion competent. Using partially-zipped complexes in cell-free assays and in vivo, we demonstrate that we can trap and analyze pre-fusion complexes. We employ these tools to analyze the docking stages of heterotypic docking and fusion of AP-3 vesicles, which in yeast mediate transport from the late Golgi to the vacuolar lysosome. SNARE-trapping experiments and other approaches show that the AP-3 vesicle coat couples to the HOPS tethering complex at the vacuole, and that at least a portion of the AP-3 complex remains membrane associated through the docking and trans-SNARE complex assembly sub-reactions.

Minisymposium 6: Synthetic Cell Biology

39

Designing Biological Systems.

P. Silver[1]; [1]Department of Systems Biology, Harvard Med Sch/Harvard Univ Grad Prog Systems Biol, Boston, MA

Biology presents us with an array of design principles. From studies of both simple and more complex systems, we understand some of the fundamentals of how Nature works. We are interested in using the foundations of biology to engineer cells in a logical and predictable way to perform certain functions. By necessity, the predictable engineering of biology requires knowledge of quantitative behavior of individual cells and communities and the ability to construct reliable models. By building and analyzing synthetic systems, we learn more about the fundamentals of biological design as well as engineer useful living devices with myriad applications. For example, we are interested in building cells that can perform specific tasks, such as remembering past events and thus acting as a biological computer. Moreover, we design cells with predictable biological properties that serve as cell-based sensors, factories for generating useful commodities and improved centers for carbon fixation. We have recently constructed synthetic protein/RNA structures to increase the efficiency of biological reactions. In doing so, we have made new findings about how cells interact with and impact on their environment.

40

Synthetic biology: from parts to modules to therapeutic systems.

R. Weiss[1]; [1]Department of Biological Engineering, Massachusetts Inst Technol, Cambridge, MA

Synthetic biology is revolutionizing how we conceptualize and approach the engineering of biological systems. Recent advances in the field are allowing us to expand beyond the construction and analysis of small gene networks towards the implementation of complex multicellular systems with a variety of applications. In this talk I will describe our integrated computational / experimental approach to engineering complex behavior in living systems ranging from bacteria to stem cells. In our research, we appropriate design principles from electrical engineering and other established fields. These principles include abstraction, standardization, modularity, and computer aided design. But we also spend considerable effort towards understanding what makes synthetic biology different from all other existing engineering disciplines and discovering new design and construction rules that are effective for

this unique discipline. We will briefly describe the implementation of genetic circuits and modules with finely-tuned digital and analog behavior and the use of artificial cell-cell communication to coordinate the behavior of cell populations. The first system to be presented is an RNAi-based logic circuit that can detect and destroy specific cancer cells based on their microRNA expression profiles. We will also discuss preliminary experimental results for obtaining precise spatiotemporal control over stem cell differentiation for tissue engineering applications. We will conclude by discussing the design and preliminary results for creating an artificial tissue homeostasis system where genetically engineered stem cells maintain indefinitely a desired level of pancreatic beta cells despite attacks by the autoimmune response, relevant for diabetes.

41

Studying Multiple Motor Ensembles using DNA Nanotechnology.

B. Goodman[1], N. Derr*[1], W. Shih[2], S. Reck-Peterson[1]; [1]Cell Biology, Harvard Medical School, Boston, MA, [2]Dana Farber Cancer Institute, Boston, MA*

In eukaryotic cells, many cargos are transported by groups of microtubule-based molecular motors. Some of these cargos move bidirectionally and can be observed switching directions during movement, but ultimately, cellular contents are sorted with spatial and temporal precision. The biophysical mechanisms that allow ensembles of same- or opposite-polarity motors to coordinate their behaviors are not known. The major technical challenge for dissecting this problem in vitro has been the inability to control the spacing, number, and type of motor present on individual cargo molecules. Using three-dimensional DNA origami, we have designed a synthetic cargo, to which precise numbers and geometries of DNA-linked dynein and kinesin motors can be attached in varying combinations of 1 to 7 motors. We find that synthetic cargo bearing multiple dynein motors can move farther, but not faster than single dynein molecules. Under physiological conditions, multiple dynein motors can move cargo processively, while single dynein motors cannot. Our results suggest that dynein motors may coordinate to move cargo efficiently. Studies of “tug-of-war” scenarios are underway to determine whether cargos driven by both dynein and kinesin exhibit stochastic bidirectional movements.

*Brian Goodman and Nathan Derr contributed equally to this work.

42

Rewiring the histone code using synthetic effectors.

K. A. Haynes[1]; [1]School of Biological and Health Systems Engineering, Arizona State University, Tempe, AZ

Synthetic transcription factors that control specific regulatory genes are of great interest for basic research, tissue engineering, and cancer therapy. To date, transcription factors have been engineered to bind DNA sequences, but do not recognize epigenetic marks that distinguish developmental and disease-related cell states. We set out to use a novel gene targeting approach that exploits chromatin signatures to target a subset of genes for reactivation. We used the human Polycomb protein CBX8 and homologues from other species to design artificial transcription factors that translate the repressive tri-methyl histone H3 lysine 27 (H3K27me3) signal into gene activation in human cells. Protein modules including the herpes simplex virus VP64 transcription activation domain, H3K27me3-binding Polycomb chromodomains (PCDs), red fluorescent mCherry, and the SV40 nuclear localization signal were combined to create a set of fluorescently tagged Polycomb-based synthetic transcription factors (Pc-TFs). Induced expression of Pc-TF leads to increased transcription of the senescence locus p16 (CDKN2a)

and other loci in a PCD- and VP64-dependent manner. We also observe induction of senescence-associated beta-galactosidase activity upon expression of Pc-TF in an osteosarcoma cell line. Our results show that a subset of genes can be regulated by an artificial transcription factor that recognizes histone methylation, rather than a specific DNA sequence. This work demonstrates the flexibility of synthetic transcription factor engineering and is the first example of chromatin-mediated TF targeting in human cells.

43

Generation of Intracellular Logic Gates with Two Orthogonal Chemically Inducible Systems.

R. DeRose[1], T. Miyamoto[1], A. Suarez[1], T. Ueno[1], M. Chen[1], T-P. Sun[2], C. Mukherjee[3], D. Meyers[3], T. Inoue[1]; [1]Cell Biology, Johns Hopkins Univ, Baltimore, MD, [2]Biology, Duke Univ, Durham, NC, [3]Pharmacology, Johns Hopkins Univ, Baltimore, MD

In the creation of non-silicon-based computers, various biomolecules have been used to construct Boolean logic gates. However, their □ecomputational□f timescale is relatively slow (tens of minutes to hours), as most of these biological logic gates utilize gene expression that requires time-consuming processes such as transcription and translation. For faster processing, we employed chemically inducible protein dimerization systems. To rapidly trigger two chemically inducible signals, we developed an efficient chemical dimerization system using a newly synthesized gibberellin analog (GA3-AM) and its binding proteins, a system that is completely orthogonal to rapamycin-mediated protein dimerization. With the two chemical inputs (rapamycin and GA3-AM), we achieved AND as well as OR gates, that produced output signals such as fluorescence and membrane ruffling on a timescale of seconds. The use of two orthogonal dimerization systems in the same cell also allows for finer modulation of protein perturbations than is possible with a single dimerizer. (The content of the study is now under review by Nature Chemical Biology.)

44

Quantitative assessment of Ras over-expression via shotgun deployment of vectors utilizing synthetic promoters.

J. P. Ferreira[1], I. E. Lawhorn[2], R. W. Peacock[2], C. L. Wang[3]; [1]Stanford University, Stanford, CA [2]Chemical Engineering, Stanford University, Stanford, CA

We sought to characterize and compare wild-type and oncogenic Ras over-expression in pre-B cells immortalized by the viral Abelson kinase. Because different levels of Ras over-expression can have different cellular outcomes, it was important to evaluate a wide range of expression. First, we generated a library of synthetic promoters capable of a 40-fold expression range. Different expression levels were then achieved by using retroviral vectors equipped with various synthetic promoters. Cells were “shotgun” transduced with a mixture of these vectors to generate heterogeneous populations exhibiting a range of expression levels. We used flow cytometry to analyze the populations and generate continuous, high resolution, Ras dose-response curves. By inactivating all isoforms of endogenous Ras using the inhibitor salirasib and transducing cells with Ras engineered to be resistant to salirasib (myristoylated Ras), we were able perform experiments in the presence of the inhibitor and characterize a complete Ras dose response ranging from nearly zero Ras activity to 10-fold over-expression. Experiments revealed that a single-copy level of oncogenic Ras generated maximal imatinib resistance and activated MAPK pathway signaling as effectively as six-fold amplification of wild-type Ras. Although further increased expression lead to even greater signal transduction, this increased expression had minimal or decreasing effects on the proliferation rate. In general, this study

introduces a method to quantify genetic dose-response relationships and identify gene expression ranges that produce an optimized phenotypic response.

Minisymposium 7: The Nuclear Periphery

45

Radial organization of the nuclear pore complex imaged by super-resolution microscopy.

A. B. Szymborska[1], A. de Marco[2], J. A. Briggs[1,2], J. Ellenberg[1]; [1]Cell Biology and Biophysics Unit, European Molecular Biology Laboratory, Heidelberg, Germany, [2]Structural and Computational Biology Unit, European Molecular Biology Laboratory, Heidelberg, Germany

Integration of atomic structures of individual proteins into macromolecular models of multiprotein assemblies is a long standing challenge in the understanding of the mechanistic details and function of cellular machinery. One of the most prominent examples is the nuclear pore complex (NPC), a ~100 MDa assembly of several hundred polypeptides that functions as the sole channel for nucleocytoplasmic transport in all eukaryotes. Cryo-electron tomography has provided an overall structure of NPC, but due to technical limitations its resolution does not allow to unambiguously map the position, stoichiometry and orientation of individual subcomplexes or atomic structures of single nucleoporins within the assembly. How the individual molecular building blocks assemble to make the nuclear pore therefore remains an open question.
Here, we have used a super-resolution light microscopy method, ground state depletion followed by individual molecule return (GSDIM), to study the substructure of the NPC in human cultured cells. We initially focused on the organization of the Nup107-160 complex, which is the major component of the vertebrate NPC's scaffold and is responsible for stabilization of the highly curved pore membrane. Using optimized immunofluorescence protocols with GSDIM compatible dyes we are able to resolve individual members of the Nup107-160 complex and measure their radial distance from the central 8-fold symmetry axis of the pore. To our knowledge this is the first time that the radial substructure of the NPC was directly visualized by light microscopy.

46

Formation of the post-mitotic nuclear envelope from extended endoplasmic reticulum cisternae precedes nuclear pore assembly.

L. Lu[1], M. Ladinsky[2], T. Kirchhausen[3]; [1]School of Biological Sciences, Nanyang Technological University, Singapore, Singapore, [2]Division of Biology and Howard Hughes Medical Institute, California Institute of Technology, Pasadena, CA, [3]Department of Cell Biology, Immune Disease Institute, Harvard Medical School, Boston, MA

During mitosis, the nuclear envelope membrane merges with the endoplasmic reticulum while the nuclear pore complexes are disassembled. In a current model, the nuclear envelope forms at the end of mitosis by re-shaping of endoplasmic reticulum tubules. Two major models have been proposed regarding the assembly of nuclear pore complexes. In the insertion model, nuclear pore complexes are assembled and embedded in the nuclear envelope following its formation. In the pre-pore model, nucleoporins, such as Nup107-160 complexes, assemble on the chromatin as an intermediate nuclear pore complex prior to nuclear envelope formation. Using multi-dimensional live cell imaging and electron microscope tomography, we find that the assembly of the nuclear envelope occurs by direct adhesion and migration of mitotic endoplasmic reticulum cisternae around the chromosome mass. Furthermore, we find that the

nuclear pore complexes only assemble on the newly formed nuclear envelope membrane. By a single molecule approach developed for this study, we demonstrate that all the chromatin associated Nup107-160 complexes are in single units instead of assembled pre-pores. Our observations thus support a model in which the post-mitotic nuclear envelope assembles directly from endoplasmic reticulum cisternae, followed by membrane-dependent insertion of nuclear pore complexes.

47

Cell Cycle-dependent Nuclear Envelope Dynein Recruitment Factors Mediate Interkinetic Nuclear Migration in Developing Brain.

T. Nayak[1], D. Hu[2], A. Akhmanova[3], V. Doye[4], R. Vallee[2]; [1]Pathology and Cell Biology, Columbia Univ., New York, NY, [2]Pathology and Cell Biology, Columbia Univ., New York, NY, [3]Cell Biology, Utrecht Univ., Utrecht, The Netherlands, [4]Inst Jacques Monod, CNRS, Univ. Paris Diderot, Paris, France

Radial glial neural progenitors (RGPCs) are highly elongated cells that span the developing neocortex from the ventricular to the pial surface. These cells exhibit long-range cell cycle-dependent "interkinetic nuclear migration" (INM; Sauer, J. Comp. Neurol., 1935, 62:377-405), the purpose and mechanism of which have long been mysterious. We have found MTs to be uniformly oriented throughout the cytoplasm of the RGPCs, while the centrosome remains at the ventricular surface throughout INM (Tsai et al. Nat. Neurosci. 2010, 13:1463-71). Our data have further revealed nuclear migration to be mediated by Kif1A in the MT plus end direction during G1 (basal migration), and by cytoplasmic dynein in the minus end direction during G2 (apical migration), followed by mitosis, which occurs only at the ventricular surface. Our results suggest that the motor proteins act from the nuclear envelope. We have now tested this hypothesis by analysis of factors previously implicated in dynein recruitment to the nuclear envelope during G2 in nonneuronal cells (BicD2, Splinter, D. et al., 2010, PLoS Biol.8: e1000350; Nup133-CENP-F, Bolhy S. et al., JCB, 2011, 192:855-71). Using in utero electroporation in E16 rat brain we find that RNAi for BicD2, Nup133, or CENP-F dramatically inhibits neuronal redistribution. Live imaging reveals specific inhibition of MT minus end-directed apical nuclear migration in RGPCs. BiCD2 RNAi produces a broad distribution of nuclei throughout the ventricular zone, whereas Nup133 RNAi arrests most RGPC nuclei within 10µm of the ventricular surface, consistent with early vs. late G2 roles for these factors. Nup133 RNAi arrested cells are phospho-histone H3-negative, identifying a novel premitotic arrest state. Together these data strongly support a role for dynein recruitment to the NE in apical nuclear migration in these cells. BicD2 and Nup133 now appear to be required for long-range nuclear migration in RGPCs, in addition to their role in centrosome positioning and force generation during NEB. Moreover, our data provide new insight into cell cycle control of INM. Supp. by HD40182 to RBV; AHA and NIH fellowships to TN; ANR-07-blan to VD; and NWO ALW-VICI to AA.

48

The nuclear pore complex protein Ndc1 is involved in nuclear positioning in migrating fibroblasts.

D. S. Osorio[1,2], J. Borrego-Pinto[1], E. R. Gomes[1]; [1]INSERM UMR 787 Myology Group, Universite Pierre et Marie Curie, Paris, France, [2]PhD Program in Biomedicine, Faculty of Medicine, University of Porto, Porto, Portugal

Positioning of the nucleus within cells has a role in different processes such as cell migration and muscle differentiation. In migrating fibroblasts the nucleus moves backwards prior to cell migration and this active movement is dependent on the actin cytoskeleton and on nuclear envelope proteins members of the LINC complex such and Nesprin and SUN proteins. In recent

years several mass spectrometry studies in mammalian cells have identified many putative transmembrane nuclear envelope proteins that may be involved in establishing or regulating the interaction between nucleus and cytoskeleton thereby being required for nuclear positioning. In order to identify novel proteins involved in this process we preformed a live-imaging screen for inhibition of nuclear movement through short interfering RNA (SiRNA) against a set of 230 potential/confirmed nuclear envelope proteins from published organellar proteomics studies. Ndc1, a conserved transmembrane protein of the nuclear pore complex (NPC) was one of our hits. The screening results were further validated by the inhibition of centrosome reorientation and nuclear positioning in a fixed cell assay. Furthermore the knockdown of Ndc1 caused cell migration defects similar to what observed in Nesprin-2 SiRNA treated cells. Although the full knock down of Ndc1 resulted in general disruptions of the nuclear envelope, consistent with its role in nuclear pore assembly, a partial knockdown was sufficient to inhibit nuclear movement without significantly affecting nuclear envelope proteins and structure. Moreover we identified a specific interaction between the N-terminal region of Ndc1 and SUN2, distinct from the proposed NPC interacting region on the conserved C-terminus of Ndc1. Expression of full length siRNA resistant Ndc1 or Ndc1 lacking the c-terminus were able to rescue centrosome reorientation in Ndc1 siRNA cells, suggesting that the interaction of Ndc1 with the nuclear pore is not required for nuclear movement. Furthermore, SUN2 and the NPC do not seem to co-localize on the nuclear envelope. We propose a model where a non-NPC subpopulation of Ndc1 is involved in the regulation of SUN2 during nuclear movement.

49

The KASH Domain Protein Nesprin 4 is essential for cochlear outer hair cell maintenance and hearing.

H. Horn[1], A. Dror[2], K. Roux[3], S. Kozlov[4], K. Avraham[2], B. Burke[1], C. Stewart[1]; [1]Institute of Medical Biology, Singapore, [2]Human Molecular Genetics and Biochemistry, Tel Aviv University, Tel Aviv, Israel, [3]Sanford Children's Health Research Center, Sioux Falls, SD, [4]Molecular and Cell Analysis, National Cancer Institute, Frederick, MD

The mechanosensory process of hearing involves highly specialized epithelial cells in the inner ear known as hair cells. Through apical stereocilia, these cells detect vibrations generated by sound waves, triggering a cellular depolarization that sends a nerve impulse to the hearing center of the brain. Hair cells are divided into two groups, inner and outer. Outer hair cells (OHCs) are critical to the cochlear sensory epithelium: impaired function or loss of OHCs results in deafness. Nesprin4 (Nesp4) is an outer nuclear membrane KASH-domain protein we previously identified in secretory epithelial cells. Nesp4 functions as a nuclear envelope (NE)-associated adaptor for Kinesin-1. Like other nesprin family members, it is a component of nuclear envelope-associated LINC (LInker of Nucleoskeleton and Cytoskeleton) complexes. These structures, consisting of inner nuclear membrane SUN proteins in association with outer nuclear membrane KASH domain proteins, provide a direct physical connection between nuclear components and the cytoskeleton. We now show that Nesp4 is expressed in OHCs, where it localizes exclusively to the NE. By deriving mice deficient for Nesp4, we are able to demonstrate that expression of this protein is essential for OHC maintenance. At birth (P0), the cochlear sensory epithelium from *Nesp4*-null animals appears indistinguishable from that of wild-type littermates with an overtly normal OHC morphology. However, by day 11 (P11), the sensory epithelium of *Nesp4*-null animals begins to lose OHCs through a process consistent with apoptotic cell death, as evidenced by TUNEL staining. No such loss was detected in wild-type littermates. By P30, this loss of OHCs is widespread within the cochlea, and *Nesp4*-null mice are deaf by the age of 8 weeks. Our conclusion is that Nesp4 is essential for the maintenance of OHC viability.

50

B-type lamins regulates neither their bound genes nor embryonic stem cells but are essential for organogenesis.

Y. Kim[1], A. Sharov[2], K. Mcdole[1], M. Cheng[3], H. Hao[4], C-M. Fan[1], N. Gaiano[3], M. Ko[2], Y. Zheng[1]; [1]Carnegie Inst for Science, Baltimore, MD, [2]Developmental Genomics and Aging Section, NIA, NIH, Baltimore, MD, [3]Department of Neuroscience, Johns Hopkins Univ., [4]Microarray core facility, JHMI, Baltimore, MD

B-type lamins are believed to regulate gene silencing of their tethered genes. They are also thought to be essential for several basic functions including cell survival, DNA replication, and cell proliferation. Using genome-wide chromatin-lamin B interaction and gene expression analyses, we show that chromatin-lamin-B interaction correlates with reduction of gene expression during embryonic stem cells (ESC) differentiation toward the trophectoderm (TE) lineage. To further investigate the significance of the chromatin-lamin-B interaction, we created lamin-B1 and -B2 double knock out (DKO) ESCs. These lamin-B DKO ESCs do not express any type of lamins including lamin-A/C, -B1, -B2 and -B3. Unexpectedly, their nuclear morphology, growth rates, ploidy, expression of pluripotent markers, and potential to differentiate to TE cells are indistinguishable from wild-type ESCs. Gene expression array analysis of these DKO ESCs and TE cells conclusively demonstrates that B-type lamins are not required for the silencing of their bound genes during ESC differentiation toward TE cells. Furthermore we report that the lamin-B DKO mice can develop to term. However they die soon after birth with a small body size and defects in multiple organs including the lung, diaphragm, phrenic nerves, and the brain. We further define the requirement for B-type lamins in regulating spindle orientation in neural progenitor cells (NPC), migration of neurons, and survival of both NPCs and neurons. While refuting several general requirements for B-type lamins, our findings redefine the essential role of these nuclear proteins in organogenesis.

Navigating the cellular landscape with new optical probes, imaging strategies and technical innovations.

J. Lippincott-Schwartz[1]; [1]NIH/NICHD, Bethesda, MD

Emerging visualization technologies are playing an increasingly important role in the study of numerous aspects of cell biology, capturing processes at the level of whole organisms down to single molecules. Recent developments in probes, techniques, microscopes and quantification are dramatically expanding the areas of productive imaging. Photoactivatable fluorescent proteins (PA-FPs) have been particular fruitful in this regard. They become bright and visible upon being exposed to a pulse of UV light. This allows selected populations of proteins to be pulse-labeled and tracked over time. Used for *in cellulo* pulse chase experiments, the PA-FPs have helped clarify mechanisms for biogenesis, targeting, and maintenance of organelles as separate identities within cells. PA-FPs have further permitted the development of single molecule-based superresolution (SR) imaging, which dramatically improves the spatial resolution of light microscopy by over an order of magnitude (~10-20 nm resolution). Involving the controlled activation and sampling of sparse subsets of photoconvertible fluorescent molecules, single molecule SR imaging offers exciting possibilities for obtaining molecule scale information on biological events occurring at variable time scales. Here, I discuss the new

fluorescent imaging techniques and the ways they are helping researchers navigate through the cell to unravel long-standing biological questions.

Symposium 3: Cellular Networks and Information Processing

52

Rho GTPase signalling modules in tumour cell migration and invasion.

C. Marshall[1];[1]Division of Cancer Biology, Institute of Cancer Research, London, United Kingdom

Cell migration requires coordination of many events such as membrane protrusion, rearrangement of the cytoskeleton and the generation of force by actomyosin contractility. Migration of tumor cells is an essential component of invasion and metastasis. Rho-family GTPase signalling coordinates the dynamic cytoskeletal changes that are required for cell migration. To delineate Rho-family GTPase signalling in cell migration we are carrying out a systematic analysis of Rho-family GTPases their regulators and signalling pathways. Using RNA interference to target all Rho-family GTPases, guanine nucleotide exchange factors (GEFs) and GTPase activating proteins (GAPs) we have described pathways controlling two distinct forms of movement in melanoma cells. Elongated, mesenchymal-type movement is driven by Rac activation mediated by a pathway containing the adaptor protein NEDD9 and the exchange factor DOCK3. In contrast rounded/amoeboid movement is driven by Rho and Cdc42 signalling to actomyosin contractility and suppressed by Rac activation. To investigate how Rho GTPase signalling is regulated we have studied upstream signalling events regulating the activation of Rac and actomyosin contractility. These studies reveal new insights into transmembrane signalling to Rho GTPases and demonstrate a tight interplay between Rho and Rac signalling in determining modes of cell movement.

53

Organizing genetic information and its processing without membrane compartmentalization.

C. Jacobs-Wagner[1], P. Montero Llopis[2], W. Schofield[2], O. Sliusarenko[3]; [1]Department of Molecular, Cellular and Developmental Biology, Yale Univ/HHMI, New Haven, CT, [2]Yale University, [3]HHMI

It has long been known that eukaryotic cells highly organize genetic information and its processing in space, notably through extensive cellular compartmentalization. More primitive organisms such as bacteria lack nuclei and other membrane-enclosed organelles. Therefore, all processes involved in the transfer of genetic information (such as transcription, translation and RNA processing and decay) occur in one single compartment: the cytoplasm. The bacterial cytoplasm is furthermore extremely crowded, with macromolecule concentration reaching 340 g/L. Such crowding implies that significant contributions from excluded volume effects reduce mobility of cytoplasmic components. Recent evidence shows that despite its apparent simplicity, the bacterial cell spatially organizes its genetic information with genes remaining within confined subcellular locations that are dictated by chromosomal gene arrangement. An active DNA segregation process and, in some bacteria, the presence of proteins localized at the cell poles help propagate this spatial information through generations. Spatial organization is also seen for specific messenger RNAs and RNA processing enzymes. These spatial constraints ultimately affect ribosome dynamics and translation.

54

Cell signaling at the single-cell level.

M. Elowitz[1]; [1]Division of Biology, California Inst Technol/HHMI, Pasadena, CA

What's special about the repertoire of signaling pathways we find in living cells? Despite increasingly comprehensive knowledge of the molecules and interactions involved in these signaling pathways, it often remains unclear how and why cells encode and represent signals in particular ways. I will discuss the quantitative analysis of signaling pathways using single-cell time-lapse microscopy, including recent work in bacteria, and in eukaryotes. Our results show that cells encode signals in unexpected and often highly dynamic ways, and that these encoding schemes enable cells to perform critical regulatory and developmental functions.

Symposium 4: Self-Organization of Cellular Structures

55

Self-Organization of Secretory Compartments.

Y. Liu[1], N. Bharucha[1], E. Papanikou[1], B. S. Glick[1]; [1]Molecular Genetics and Cell Biology, The University of Chicago, Chicago, IL

During the past decade, the concept of self-organization has been increasingly used to describe the biogenesis of secretory compartments. We have applied this concept to analyze transitional ER (tER) sites and the Golgi apparatus. These studies have focused on two budding yeasts: *Pichia pastoris*, which has a few large tER sites that are linked to Golgi stacks, and *Saccharomyces cerevisiae*, which has numerous small tER sites and a nonstacked Golgi. We found that *P. pastoris* tER sites are long-lived structures that form *de novo*, fuse upon collision, and grow or shrink to attain a steady-state size. This behavior can be explained by a self-organization model. Specifically, we postulate that capture of new tER components is balanced by shrinkage driven by the budding of COPII coated transport vesicles. To test this model, we used a genetic screen to identify Sec16 as a key player in tER organization. Sec16 is a large peripheral ER membrane protein that interacts with multiple COPII components. Our results suggest that Sec16 partitions between the ER membrane and the cytosol, and that the membrane-associated form acts as a negative regulator of ER export. According to this view, Sec16 functions primarily to control tER dynamics rather than to nucleate tER site formation. Interestingly, the redistribution of Sec16 to the cytosol is influenced by association of the central conserved domain of Sec16 with the COPII component Sec13. The combined data imply that Sec16 defines a new level of regulation for the ER export system. To study Golgi organization, we took advantage of the nonstacked Golgi cisternae in *S. cerevisiae*. Our 4D confocal microscopy studies revealed that Golgi cisternae mature by progressively acquiring and then losing early resident Golgi proteins followed by late resident Golgi proteins. Recently, we have found that early Golgi compartments are closely associated with tER sites even in *S. cerevisiae*, consistent with the idea that Golgi cisternae assemble by the coalescence of ER-derived vesicles. However, the mechanisms of subsequent Golgi maturation are more obscure. One possibility is that COPI coated vesicles drive the recycling of resident Golgi proteins from older to younger cisternae, but the experimental evidence for the role of COPI has been ambiguous. We are now using new approaches to achieve rapid and selective inactivation of COPI and other key trafficking components in *S. cerevisiae*. The long-term goal is to elucidate the cascade of interactions that enables the cell to rebuild the Golgi apparatus with each round of transport.

56

Spatiotemporal Integration of Chemical and Mechanical Signals in Cell Migration.

G. Danuser[1]; [1]Department of Cell Biology, Harvard Medical School, Boston, MA

Cell migration is driven by the self-organization of innumerable, coupled chemical and mechanical processes. Chemical signals activate and deactivate the assembly and disassembly of cytoskeleton polymer networks. Both assembly and disassembly generate mechanical forces that push parts of the cell forward and retract others. They also define the mechanical properties of the cytoskeleton, which in turn determine how forces translate into cell shape deformation and movements. Chemical signals modulate the activity of molecular motors that produce contractile forces. By pulling on the polymer networks, these same motors organize the architecture of the cytoskeleton. This affects again the mechanical properties of the cytoskeleton. Motors may even mediate polymer disassembly, inducing a secondary contractile response of the cytoskeleton. All these entangled mechanical outputs feed back into the activation of the upstream chemical signals, a process that can be referred to as cell intrinsic mechanotransduction. Decades of biochemical, genetic and molecular analyses have generated the parts lists for most of these chemical and mechanical processes as well as hypotheses of process interactions. However, there is still very limited understanding as to how the processes are spatially and temporally organized in a system with emergent properties. There are multiple challenges associated with addressing this question: First, the process hierarchies are transient and distributed over multiple time and length scales. Thus, new technology is required to monitor multiple processes working in parallel but at different time points and cellular locations; and analytical tools are needed to extract from these data the spatial, temporal, and functional linkages between processes. Second, because of the nested nonlinear interactions among processes, the stimulation or perturbation of a particular process component often propagates in complex ways, obscuring the relation between system response and component function. For the past ten years my lab has made attempts to implement approaches that tackle these issues. We have invested in the development of quantitative multi-parametric live cell imaging to acquire simultaneous measurements of cell morphodynamics, cytoskeleton dynamics, resulting intracellular forces, and chemical signals. We also have worked on multiplexing methods to couple these measurements across different experiments, allowing us to “stitch together” larger process models. Very recent work in the lab has focused on novel mathematical tools to predict complex nonlinear process hierarchies. Central to our approach is the use of minimally perturbing experimental strategies that avoid the ambiguities of nonlinear system responses induced by stronger interventions. This talk will highlight some of the most surprising discoveries we have made with this work and will give an outlook to the many challenges we are still facing in order to establish a comprehensive understanding of cell migration.

57

Modeling cytoskeletal structures with Cytosim.

F. Nedelec[1]; [1]Cell Biology and Biophysics, EMBL, Heidelberg, Germany

Living cells have a system of fibers and associated proteins, called the cytoskeleton, that provides an essential mechanical support during migration, polarization, division, etc. Cytoskeletal fibers form spontaneously by self-assembly of monomers, and multiple fibers can further self-organize into assemblies of cellular scale. In this talk, we will introduce cytosim, a simulation software with the aim to study systems of many fibers. We will explain how the user can easily configure the simulation with simple examples. We will also illustrate techniques that can be used to systematically explore the possibilities embedded in a cytoskeletal system.

Minisymposium 9: Bioengineering and Mechanobiology

Lamin A/C mutations linked to muscular dystrophies, but not lipodystrophies, cause impaired nuclear structure and mechanics in cells and tissue.

M. Zwerger[1], D. E. Jaalouk[1], M. Lombardi[1], P. Isermann[1], J. Lammerding[1,2];
[1]Medicine, Brigham and Women's Hospital, Boston, MA, [2]Biomedical Engineering, Cornell University, Ithaca, NY

Objective: Mutations in the *LMNA* gene that encodes the nuclear envelope proteins lamin A and C cause a plethora of human diseases (laminopathies), including muscular dystrophies, cardiomyopathies, and familial partial lipodystrophy. It remains unclear how mutations in a single gene can result in such a variety of diseases, many of them specifically affecting muscle tissues, while other mutations cause little or no muscle involvement. Since lamins A and C are the main contributors to nuclear stiffness, we hypothesized that lamin mutations associated with muscular phenotypes could impair the structural properties of the nuclear lamin network, weakening the nuclear integrity and resulting in cells more susceptible to mechanical stress.

Methods: We measured nuclear stiffness in fibroblasts derived from patients with diverse laminopathies and in lamin A/C–deficient mouse embryonic fibroblasts (MEFs) engineered to stably express physiological levels of specific lamin A mutants. In a subset of cells, we also probed nucleo-cytoskeletal coupling with a custom-developed microneedle assay. To assess the in situ effect of lamin mutations in muscle, we measured nuclear stiffness in body wall muscle of Drosophila melanogaster expressing lamin C mutations associated with human laminopathies or wildtype lamin.

Results: Patient fibroblasts carrying *LMNA* mutations associated with muscular dystrophies had significantly softer nuclei than cells from healthy controls ($P<0.001$), while fibroblasts from lipodystrophy patients had normal nuclear mechanics. Extending our studies to MEFs expressing a broad panel of lamin A mutations, we found that 4 of the 15 tested lamin A mutations caused decreased nuclear stiffness. Importantly, all four mutations were associated with laminopathies affecting muscle tissue, whereas mutations linked to lipodystrophy had no effect on the structural function of lamin A. Of note, most mutations linked to muscular disease also showed disturbed nucleo-cytoskeletal coupling. Experiments with freshly isolated Drosophila melanogaster body wall muscle subjected to mechanical strain confirmed that specific lamin A mutations affect nuclear mechanics not only in isolated cells, but also in intact muscle tissue.

Conclusions: *LMNA* mutations associated with muscular laminopathies can cause impaired nuclear mechanics, which may lead to increased cellular sensitivity to mechanical stress and contribute to the muscle specific phenotype in these diseases. In conclusion, our results demonstrate the importance of lamins A and C on nuclear mechanics in laminopathies, but also indicate that additional factors such as altered nucleo-cytoskeletal coupling influence the disease outcome.

59

Vinculin is important for p130Cas-mediated mechanotransduction.

T. Dey[1], R. Janostiak[2], D. Rosel[2], J. Brabek[2], B. Fabry[1], W. H. Goldmann[1]; [1]Biophysics, University of Erlangen-Nuremberg, Erlangen, Germany, [2]Department of Cell Biology, Charles University Prague, Czech Republic

Fibroblasts, when subjected to mechanical stress, reinforce their focal adhesion contacts by activating the focal adhesion protein p130Cas, followed by binding of p130Cas with focal adhesion kinase (FAK) and talin, and subsequent activation of downstream pathways such as extracellular-signal-regulated kinase, $ERK^{1/2}$ phosphorylation. A newly discovered phosphorylation site (Y12) on p130Cas has been suggested to play an important role in modulating the binding with FAK, and potentially with vinculin. In particular, phosphorylation of position Y12 or mutation with phospho-mimicking glutamate (Y12→E) suppresses binding to vinculin. Our question was how Y12 phosphorylation and vinculin binding affects the distribution of p130Cas in cells and its activation upon mechanical stress. The presence of p130Cas in the focal adhesion complexes was not altered in vinculin-deficient fibroblasts. Baseline and stretch-induced phosphorylation of p130Cas, however, was reduced compared to vinculin wildtype cells. Moreover, phospho-mimicking mutation (Y12→E) on p130Cas, which prevents vinculin binding, increases downstream phosphorylation of $ERK^{1/2}$ in stretched cells. Taken together, these data demonstrate that vinculin is an important modulator of the p130Cas-mediated mechanotransduction pathway in cells.

60

A mechanosensory system governs myosin II cleavage furrow accumulation.

Y. Kee[1], Y. Ren[1], D. Dorfman[1], M. Iijima[1], R. Firtel[2], P. Iglesias[3], D. Robinson[1]; [1]Department of Cell Biology, Johns Hopkins University, Baltimore, MD, [2]Section of Cell & Developmental Biology, University of California San Diego, CA, [3]Department of Electrical and Computer Engineering, Johns Hopkins University, Baltimore, MD

The mitotic spindle is generally considered to be the initiator of furrow ingression. However, recent studies have shown that furrows can form in the absence of spindles, particularly during asymmetric cell division. In *Dictyostelium*, the mechanoenzyme myosin II and the actin crosslinker cortexillin I form a mechanosensor that responds to mechanical stress, which could account for spindle-independent contractile protein recruitment. Here, we show that the cleavage furrow regulatory and contractility network, composed of myosin II, cortexillin I, IQGAP1, IQGAP2, kinesin-6 (kif12) and INCENP, is a mechanical stress-responsive system. Myosin II and cortexillin I form the core mechanosensor, and mechanotransduction is mediated by IQGAP2 through kif12 and INCENP. Additionally, IQGAP2 is antagonized by IQGAP1 to modulate the mechanoresponsiveness of cortexillin I, suggesting a possible mechanism for discriminating between mechanical and biochemical inputs. Furthermore, IQGAP2 is important for maintaining normal spindle morphology and recruitment of kif12 and myosin II to the cleavage furrow. Finally, the mitotic spindle is dispensable for the system. Overall, we suggest that this mechanosensory system is structured like a control system characterized by mechanochemical feedback loops that regulate the myosin II levels at the cleavage furrow.

61

Matrix compliance regulates epithelial-mesenchymal transition.

K. Lee[1], Q. Chen[1], C. Lui[1], M. Cichon[2], D. Radisky[2], C. Nelson[1]; [1]Chemical and Biological Engineering, Princeton University, Princeton, NJ [2]Mayo Clinic Cancer Center

Epithelial-mesenchymal transition (EMT) is a phenotypic switch wherein cells detach from a polarized epithelium and acquire a motile, fibroblastic phenotype. Matrix metalloproteinases (MMPs) have been shown to be key factors associated with pathological EMT. We found that microenvironmental context, specifically substratum stiffness, plays a pivotal role in the regulation of EMT by MMP3. Soft substrata, with compliances comparable to that of normal mammary tissue, are protective against MMP3-induced EMT, whereas stiffer substrata, with compliances characteristic of breast tumors, promote EMT. Matrix rigidity governs EMT by controlling the subcellular localization of Rac1b, a highly activated splice variant of Rac1 found in breast and colorectal tumors. Culture on soft substrata inhibits focal adhesion formation and the membrane localization of Rac1b, and thereby interrupts its interaction with NADPH oxidase. This subsequently inhibits MMP3- and Rac1b-induced production of reactive oxygen species (ROS), expression of Snail, and activation of the EMT program. Altering Rac1b prenylation or integrin clustering using mutated forms of these proteins can bypass the signals induced by substratum compliance. These results suggest the role of a novel mechanotransduction pathway in the regulation of EMT.

62

Bleaching/blinking assisted localization microscopy (BALM) for super-resolution imaging using standard fluorescent molecules.

D. Burnette[1], P. Sengupta[1], Y. Dai[2], J. Lippincott-Schwartz[1], B. Kachar[2]; [1]CBMB, National Institute of Child Health and Human Development, NIH, Bethesda, MD, [2]National Institute on Deafness and Other Communication Disorders, NIH, Bethesda, MD

Super-resolution imaging techniques circumvent the diffraction-limit of light microscopes and are useful in cell biological research because they bridge the gap between the image-resolution possible from diffraction-limited light microscopy (hundreds of nanometers) and the resolution possible from electron microscopy (less than 1 nanometer). Point localization techniques, such as Photoactivated Localization Microscopy (PALM) and Stochastic Optical Reconstruction Microscopy (STORM), achieve a particularly high resolution by fitting single fluorescent molecules with a theoretical Gaussian to localize them with a precision on the order of tens of nanometers. PALM/STORM rely on photoactivatable proteins and photoswitching dyes, respectively, making them technically challenging and preventing them from being easily added to a cell biologist's "tool box". Here, we present a simple and practical way of producing point localization-based-super-resolution images, bleaching/blinking localization microscopy (BALM), that relies on the intrinsic bleaching (irreversibly turn off) and blinking (reversibly turn off and on) behaviors characteristic of all commonly used fluorescent molecules. To do BALM, the researcher first acquires a streaming recording of a fixed sample labeled with a fluorescent probe, which will bleach over time. Single molecule-turn off (bleach or blink off) events can be detected by subtracting from each image of the acquisition the next subsequent image. Similarly, blink on events are detectable by subtracting from each frame the previous one. To validate that BALM works using a standard EMCCD camera we first imaged microtubules in COS7 cells labeled with Alexa-488. After image subtractions, the localization precision of single Alexa-488 molecules was subsequently calculated (σ=26.6 +/- 14 nm) which is similar to that achieved by PALM. We then verified the increase in structural resolution by comparing microtubules reconstructed with BALM with those reconstructed with PALM. We then performed BALM on Myosin IIC-GFP to show that it works with exogenously expressed fluorescent

proteins. Finally, we performed BALM on microtubules labeled with Alexa-488, Alexa-561, and Alexa-647 to show that BALM can be used to localize several different fluorescent probes in the same cell. Thus, BALM is a practical and flexible super-resolution technique, which is only limited by the users ability to separate the emission of different fluorophores.

63

Adipose-Derived Stem Cells Form Functional Myotubes Via Mechanical Induction whereas Marrow-derived cells Do Not.

Y. Choi[1], L. Vincent[1], A. Lee[1], M. Dobke[2], A. Engler[1]; [1]Bioengineering, Univ California-San Diego, La Jolla, CA, [2]Plastic Surgery, Univ California-San Diego, La Jolla, CA

Undifferentiated stem cells integrate cues around themselves to differentiate, but often for fibrotic muscle diseases that stiffen the microenvironment, e.g. muscular dystrophy and myocardial infarction, differentiation is misdirected. When co-delivered with exogenous growth factors, bone marrow-derived stem cells (BMSC) commit to their appropriate mesodermal-derived lineages, but efficiency is not sufficiently high enough to restore function. Biochemical methods overlook biophysical interactions between cells and extracellular matrix (ECM), which is stiffened by fibrosis and clearly impacts cell function in vivo. Though they express a similar molecular signature and can commit to mesodermal lineages via growth factors, differences between adipose-derived stem cell (ASC) and BMSCs may likely impact their differentiation efficiency in diseased muscle. Here we found that ASCs reflect the same qualitative stiffness sensitivity as BMSCs with morphological changes reflecting differentiated phenotypes (Engler et al, Cell 2006). However, quantitative analysis of lineage expression showed ASCs correctly express the appropriate temporal sequence of muscle transcriptional regulators, e.g. MyoD, Myogenin, MEF2C, etc., and do so at levels at least 10-fold higher than BMSCs. Moreover by 7 days in culture, 2.1% of ASCs form multi-nucleated myotubes with a continuous network that is not the result of misdirected cell division. This process mirrors that in primary muscle cells, and most importantly, BMSCs were never observed to undergo this process. Treatment with myoseverin, a microtubule depolymerizing drug that severs myotubes, could disrupt ASC-derived myotubes, but 7 days after drug washout, ASCs refused and formed myotubes at a rate similar to their pretreated value. To understand why ASC are more myogenic when stimulated by ECM, it was determined that they appear more contractile and form adhesions faster than BMSCs. Their fate is also alpha5 and alphaV integrin-dependent as they do not undergo myogenesis in their absence. Interestingly, ASC replated on non-permissive substrates maintain their state, which implies that they are less plastic and may likely be more successful in engrafting and restoring function in fibrotic muscle.

Minisymposium 10: Cell Polarity

64

PAR proteins regulate the cortical localization of LET-99 during asymmetric division.

J-C. Wu[1], E. Espiritu[1], L. Rose[1]; [1]Department of Molecular and Cellular Biology, Univ California-Davis, Davis, CA

Positioning of the mitotic spindle is essential for a number of developmental processes, including asymmetric divisions that generate cell diversity. During such divisions, the spindle must align with the cell polarity axis, and the spindle is often displaced so that division is unequal. The PAR proteins establish polarity in many cell types. PAR proteins also regulate spindle movements, in part via a cortical complex that includes Gα, GPR (LGN/Pins) and LIN-5

(NuMA/Mud). This complex is thought to activate dynein to pull on astral microtubules and move the spindle. During the first asymmetric division of the *C. elegans* embryo, GPR and LIN-5 are localized asymmetrically. We previously showed that LET-99 is an intermediate in this spindle-positioning pathway and is required for both spindle orientation and displacement. LET-99, a DEPDC1 family protein, is localized at the cortex in a lateral-posterior band, where it prevents GPR accumulation, thus generating asymmetry. PAR-3 inhibits LET-99 localization at the anterior, while PAR-1 inhibits LET-99 at the posterior-most cortex. In other systems, phosphorylation of PAR-3 by the PAR-1 kinase generates binding sites for 14-3-3 proteins, which prevents cortical accumulation. We found that the PAR-5 14-3-3 protein and PAR-1 associate with LET-99, and have identified two serine residues in LET-99 essential for PAR-5 binding. To determine the in vivo relevance of these sites, two S to A mutations were introduced into a LET-99 transgene (LET-99-AA). LET-99-AA localized to the entire posterior cortex of the one-cell embryo instead of a band. These and other results support the model that PAR-5 binds to LET-99 to dissociate it from the cortex, and that this interaction is regulated by phosphorylation of LET-99 by PAR-1 at the posterior. In contrast, LET-99-AA is inhibited from the anterior cortex, which suggests that PAR-3 regulates LET-99 through a PAR-5 independent mechanism. We are currently determining if other anterior PAR proteins are required for LET-99 asymmetry, as well as investigating the mechanism by which LET-99 inhibits GPR localization.

65

Oscillatory dynamics and spatial self-organization of Cdc42 GTPase in the control of polarized cell growth.

M. Das[1], T. Drake[2], P. Buchwald[1], D. Vavylonis[2], F. Verde[1]; [1]Mol. Cell. Pharmacology, University of Miami, Miami, FL, [2]Department of Physics, Lehigh University, Bethlehem, PA

The conserved Cdc42 GTPase has a crucial role in the establishment of cell polarity by promoting cytoskeletal asymmetry. Previous studies have shown that Cdc42 breaks symmetry by clustering on a single membrane spot via a complex mechanism mediated in part by “winner-take-all” Cdc42 autocatalytic amplification. This however cannot explain how multiple growing zones form simultaneously in a cell. Fission yeast switches from monopolar to bipolar growth during cell cycle progression in a process known as “new end take off” (NETO), making it an ideal system to study how bipolarity arises and is regulated in cells. Here we show that tip-bound active Cdc42 concentrations correlate with changes in growth pattern and exhibit large oscillations with an average period of five minutes. A mathematical model invoking Cdc42 autocatalytic amplification, competition between growth sites, and delayed negative feedback reproduces the observed dynamics and its predictions are confirmed by experimental tests. We find that Cdc42 oscillations facilitate transitions between polarization states and are critical for active redistribution of growth. Our findings are consistent with observations in mammalian and plant cells, suggesting that related mechanisms of self-organization underlie the emergence of cell form.

66

The centrosome and PAR-3 are required during epithelial polarization for the normal hand-off of microtubule organizing center function.

J. L. Feldman[1], J. R. Priess[1]; [1]Basic Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA

Although the centrosome is the major microtubule organizing center (MTOC) of the cell, MTOC function often is reassigned to the apical membrane in epithelial cells. In the development of the *C. elegans* intestine, for example, microtubule-nucleating proteins such as γ-tubulin and CeGrip-1/dgrip91/Spc98p that normally are found at the centrosome are present at the apical

membrane; the apical cortex becomes highly enriched in microtubules, but few or no microtubules appear associated with the centrosome. The apical deposition of γ-tubulin and CeGrip-1 occurs when intestinal cells are post-mitotic and starting to polarize. During this stage, centrosomes that were near either anterior or posterior lateral membranes following cell division migrate orthogonally toward the future apical membrane. Centrosomes and centrosome positioning appear to influence apical deposition of γ-tubulin and CeGrip-1: First, embryos lacking the polarity protein PAR-3 fail to apically position their centrosomes, and have aberrant localization of γ-tubulin and CeGrip-1. Second, γ-tubulin fails to accumulate apically in wild-type cells following laser ablation of the centrosome. Using live imaging, we show that centrosomes localize apically by first moving toward lateral foci of PAR-3 and PAR-6. These foci move together with the centrosomes toward the future apical surface. Remarkably, γ-tubulin appears to redistribute directly from the migrating centrosome onto the lateral/apical membrane. Together, these data suggest that PAR-3 contributes to apical polarity in part by positioning centrosomes, and that the hand-off of MTOC function from centrosomes to the apical membrane is associated with a physical hand-off of nucleators of microtubule assembly. γ

67

Spatial Guidance of Microtubule Organization in Polarizing Epithelia.

J. Bowen[1], D. Hwang[1], X. Bai[1], D. Roy[1], E. Spiliotis[1]; [1]Biology, Drexel University, Philadelphia, PA

Establishment of epithelial polarity requires the reorganization of the microtubule (MT) cytoskeleton from a radial array into a network positioned along the apicobasal axis of the cell. Little is known about the mechanisms that spatially guide the remodeling of MTs during epithelial polarization. Septins are filamentous GTPases that associate with MTs, but the function of septins in MT organization and dynamics is poorly understood. Using the Madin-Darby Canine Kidney (MDCK) model system of epithelial polarity, we have found that septin filaments provide a navigation mechanism for the positioning of MTs along the emerging axis of apicobasal polarity. We show that cell-cell adhesion triggers the formation of perinuclear septin filaments, which colocalize exclusively with MT bundles that transverse the apex and sides of the nucleus. Using septin RNAi and dominant negative constructs and in vitro biochemistry, we show that septins mediate the formation of MT bundles by suppressing MT catastrophe. As epithelial cells grow taller and become more columnar, septin-MT bundles arch back and begin to extend vertically along the developing apicobasal axis. Our results indicate that these septin-MT bundles provide a directional cue for the establishment of the apical MT meshwork. We show that MT-septin bundles are often targeted by MT ends, which dock and change their directionality of growth along septin filaments. Upon septin knock down, MTs meander stochastically and the MT network becomes highly entangled. Importantly, the percentage of MT plus ends found in the apical cytoplasm is significantly reduced, causing a shift in MT distribution toward the basal and medial cytoplasm. Taken together, these data indicate that septins navigate the growth and positioning of epithelial MT during the establishment of apicobasal polarity.

68

Self-organization of stress-fibers and focal adhesions into polar arrays.

T. Shemesh[1], Y. Tee[2], M. Kozlov[3], A. Bershadsky[1,2]; [1]Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel, [2]Mechanobiology Institute, National University of Singapore, [3]Tel Aviv University, Israel

Fibroblasts attached to a flat rigid isotropic substrate spread first isotropically and form isotropic system of radial and circumferential (tangential) actomyosin bundles (stress fibers, SFs)

associated with the radial focal adhesions (FAs). In a couple of hours, however, these cells undergo polarization manifested by cell elongation, segregation of cell periphery into active (lamellipodia forming) and stable regions, and formation of the array of SFs oriented along the long axis of the cell. Here we show that orientation of the FAs and organization of the array of parallel SFs precedes cell elongation and formation of active and stable cell edges. Moreover, parallel orientation of SFs/FAs develops eventually even in cells in which elongation was artificially suppressed by plating on circular adhesive islands. In such cells, formation of parallel SFs array was often preceded by synchronous turn of the radial SFs ("cytoplasmic swirl" phenomenon). We present a model for the dynamic re-distribution of tangential and radial SFs that precedes and promotes polarization of the cell body. Our model hypothesis that the tangential SFs, emerging at lamellipodium-lamellum interface, are at first anchored to the mature Fas and remain bound at their both ends to the radial SFs that project from the FA towards the cell center. Energy consuming contraction of acto-myosin complexes within the actomyosin SFs generates stresses, which are translated to effective forces acting on the bound ends of the tangential SFs. These effective forces result in a global centripetal motion of the tangential SFs. The orientation of the radial SFs, the motion patterns, and the forces acting on the FAs are coupled together. Using numerical simulations we demonstrate that noise in the system can cause a spontaneous symmetry breaking of the SFs arrangement, resulting in such experimentally observed phenomena as cytoplasmic swirl and polarization of the SFs.

Abstract 69- WITHDRAWN

Front-Rear Polarization of the Cytoskeleton develops in Cell migration from Soft to Stiff Matrix.

M. Raab[1], J. Swift[1], D. Discher[1]; [1]University of Pennsylvania, Philadelphia, PA

It has become increasingly clear that cytoskeletal polarity is strikingly different in cells functioning in an in vivo environment compared to cells studied in vitro. Reasons for this discrepancy are unknown and whether matrix rigidity plays a role in affecting cell polarity is has yet to be studied. Tissues have been measured to have varying stiffnesses or deformabilities, and examples of matrix stiffening include scarring in the heart after a myocardial infarction or scarring of the liver in cirrhosis – which lead to rigidification of tissue through extensive collagen crosslinking, and it has been reported that adherent cells, including mesenchymal stem cells (MSCs) accumulate or 'home' to such scarred tissue. It is unknown how MSCs localize and, in particular, whether cell polarity plays a role in directing their migration from soft to stiff matrix. Our data show that the position of the microtubule organizing center (MTOC) with respect to the nucleus is influenced by matrix rigidity and thus microtubule density within the cell also depends on surface stiffness. Because myosin is responsible for cell contractility which deforms and probes matrix stiffness, we investigated the role non-muscle myosin (both MIIA and MIIB isoforms) may have in cell polarity and directed cell migration to stiff matrix. Using siRNA knockdown we determined that directed migration toward stiff matrix is more sensitive to MIIB and less so to MIIA, even though mass spectrometry determines there is ~10-fold more expressed MIIA in MSCs than MIIB on the protein level. Reports have shown that MIIB localizes to the cell rear in polarized migrating cells, but as we alter the matrix stiffness we demonstrate that this polarization diminishes when matrix stiffness becomes softer than 7 kPa. Our studies also show that the MTOC begins to polarize to the cell front at matrix stiffness above 7 kPa, suggesting a similar mechanism for stiffness induced polarization of MTOC and MIIB. Scratch wound assays induced polarization of MTOC toward the wound edge on stiff substrates but failed to do so when performed on soft matrix. Interestingly, we also found the same stiffness dependent rearward polarization in MIIB in anuclear cell fragments. We find that the polarity of

the cytoskeleton is not required for cell migration but for directing cells toward stiffer matrix. Based on our data, we believe cytoskeletal polarization thus acts as an elasticity-sensitive compass in directing migration toward stiff matrix.

Minisymposium 11: Cellular Functions of Ubiquitin and Ub-related Proteins

70

Neurodegeneration and the Listerin (Ltn1) pathway of ribosome-associated protein quality control.

C. Joazeiro[1]; [1]Department of Cell Biology, The Scripps Research Institute, San Diego, CA

mRNA lacking stop codons ('non-stop mRNA') can arise from errors in gene expression, and encode aberrant proteins whose accumulation could be deleterious to cellular function. In bacteria, these 'non-stop proteins' become co-translationally tagged with a peptide encoded by *ssrA*/tmRNA (transfer-messenger RNA), which signals their degradation by energy-dependent proteases. How eukaryotic cells eliminate non-stop proteins remained unknown. We have recently reported that the *S. cerevisiae* Ltn1 RING-domain-type E3 ubiquitin ligase acts in the quality control of non-stop proteins (Bengtson & Joazeiro 2010. Nature 467:470-3). The Ltn1-mediated process is mechanistically distinct but conceptually analogous to that performed by *ssrA*: Ltn1 is predominantly associated with ribosomes, and marks nascent non-stop proteins with ubiquitin to signal their proteasomal degradation. Ltn1-mediated ubiquitylation of non-stop proteins seems to be triggered by their stalling in ribosomes on translation through the poly(A) tail. The biological relevance of this process is underscored by the finding that loss of Ltn1 function confers sensitivity to stress caused by increased non-stop protein production. We speculate that defective protein quality control may underlie the neurodegenerative phenotype that results from mutation of the mouse Ltn1 homologue, Listerin. In my talk, I will review these data and will present recent findings and further characterization of the Listerin/Ltn1 pathway.

71

A novel linear ubiquitin ligase complex regulating TNFα-induced NF-κB activity and apoptosis.

F. Ikeda[1,2], Y. Lissanu Deribe[2], M. Franz-Wachtel[4], B. Macek[3], I. Dikic[2]; [1]IMBA, Vienna, Austria, [2]Institute of Biochemistry II, Goethe University Medical School, Frankfurt, Germany, [3]Proteome Center Tuebingen, Interfaculty Institute for Cell Biology, University of Tuebingen, Germany

SHARPIN is a ubiquitin-binding and ubiquitin-like domain-containing protein which, when mutated in mice, results in immune system disorders and multiorgan inflammation. We found that SHARPIN functions as a novel component of the Linear Ubiquitin Chain Assembly Complex (LUBAC) and that the absence of SHARPIN causes disregulation of NF-κB and apoptotic signalling pathways, explaining the severe phenotypes displayed by chronic proliferative dermatitis in SHARPIN deficient mice. Upon binding to the LUBAC subunit HOIP, SHARPIN stimulates the formation of linear ubiquitin chains in vitro and in vivo. Co-expression of SHARPIN and HOIP promotes linear ubiquitylation of NEMO, an adaptor of the IκB kinases (IKKs) and subsequent activation of NF-κB signalling, while SHARPIN deficiency in mice causes an impaired activation of the IKK complex and NF-κB in B cells, macrophages, and mouse embryonic fibroblasts (MEFs) by CD40L, LPS and TNFα, respectively. This effect is further enhanced upon concurrent downregulation of HOIL-1L, another HOIP-binding component of LUBAC. In addition, SHARPIN deficiency leads to rapid cell death upon TNFα stimulation via

FADD- and Caspase-8-dependent pathways, which was not induced by HOIL-1L deficiency. SHARPIN thus activates NF-κB and inhibits apoptosis via distinct pathways in vivo.

72

ICAP-1 monoubiquitylation regulates cell migration. A-P. Bouin[1], A-S. RIBBA[1], M. Regent[1], E. Planus[1], C. Albiges-Rizo[1]; [1]Institut Albert Bonniot, Grenoble, France

Cell migration is a complex biological process that requires spatiotemporally regulation of integrin activation, assembly/disassembly of focal adhesion and dynamic organization of actin cytoskeleton. Extracellular matrix rigidity is an external factor influencing cell migration. ICAP-1, a beta1-integrin tail-binding protein, is essential for ensuring integrin activation cycle and focal adhesion formation by interfering with talin binding. In this study, we provide evidence that ICAP-1 function can be regulated by monoubiquitylation. We identified the monoubiquitylation site on ICAP-1. This modification is not involved in protein degradation via proteasome but rather might regulate the assembly and organisation of adhesion sites likely through modulation of protein interactions. Indeed, the monoubiquitylation of ICAP-1 prevents its beta1 integrin binding whereas the non-ubiquitinable form of ICAP-1 interacts with beta1 integrin. Expression of the non ubiquitinable form of ICAP-1 in ICAP-1 deficient cells impacts on beta1 integrin localisation and focal adhesion organization. By testing different matrix rigidities we show that cells expressing the non ubiquitinable form of ICAP-1 exhibit a modification in the matrix density and rigidity sensing which affect cell migration. The monoubiquitylation of ICAP-1 might play a key role in integrin-mediated cell migration through matrix rigidity perception. The using of ROCK inhibitor suggests that this specific role of ICAP-1 is linked to ROCK signalling pathway. Our results show that the ubiquitylation system is integrally involved in the process of cell migration acting as a nodal regulator between partners of beta1 integrin.

73

Ubiquitin and cell cycle regulation of Golgi membrane dynamics.

Y. Wang[1], D. Tang[1], Y. Xiang[1]; [1]Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI

Partitioning of the Golgi membrane into daughter cells during mammalian cell division occurs through a unique disassembly and reassembly process. Several converging lines of evidence have suggested that monoubiquitination plays an essential role in the regulation of post-mitotic Golgi membrane fusion. Monoubiquitination, as a regulatory signal, occurs during mitotic Golgi disassembly and is required for subsequent Golgi reassembly. The p97/p47 complex binds to monoubiquitin through the UBA domain of the adaptor protein p47. Inhibition of the p47-ubiquitin interaction suppresses p97-mediated Golgi membrane fusion. VCIP135, a cofactor of the p97/p47 complex, is a deubiquitinating enzyme whose activity is required for post-mitotic Golgi reassembly. Proteasome activity is not involved in either Golgi disassembly or reassembly. These data suggest that cycles of addition and removal of ubiquitin to and from substrates is necessary for Golgi reassembly. Here, we report the identification of the ubiquitin ligase and the ubiquitinated substrates on the Golgi membranes and provide further evidence that ubiquitin plays a critical role in Golgi biogenesis during the cell cycle.

74

ATG12 In Mitochondrial Homeostasis and Hypothalamic Function.

J. Debnath[1], L. Radoshevich[1], R. Malhotra[1], L. Murrow[1]; [1]Pathology, UCSF, San Francisco, CA

Until recently, ATG12, a UBL required for autophagy, was proposed to conjugate a single target, ATG5. We discovered ATG3, the E2-like enzyme required for ATG8/LC3 lipidation during

autophagy, as a novel ATG12 conjugation target. ATG12-3 complex formation requires ATG3 E2 autocatalytic activity, resulting in the covalent linkage of ATG12 onto a single lysine on ATG3. Mutation of this lysine abolishes ATG12-3 complex formation but surprisingly, does not impact nonselective autophagy. Rather, cells lacking ATG12-3 display increased mitochondrial mass and fragmentation, arising from combined defects in mitophagy and mitochondrial fusion. Cells lacking ATG12-3 are also resistant to intrinsic apoptosis. Importantly, these unique functions of the ATG12-3 complex are completely separable from the established roles of either individual ATG in autophagy. Furthermore, our biochemical analysis demonstrates that multiple ATG12 conjugation targets exist (in addition to ATG5 and 3). Overall, these results reveal unexpected roles for ATG12-3 in mitochondrial homeostasis and implicate the ATG12 conjugation system in novel cellular functions. To further test this hypothesis in vivo, we created complete or conditional *atg12* deletion mice. Similar to *atg5* deficiency, complete *atg12* null mice die on postnatal day 1, corroborating an essential role for ATG12-5 for autophagy during the neonatal period. However, *atg12* (but not *atg5*) transcripts are highly enriched in the hypothalamus, which plays critical roles in mammalian food intake and energy balance. Upon *atg12* deletion in a subset of hypothalamic neurons (POMC neurons), mice display significantly reduced body weight and adiposity, as well as improved glucose tolerance, but no significant changes in food intake or leptin sensitivity. Currently, we are dissecting how ATG12 in POMC neurons directs energy expenditure and regulates diet-induced obesity, and creating POMC *atg5* deficient mice to parse if this phenotype is due to a general defect in autophagy versus a unique function mediated by ATG12.

75

Regulation of SUMO enzymes by oxidative stress.

N. Stankovic[1], F. Melchior[1]; [1]ZMBH-Univ Heidelberg, Heidelberg, Germany

Sumoylation is an essential posttranslational mechanism that affects hundreds of proteins in all eukaryotic species. The mechanism of sumoylation resembles the ubiquitination cascade: modification with SUMO requires ATP, a SUMO activating enzyme, a SUMO E2 conjugating enzyme, and usually one of several E3 ligases. Isopeptidases ensure reversibility of the modification. Modification of most targets is a highly dynamic process that requires additional cues such as a specific time in the cell cycle, developmental stage, DNA damage, or heat shock. A number of years ago, we found that the reactive oxygen species hydrogen peroxide causes rapid disappearance of SUMO conjugates when added to tissue culture cells. This is due to direct and reversible inhibition of SUMO conjugating enzymes through the formation of a disulfide bond between the catalytic cysteines of the SUMO E1 subunit Uba2 and the E2-conjugating enzyme Ubc9. Importantly, enzyme inactivation by disulfide bond formation was also observed upon induction of endogenous ROS production, i.e., the respiratory burst in macrophages (Bossis and Melchior, Mol Cell 2006). These findings add SUMO conjugating enzymes to the small list of specific direct effectors of H2O2 and implicate ROS as key regulators of the sumoylation pathway. To begin to understand the role of SUMO enzyme oxidation, we embarked on a search for redox insensitive Ubc9. Using random mutagenesis and in vitro sumoylation, we identified a single point mutant in the E2 conjugating enzyme Ubc9 that is as active as wt Ubc9 on E3 ligase dependent and independent targets, but insensitive to oxidation. Analysis of this mutant in mammalian tissue culture cells suggests that reversible SUMO E1-E2 disulfide bond formation contributes to oxidative stress response.

Folding principles of genomes.

J. Dekker[1]; [1]Biochemistry and Molecular Pharmacology, Univ Massachusetts Sch Med, Worcester, MA

We study how chromosomes are organized in three dimensions. The three-dimensional (3D) organization of chromatin is critical for regulating gene expression by bringing genes in close spatial proximity to distal regulatory elements such as enhancers. We used 5C to map long-range interaction networks throughout 1% of the human genome (the ENCODE pilot regions) across a panel of cell lines. Specifically, we interrogated 1,348,361 unique pairwise interactions between annotated transcription start sites and distal loci to discover networks of long-range interactions that connect regulatory elements to their target genes. Analysis of the data reveals that long-range interactions are abundant and widespread. Long-range acting elements are found to frequently overlap with other ENCODE annotations, including DNaseI hypersensitive sites, predicted enhancers and sites bound by CTCF. The data provide new insights into the surprisingly complex and interwoven architecture of long-range gene regulation.

We also developed novel modeling approaches to build 3D models of chromosomes using 5C data as input. Using this approach we derived 3D models of the alpha-globin gene domain in human cells. We also generated 3D models of the complete genome of the bacterium Caulobacter crescentus, which has led to the identification of DNA elements that are critical for organizing the genome inside the cell.

Combined our approaches allow the uncovering of the folding principles, and DNA elements that drive folding of chromosomes in relation to gene regulation and other genomic processes.

77

The SCF^{Slimb} ubiquitin-ligase regulates Cap-H2 levels to control interphase chromosome condensation and spatial organization.

S. Daniel[1], S. L. Windler[2], D. W. Buster[3], M. Roberts[1], J. Meserve[1], D. Bilder[2], G. Bosco[1], G. C. Rogers[3]; [1]Molecular & Cellular Biology, University of Arizona, Tucson, AZ, [2]Molecular & Cell Biology, University of California at Berkeley, CA, [3]Cellular & Molecular Medicine, University of Arizona

Chromosome condensation is essential during mitosis, however little is known about how or if interphase chromosome compaction is also modulated. Two conserved complexes (condensins I and II) facilitate chromosome condensation in mitosis. Recent work has revealed that condensin II also functions as an anti-pairing factor, preventing polytene chromosome assembly in non-dividing *Drosophila* nurse cells and inhibits homolog pairing essential for transvection. These interphase functions suggest that condensin is regulated throughout the cell cycle and, at present, it is not clear how interphase condensin is different from its mitotic activities. Since control of protein turnover is a prominent mechanism cells use to regulate cell cycle-dependent events, we examined whether the ubiquitin machinery could play a role in chromosome condensation. By examining a previous RNAi screen of the Cullin-based E3 ubiquitin-ligase family, we found that depletion of the SCF components (Cullin-1 or SkpA) or the F-box protein, Slimb, resulted in a chromosome hyper-condensation phenotype in cultured *Drosophila* S2 cells. Specifically, SCF^{Slimb} RNAi causes a dramatic change in the morphology of chromatin in non-mitotic cells; compacting chromosomes into a cluster of 8-12 spheres per nuclei that we call

the 'gumball' phenotype and are likely to be individualized chromosome territories. Strikingly, we find that double RNAi of Slimb and either SMC-2, Cap-D3, or Cap-H2 completely rescues the gumball phenotype, suggesting that condensin II activity is negatively regulated by SCF^{Slimb}. Indeed, we also find that the non-SMC subunit, Cap-H2, is a novel Slimb ubiquitin-target, as Cap-H2 possesses a conserved Slimb-binding domain, co-immunoprecipitates with Slimb, and is stabilized upon Slimb depletion. Furthermore, mutation of the Slimb-binding domain stabilizes Cap-H2 and expression of this mutant in S2 cells is sufficient to induce the hyper-condensation gumball phenotype. Here, we also present *in vivo* evidence supporting a Slimb/Cap-H2 genetic interaction in modulating polytene chromosome assembly and pairing. Our results reveal a previously unknown mechanism for regulating condensin that utilizes ubiquitin-mediated proteolysis of a key regulatory subunit to attenuate chromosome compaction and spatial organization during interphase of the cell cycle. We propose a model where SCF^{Slimb} controls Cap-H2 proteins levels thereby linking mitotic exit and chromosome decondensation to interphase specific compaction and chromosome organization.

78

DNA Topoisomerase II acts as a mitotic scaffold protein in chromosome assembly in *C. elegans.*

R. Ranjan[1], J. F. Dorn[1], P. S. Maddox[1]; [1]Pathology, IRIC, Montreal, QC, Canada

Assembly of mitotic chromosomes is a dynamic event, occurring rapidly during prophase of each cell cycle. Given the complexity of this process, genetic and biochemical approaches have identified surprisingly few factors involved in condensation, notably histone H1, the condensin complex, DNA TOPOisomerase II (TOPO II) and CENtromere-Protein A (CENP-A). TOPO II can cut and reseal DNA and has been hypothesized to act in a structural capacity, but how it acts in mitotic chromosome condensation remains unknown. To define the roles of known and novel proteins in chromosome condensation, we are performing high-resolution live imaging of the *C. elegans* zygote. Images of fluorescently-tagged core histones are thresholded and segmented to quantify the distribution of chromatin within the prophase nucleus over time. When TOPO II is depleted by RNAi, chromosomes collapse prematurely during prophase. When the catalytic activity of TOPO II is inhibited with Dexrazoxane, chromosomes do not collapse prematurely; rather, chromatin remains diffuse throughout prophase. These results indicate that independent of its catalytic activity, TOPO II acts to scaffold condensation. Its decatenating activity is also important for chromosome resolution during condensation. Interestingly, simultaneous depletion of Topo II and centromeric chromatin partially rescues the TOPO II depletion phenotype, but simultaneous depletion of condensin and TOPO II does not. This suggests that TOPO II with CENP-A have opposing contributions to mitotic chromosome assembly. Endogenous TOPO II localizes to an axis along metaphase chromosomes distinct from that formed by CENP-A, further indicating that their mechanisms of action are independent. We conclude that metaphase chromosomes are built by the distinct scaffold activities of three proteins: TOPO II, CENP-A and Condensin. Importantly, our analysis revealed that depletion of candidate proteins results in quantitatively distinct phenotypes, indicating that they function in discrete events during mitotic chromosome assembly.

79

An Inverse Relationship to Germline Transcription Defines Centromeric Chromatin in *C. elegans.*

R. Gassmann[1], A. Rechtsteiner[2], K. Yuen[1], T. Egelhofer[2], A. Muroyama[1], L. Gaydos[2], F. Barron[1], P. Maddox[1], J. Monen[1], S. Ercan[3], K. Oegema[1], J. Lieb[3], S. Strome[2], A. Desai[1]; [1]Ludwig Institute for Cancer Research, San Diego, CA, [2]Department of Molecular Cell and Developmental Biology, UCSC, [3]Department of Biology, Carolina Center for Genome Sciences and Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill

Centromeres direct segregation of the genome during cell division. The histone H3 variant CENP-A/CenH3 defines centromeres in both monocentric organisms, in which the centromere is localized at a discrete site on the chromosome, and holocentric organisms, in which centromere activity is distributed along the chromosome length. Stable inheritance of CENP-A nucleosomal chromatin, with replenishment once per division that is guided by the inherited nucleosomes, is postulated to epigenetically propagate centromere identity. As the highly repetitive DNA found at most centromeres is neither necessary nor sufficient for centromere function, the genomic features conducive to the establishment of CENP-A chromatin remain largely uncharacterized. We show that CENP-A is not inherited on chromatin through fertilization in the holocentric nematode C. elegans, indicating that pre-existing CENP-A nucleosomes are not required to target assembly of new CENP-A nucleosomes. Genome-wide mapping of CENP-A in embryos and counting of CENP-A molecules in embryonic nuclei indicated that CENP-A is incorporated at a low density in discrete domains that cumulatively occupy ~47% of the genome. To identify the property that makes a genomic region permissive for CENP-A incorporation, we compared the distribution of CENP-A to other chromatin and genomic features. This analysis revealed a genome-wide inverse correlation between CENP-A and RNA Polymerase II (Pol II) occupancy, suggesting that transcriptional activity in the embryo defines the CENP-A distribution. However, inhibition of transcription did not affect either loading of CENP-A or chromosome segregation in early embryos, and the CENP-A distribution did not change during embryonic development, arguing against this idea. Analysis of CENP-A and Pol II occupancy on various gene sets defined by their expression profiles revealed that genes that are expressed in the germline but transcriptionally inactive in embryos, did not incorporate CENP-A. This suggested that memory of germline transcription in the mother, as opposed to active transcription, defines the CENP-A distribution in embryos. Consistent with this, a mutant that ectopically triggers epigenetic memory of germline transcription at a small subset of genes shows loss of CENP-A at those genes in embryos. This change is observed without transcriptional activation in embryos, as assessed by Pol II occupancy. Thus, memory of germline transcription defines the genomic regions in embryo progeny permissive for CENP-A incorporation to build the C. elegans holocentromere. These findings link centromere identity to epigenetic memory of gene expression and shed light on the evolutionary plasticity of centromeres.

In vitro centromere and kinetochore assembly on defined chromatin templates.

A. Guse[1], C. W. Carroll[1], B. Moree[1], C. J. Fuller[1], A. F. Straight[1]; [1]Stanford Univ Sch Med, Stanford, CA

During cell division, chromosomes are segregated to nascent daughter cells by attaching to the microtubules of the mitotic spindle through the kinetochore. Kinetochores are assembled on a specialized chromatin domain, called the centromere that is characterized by the replacement of nucleosomal histone H3 with the histone H3 variant centromere protein A (CENP-A). CENP-A is essential for centromere and kinetochore formation in all eukaryotes but it is unknown how

CENP-A chromatin directs centromere and kinetochore assembly. Here we generate synthetic CENP-A chromatin that recapitulates essential steps of centromere and kinetochore assembly *in vitro*. We show that reconstituted CENP-A chromatin when added to cell free extracts is sufficient for the assembly of centromere and kinetochore proteins, microtubule binding and stabilization, and mitotic checkpoint function. Using chromatin assembled from histone H3/CENP-A chimeras, we demonstrate that the conserved C-terminus of CENP-A is necessary and sufficient for centromere and kinetochore protein recruitment and function but that the CENP-A targeting domain (CATD), required for new CENP-A histone assembly, is not. These data show that two of the primary requirements for accurate chromosome segregation, the assembly of the kinetochore and the propagation of CENP-A chromatin are specified by different elements in the CENP-A histone. Our unique cell-free system enables complete control and manipulation of the chromatin substrate and thus presents a powerful tool to study centromere and kinetochore assembly in higher eukaryotes.

81

Analysis of Native Kinetochore Particles.

B. Akiyoshi[1], S. Gonen[2], K. Sarangapani[3], A. Powers[3], H. Arellano-Santoyo[3], N. Duggan[1], C. Asbury[3], T. Gonen[2], S. Biggins[4]; [1]Division of Basic Sciences, Fred Hutchinson Cancer Research Center, [2]Department of Biochemistry, University of Washington, [3]Department of Physiology and Biophysics, University of Washington, [4]Division of Basic Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA

The precise regulation of chromosome segregation is critical to processes such as self-renewal, proliferation and development. Chromosomes segregate using their kinetochores, the specialized protein structures that are assembled on centromeric DNA sequences. The most fundamental activity of kinetochores is to maintain load-bearing attachments to the assembling and disassembling tips of spindle microtubules. A complete mechanistic understanding of the kinetochore requires reconstitution of kinetochore-microtubule attachments in vitro, yet these studies have not been previously possible due to the lack of a method to isolate kinetochores. We recently developed a technique to purify functional native kinetochore particles from budding yeast and are further characterizing their properties by biochemical and biophysical techniques. To elucidate the mechanism by which kinetochores bind to microtubules, we have also visualized the particles by electron microscopy. Strikingly, we find that kinetochores make multiple contacts to microtubules and often contain a ring that encircles the microtubule. These data suggest that kinetochores bind to microtubules through multivalent attachments as previously proposed. These studies lay the foundation for uncovering the mechanisms that underlie the key mechanical and regulatory functions of kinetochores.

Luteinizing Hormone Reduces Guanylyl Cyclase Activity in the Granulosa Cells of the Mouse Ovary, Leading to the Resumption of Meiosis in the Oocyte.

J. W. Robinson[1], L. C. Shuhaibar[2], J. J. Eppig[3], L. R. Potter[1], L. A. Jaffe[2]; [1]Biochemistry, Molecular Biology, and Biophysics, University of Minnesota, Minneapolis, MN, [2]Cell Biology, University of Connecticut Health Center, Farmington, CT, [3]The Jackson Laboratory, Bar Harbor, ME

In the mouse ovarian follicle, the granulosa cells keep the oocyte arrested in meiotic prophase. The inhibitory signal is cGMP, which diffuses from the granulosa cells to the oocyte through gap junctions. The cGMP is generated by the guanylyl cyclase NPR2 (Zhang et al., 2010, *Science* 330, 366-369). Luteinizing hormone (LH) then acts on the granulosa cells to stimulate meiosis to resume, by closing the gap junctions and by lowering granulosa cell cGMP (Norris et al., 2009, *Development* 136, 1869-1878). Here we investigate whether LH causes a decrease in guanylyl cyclase activity that contributes to the decrease in cGMP. In membranes prepared from ovarian follicles, guanylyl cyclase activity can be stimulated by the NPR2 agonist, C-type natriuretic peptide (NPPC). In response to LH application to follicles, this NPPC-dependent guanylyl cyclase activity decreases, falling to about half by one hour after LH application. In addition, the NPPC content of the ovary decreases in response to LH, reaching 39% of the basal level by 2 hours, 23% by 4 hours, and 7% by 8 hours. Correspondingly, nuclear envelope breakdown in the oocyte, which marks the resumption of meiosis, begins at ~2 hours after LH exposure. Thus the guanylyl cyclase activity of the granulosa cells is reduced by two mechanisms: a decrease in the NPPC-dependent NPR2 activity, and a decrease in the amount of NPPC. Both contribute to reducing cGMP and triggering meiotic resumption.

83

Greatwall Kinase Is an Essential Component of MPF.

M. Hara[1], Y. Abe[1], T. Tanaka[1], T. Kishimoto[1]; [1]Laboratory of Cell and Developmental Biology, Tokyo Institute of Technology, Yokohama, Japan

Cyclin B-Cdk1 is sometimes called MPF (maturation or M-phase promoting factor), and it is currently well accepted that both are synonymous. Originally, however, MPF was identified by a functional assay in oocyte systems. That is, MPF was first described as a cytoplasmic activity of hormone-treated maturing oocytes that upon tranfer causes recipient immature oocytes to undergo meiotic resumption without hormonal stimulation (Masui and Markert, 1971. J. Exp. Zool. 177:129-145; Kishimoto and Kanatani, 1976. Nature 260:321-322). Based on such a functional assay in the oocytes of starfish and frog, here we show that MPF is not identical to cyclin B-Cdk1 but composed both of cyclin B-Cdk1 and Greatwall kinase (Gwl), which is known to indirectly inhibit the phosphatase PP2A-B55 that antagonizes cyclin B-Cdk1. In quantitative comparison, the level of cyclin B-Cdk1 activity required for meiotic resumption was roughly one order of magnitude higher when using purified cyclin B-Cdk1 than when using cytoplasmic MPF, implying that the physiological level of cyclin B-Cdk1 is not sufficient for MPF. In the absence of Gwl, MPF was undetectable from oocyte cytoplasm, even though cyclin B-Cdk1 was fully active. When recombinant Gwl was put back, MPF activity was restored. Although Gwl alone exhibited no activity for inducing meiotic resumption, addition of Gwl greatly reduced the amount of purified cyclin B-Cdk1 required for induction of meiotic resumption. These observations establish that MPF includes at least two separate kinases, cyclin B-Cdk1 that directs mitotic entry and Gwl that suppresses the phosphatase opposing cyclin B-Cdk1.

84

Chromosome transport by a homogeneously contracting F-actin meshwork in starfish oocytes.

M. Mori[1], N. Monnier[2], N. Daigle[1], J. Ellenberg[1], M. Bathe[2], P. Lenart[1]; [1]Cell Biology and Biophysics, EMBL, Heidelberg, Germany, [2]Biological Engineering, MIT, Cambridge, MA

Actomyosin-based contractility mediates cell shape changes underlying cellular functions including cell division, cell migration or would healing that have been extensively studied and the mechanisms beginning to be understood. In contrast, the role of actin in intracellular transport is much less clear with the prevailing view that filamentous actin (F-actin) cables serve as tracks for motor-driven transport of cargo. We recently discovered an alternate mode of actin-driven intracellular transport in starfish (*Patiria miniata*) oocytes involving a contractile F-actin meshwork that mediates the long-range, directed transport of chromosomes to the forming meiotic spindle.
Here we used live-cell imaging combined with quantitative analysis of chromosome trajectories and meshwork velocities to address the mechanism by which this meshwork translates its contractile activity into directional force to transport chromosomes. Our data indicate that the 3D F-actin meshwork contracts homogeneously and isotropically throughout the nuclear space. By precisely timed drug perturbations we could show that contraction is generated internally in the meshwork that is therefore under tension. This tension is released by continuous polymerization of new actin filaments at membranes at the boundary of the meshwork. Thus, the actual rate of contraction is determined by the constant rate of filament production. Centrifugation experiments further reveal that this homogeneous contraction is translated into asymmetric, directional transport by anchoring of the meshwork to the cell cortex. Finally, by injecting inert beads and bead aggregates of different sizes, we show that this directional transport activity is size-selective and transduced to chromosomal cargo at least in part by passive sieving. Thus, dissecting the mechanism of actin-driven chromosome transport in starfish oocytes revealed design principles of a novel and potentially versatile mode of intracellular transport based on sieving by an anchored homogeneously contracting F-actin meshwork.

85

Characterization of a novel subcortical actin layer regulating spindle positioning and cortical plasticity in mouse oocytes.

A. Chaigne[1], C. Campillo[2], J. Azoury[3], C. Umana[3], P. Nassoy[2], C. Sykes[2], M-H. Verlhac[1], M-E. Terret[1]; [1]UMR7241, CNRS/INSERM, College De France, Paris, France, [2]UMR168, CNRS, Institut Curie, Paris, France, [3]UMR7622, CNRS, UPMC, Paris, France

Meiotic maturation is the last step of female meiosis. It leads to the formation of one oocyte and two polar bodies after two divisions very asymmetric in size. Therefore the oocyte keeps most of the maternal stores required for embryonic development. These divisions are asymmetric in size because of spindle off-center positioning. During the first division, the spindle forms where the nucleus was in prophase I, in the center of the oocyte, and then migrates to the periphery, allowing after cytokinesis the formation of a big cell, the oocyte, and a small cell, the first polar body. This movement is actin dependent. Actin forms a cytoplasmic meshwork, which requires Formin-2 and Spire 1 and 2, and which densifies during the first meiotic division. This meshwork is essential for female fertility.
We observed that another actin meshwork is present in mouse oocytes, a subcortical actin layer which is Formin-2 independent. This layer thickens progressively below the cortex at the time of spindle migration until polar body extrusion. Arp2/3 is a nucleator of this actin layer and the Mos/…/ MAPK pathway regulates its formation. The inhibition of Arp2/3 abolishes spindle migration, leading to a symmetric division. Thus this layer is essential for the asymmetry of the

division. Eventually, we performed cortical stiffness assays in various contexts and we demonstrate that this layer regulates oocyte plasticity. Altogether our work suggests that oocytes, which are non-adherent cells, require the formation of a subcortical actin layer to support efficient spindle positioning. In culture cells, actin fibers mediated adhesion of the cell prior to cell rounding has been shown to control the positioning of the mitotic spindle. Thus, actin remodelling at the cortex might be a universal feature of spindle positioning.

86

A post-replicative role for Deco in meiotic cohesion and chiasma maintenance.

K. Weng[1], C. Jeffreys[1], S. Bickel[1]; [1]Biological Sciences, Dartmouth College, Hanover, NH

Human meiosis suffers high error rates and most aneuploid gametes arise from chromosome segregation errors during female meiosis I. These errors are the leading cause of birth defects and miscarriages, and as women age, the risk of aneuploid pregnancy increases exponentially. Accurate chromosome segregation in human oocytes requires that meiotic sister-chromatid cohesion remain intact for decades and work in model organisms indicates that deterioration of meiotic cohesion over time may be a major determinant of age-related aneuploidy. One unresolved question is whether oocytes rely exclusively on cohesive linkages that are established during meiotic S phase or if maintenance of meiotic cohesion is an active process that requires rejuvenation of cohesion throughout the extended period of prophase I.

We are using Drosophila oocytes to investigate the mechanisms controlling cohesion maintenance during meiotic prophase. Deco is the Drosophila homolog of the yeast cohesion establishment factor, Eco1, an acetyltransferase that is essential for formation of cohesive linkages between sisters during S phase. To ask whether Deco activity contributes to the maintenance of meiotic cohesion during prophase I, we used a Gal4/UAS inducible system to knock down Deco in Drosophila oocytes after meiotic S phase. Because the synaptonemal complex (SC) depends on normal meiotic cohesion, we used the SC protein C(3)G as a cytological marker to monitor cohesion and found that severe SC defects arise during mid prophase, after the RNAi driver is turned on. Moreover, when Deco is knocked down during prophase I, we observed a significant increase in meiotic nondisjunction (NDJ). Using a genetic assay to determine the recombinational history of missegregating chromosomes, we found that chiasmata are formed but not maintained when Deco is knocked down after meiotic S phase. Our results demonstrate that the cohesion establishment factor Deco plays a critical post-replicative role in maintaining the cohesive linkages between sister chromatids during meiotic prophase I. In addition, our observation that Smc3 and SA knockdown also result in premature SC disassembly supports the model that turnover of chromatin-associated cohesin during prophase I contributes to cohesion maintenance. Together these data argue that cohesion rejuvenation takes place during the extended prophase I of metazoan oocytes. Such activity may represent an evolutionarily conserved mechanism that functions to help counteract the deterioration of meiotic cohesion in aging oocytes.

87

Cohesin Composition Determines Mechanisms of Cohesin Loading, Cohesion Establishment, and Cohesin Removal during *C. elegans* Meiosis.

A. F. Severson[1], B. Meyer[1]; [1]HHMI and UC-Berkeley, Berkeley, CA

Faithful transmission of the genome through sexual reproduction requires reduction of genome copy number during meiosis to produce haploid sperm and eggs. Three processes unique to meiosis are crucial for reducing ploidy. First, homologous chromosomes become linked through crossover recombination. Second, the two sister chromatids of each homolog attach to

microtubules (MTs) from the same spindle pole (co-orient) in meiosis I and attach to MTs from opposite spindle poles (bi-orient) in meiosis II. Third, sister chromatid cohesion (SCC) is released in two steps to allow separation of homologs and then sisters during meiosis I and II. Work in yeast has shown that establishing the meiotic pattern of chromosome segregation requires that Scc1, the “kleisin” subunit of cohesin complexes that mediate mitotic SCC, is replaced by the meiosis-specific paralog Rec8. Subsequently, *rec8* mutations have been used to define meiotic cohesin functions in many organisms. We have shown that REC-8 is not the sole meiotic kleisin in *C. elegans*, and based on our work and other published data we propose that involvement of multiple kleisins is common in meiosis. *C. elegans* REC-8 and two redundant kleisins called COH-3 and COH-4 (COH-3/4 hereafter) perform specialized meiotic functions. For example, although both REC-8 and COH-3/4 are required for meiotic SCC and meiotic recombination, only REC-8 cohesin can co-orient sister chromatids and mediate SCC beyond anaphase I. Thus, cohesin complexes that differ in their kleisin subunit can perform distinct tasks in a single nucleus, and cohesin function is determined by kleisin identity. The kleisin also influences the mechanism of cohesin loading and of SCC establishment. The axial element protein HTP-3 is required for loading of REC-8 cohesin but not COH-3/4 onto meiotic chromosomes. Once loaded, COH-3/4 cohesin is triggered to become cohesive by SPO-11-dependent double strand breaks, while REC-8 cohesin generates SCC independently of SPO-11. Finally, REC-8 and COH-3/4 become asymmetrically distributed on meiotic chromosomes late in prophase of meiosis I, consistent with their distinct roles in meiotic chromosome segregation: COH-3/4 becomes enriched where SCC is released at anaphase I and REC-8 becomes enriched where sister chromatids co-orient and SCC persists until anaphase II. Because REC-8 alone can co-orient sisters and mediate SCC that persists following anaphase I, this reciprocal pattern of cohesin localization may underlie the stepwise separation of homologs and sister chromatids.

Minisymposium 14: Modeling and Simulation of Cellular Functions

Kinetic Aspects of Clathrin Coated Pit Formation.

A. Banerjee[1], R. Nossal[1]; [1]National Institutes of Health, Bethesda, MD

The dynamics of clathrin coated pit (CCP) formation, observed through TIRF measurements, shows considerable diversity. Foremost is fate heterogeneity, which leads to “abortive” and “productive” pits, i.e., structures which, respectively, do or do not mature into clathrin coated vesicles (CCVs). Also, there is notable heterogeneity in the lifetimes of abortive pits and the apparent times to completion of productive CCPs. We explore the extent to which the stochastic nature of CCP growth can explain these observations by building a simple model for CCP dynamics which includes the free energy of CCP formation and a related kinetic scheme. We investigate (using Monte Carlo simulations) the time development of CCP size and use the model to explain the origin of abortive pits and features of their lifetime distribution. The lifetime distribution calculated from our model agrees very well with that obtained from laboratory experiments. We also show how the binding of cargo might modify the coat parameters and thereby facilitate CCV formation. Finally, we observe how heterogeneity in CCV lifetimes is linked to the stochastic associations and disassociations of the coat components.

89

Mechanical stresses and biochemical patterning: a regulation-transport feedback loop.

J. S. Bois[1], F. Jülicher[2], S. W. Grill[2,3]; [1]Chemistry and Biochemistry, UCLA, Los Angeles, CA, [2]Max Planck Institute for the Physics of Complex Systems, Dresden, Germany, [3]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

Chemical reactions are inherently local phenomena, occurring when individual molecules are proximal. Nevertheless, biochemical species exhibit spatial patterns on length scales much larger than the size of individual molecules. Here, we discuss a new mechanism for pattern formation in which biochemical species regulate mechanical stress in cells, e.g., by manipulating cytoskeletal components. Stress imbalances drive movement of cytoplasmic and cytoskeletal material, resulting in transport of stress regulators. This results in a build-up of regulators, thereby forming a regulation-transport feedback loop. We develop a hydrodynamic theory describing this feedback, also including the possibility of chemical reactions. We show that mechanical stress-based patterning can be more rapid and more robust than classic reaction-diffusion mechanisms. Application of the theory suggests that known interactions between polarity-determinant proteins (the PAR proteins) and their regulation of cortical stress are sufficient to produce the observed polarization and cortical flow of the one-cell C. elegans embryo.

90

Modeling mechanics of cell turning.

K-C. Lee[1], G. Allen[2], E. Barnhart[2], J. Theriot[3], A. Mogilner[4]; [1]Department of Neurobiology, Physiology and Behavior, University of California, Davis, Davis, CA, [2]Department of Biochemistry, Stanford University School of Medicine, Stanford, CA, [3]Department of Biochemistry and Department of Microbioogy and Immunology, Stanford University School of Medicine, Stanford, CA, [4]Department of Neurobiology, Physiology and Behavior, and Department of Mathematics, University of California, Davis, Davis, CA

Our current fair understanding of the cell migration's physics is largely derived from experiments, models and intuition developed for cells crawling straight forward. On the other hand, mechanics of cell turning remains unclear. We used observations of asymmetric geometry and key protein distributions of steadily turning fish keratocyte to develop a mechanical model according to which stick-slip property of adhesions, effective myosin drift in the moving cell framework and myosin-dependent actin disassembly lead to the cell turning. Specifically, our calculations indicate that these three processes combine to provide positive mechanical feedbacks causing long-lasting transient imbalances of myosin and adhesion distributions, actin flows and traction forces at two 'wings' of turning keratocyte. Computer simulations of the model reproduce characteristic cell shapes and movements and provide clues for understanding of unsteady cell motility underlying chemotactic response and other physiologically important cell behaviors.

91

Asymmetry is an emergent property of the cytokinetic ring.

J. Dorn[1], L. Zhang[1], C. Patino-Descovich[1], T-T. Phi[1], P. Maddox[1], J. Liu[2], A. Maddox[1]; [1]Univ Montreal, Montreal, QC, Canada, [2]National Institute of Health

Cytokinesis is a complex cellular event requiring spatiotemporal regulation of the actomyosin and microtubule cytoskeletons and membrane dynamics. Cell shape change in cytokinesis is accomplished by a contractile ring rich in F-actin and myosin. For almost forty years, the prevailing model for ring closure has been the “purse-string hypothesis” of actomyosin sliding

filament activity that uniformly and concentrically contracts at the cell equator. Perhaps due to the transient nature of this event and the apparent differences among cell types, almost no progress has been made to refine the purse-string hypothesis.

We devised a minimal model of the mechanics of ring initiation and closure and tested these ideas in silico. Briefly, we model that filament alignment facilitates contractility, contractility provides force to deform the cell, and the shape of the ingressed membrane favors circumferential filament alignment. We are modeling cytokinesis in the C. elegans zygote, in which cell division is highly stereotypical, essential proteins can be well depleted, and the cytokinetic ring closes non-concentrically. In order to quantitatively compare simulation output to experimental results, we developed software for semi-automated quantitative image analysis of our high-resolution live cell imaging data.

Our computational model recapitulates not only the kinetics of ring initiation and closure, but also the non-concentric geometry of closure, a prevalent but poorly understood feature of cytokinesis. With experimentally justified adjustments, the model also recapitulates the outcome of perturbations of conserved contractile ring proteins and of the spindle midzone.

Finally, we took advantage of our computational model to ask whether there is a cellular advantage to non-concentric ring closure. Our model predicts that non-concentric ring closure is indeed energetically favorable, thus suggesting a mechanism for conservation of proteins that ensure this mysterious feature of metazoan cytokinesis. Interestingly, further search of the parameter space outside that occupied by the C. elegans zygote revealed an even more efficient mode, which is more concentric, and involves a poorly organized contractile ring, but takes longer than the embryonic cell cycle. Thus, our model suggests that a trade-off between speed and energy efficiency dictates the mode of cytokinesis used by a cell.

92

Polar acto-myosin contractility and cleavage furrow stability during cytokinesis.

J. Sedzinski[1,2], M. Biro[1,2], G. Salbreux[3], E. Paluch[1,2]; [1]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, [2]International Institute of Molecular and Cell Biology, Warsaw, Poland, [3]Max Planck Institute for the Physics of Complex Systems, Dresden, Germany

Cytokinesis relies on tight regulation of the mechanical properties of the cell acto-myosin cortex. Although most studies of cytokinetic mechanics focus on force generation at the equatorial acto-myosin ring, a contractile cortex remains at the poles of dividing cells throughout cytokinesis. Whether polar forces influence cytokinetic cell shape is poorly understood. Combining experiments, quantitative imaging and theoretical modeling, we demonstrate that the polar cortex makes cytokinesis inherently unstable and that any imbalance in contractile forces between the poles compromises furrow positioning. We show that limited asymmetric polar contractions occur during normal cytokinesis, and that perturbing the polar cortex leads to cell shape oscillations and division failure. A theoretical model based on a competition between cortex turnover and contraction dynamics accounts for the oscillations and yields predictions on how the mechanical control of cytokinetic shape is achieved. Taken together, our experiments and model show that the physical properties of the entire cell are integrated into a fine-tuned mechanical system ensuring successful cytokinesis.

93

Cellular Noise Regulons Underlie Fluctuations in Saccharomyces cerevisiae.

J. Stewart-Ornstein[1], J. Weissman[2], H. El-Samad[1]; [1]California Institute of Quantitative Biosciences (QB3), Univ California-San Francisco, San Francisco, CA, [2]Cellular and Molecular Pharmacology, Univ California-San Francisco and HHMI, San Francisco, CA

Stochasticity is a hallmark of cellular processes and different classes of genes show large differences in their noise levels. The roots and consequences of these differences have largely remained unexplored. Here, we systematically dissect the structure of expression noise in S. cerevisiae. On top of local variability unique to a single gene, which is determined by expression level and a low level of global variability shared by all genes, there is strong pathway variability shared across similarly regulated genes. This noise induces quantitative correlations that are strongly predictive of the genes dynamic response to stimulus. Furthermore, analysis of fluctuation induced correlations defines well-structured "noise regulons" spanning distinct functional classes such as the MSN2/4 stress response pathway, amino-acid biosynthesis, and mitochondrial maintenance. Bioinformatic analyses and controlled genetic perturbations reveal PKA and Tor pathway as major contributors to this modular organization. Our results reveal that there is a small number of well-delineated noise regulons operating across a yeast cell, and that pathway noise is a powerful quantitative tool for exploring pathway features and regulatory relationships.

Minisymposium 15: Motors and Microtubule Dynamics

94

TPX2 Regulates the Localization and Activity of Eg5 in the Mammalian Mitotic Spindle.

J. Titus[1], N. Ma[2], A. Gable[3], J. Ross[4], P. Wadsworth[1]; [1]Biology, University of Massachusetts Amherst, [2]Medical Oncology, Dana Farber Cancer Institute, Boston, MA, [3]Virology, WuXi AppTec, Inc, Philadelphia, PA, [4]Physics, University of Massachusetts, Amherst, MA

The assembly and function of the mitotic spindle requires the precise temporal and spatial regulation of numerous motor and non-motor proteins. In mammalian cells, the kinesin-5 family member, Eg5, cross-links and slides apart anti-parallel microtubules *in vitro* and is required for bipolar spindle formation in mitosis. Eg5 localizes to spindle microtubules and is enriched at spindle poles. In live cells, FRAP experiments show that at a population level, Eg5 is highly dynamic in all spindle regions, with a turnover half-time for fluorescence recovery of < 10 sec. Eg5 interacts with the Ran-regulated spindle-assembly factor, TPX2 and the proteins co-localize throughout mitosis. To determine if TPX2 regulates the localization and dynamics of Eg5, we examined spindle formation in cells expressing TPX2 lacking the Eg5 binding domain. In these cells, spindles were disorganized with multiple poles. The TPX2-Eg5 interaction was required for the formation of cold-stable kinetochore fibers and to localize the motor to spindle microtubules, but not spindle poles. FRAP showed that the interaction with Eg5 regulated TPX2 turnover, however Eg5 turnover was not changed in the absence of an interaction with TPX2. Microinjection of the Eg5 binding domain of TPX2 into metaphase cells resulted in spindle elongation, suggesting that TPX2 functions to inhibit Eg5 activity. To test this possibility, *in vitro* motility assays with purified proteins were performed. The results demonstrate that TPX2 reduces the velocity of Eg5-dependent microtubule gliding, inhibits microtubule sliding, and results in the accumulation of motors on microtubules. These results show that the localization and activity of Eg5 are regulated by interactions with the microtubule-associated protein TPX2.

95

The depolymerizing kinesins Kip3 (kinesin-8) and MCAK (kinesin-13) are catastrophe factors that destabilize microtubules by different mechanisms.

J. Howard[1], M. Zanic[1], M. Gardner[2]; [1]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, [2]Genetics, Cell Biology and Development, University of Minnesota

Microtubules are dynamic filaments whose plus ends alternate between periods of slow growth and rapid shortening as they explore intracellular space and move intracellular organelles. A key question is how regulatory proteins such as the depolymerizing kinesins modulate catastrophe, the conversion from growth to shortening. To study this process, we reconstituted microtubule dynamics in the absence and presence of the kinesin-8 Kip3 and the kinesin-13 MCAK. Surprisingly, we found that even in the absence of the kinesins, the microtubule catastrophe frequency depends on the length and age of the microtubule, indicating that catastrophe is a multistep process. Kip3 slowed microtubule growth in a length-dependent manner and increased the rate of accumulation of lattice destabilizing features that lead to catastrophe. In contrast, MCAK did not change the feature formation rate, but instead transformed catastrophe into a single step process. Thus, both kinesins are catastrophe factors, but differentially reshape the microtubule cytoskeleton.

96

MCAK activity controls microtubule dynamics and directed cell migration.

K. A. Myers[1], C. M. Waterman[1]; [1]Cell Biology and Physiology Center, NHLBI/NIH, Bethesda, MD

Cell polarization during directed cell migration is coordinated by (MT) growth toward the leading edge. Cells can locally control MT growth or shortening through the regulation of depolymerizing kinesins (MCAK), which catalyze the destabilization of MT plus ends, causing MTs to transition from growth to shortening (catastrophe). However, it is not known if MCAK regulation affects polarized MT growth dynamics that mediate cell migration. We hypothesized that MCAK is locally inhibited to establish preferential MT growth toward the leading edge to promote directed migration. To test this hypothesis, we performed high resolution imaging of fluorescently tagged EB3 that dynamically associates with growing MT plus-ends, coupled with automated image-based tracking of MT growth speeds and growth lifetimes (1/catastrophe frequency). We found that knockdown of MCAK (MCAK-KD) promoted increased MT growth lifetimes globally, abolishing the polarized differences in MT growth lifetime in the cell center and edge seen in control cells. As a result, directional cell migration was significantly reduced, suggesting that local regulation of MCAK activity is critical for establishing polarized MT growth and directing cell migration. To determine how local regulation of MCAK might be achieved, we investigated the role of Aurora-A kinase, which when activated by phosphorylation localizes to mitotic centrosomes and behaves as a phospho-inhibitor of MCAK depolymerase activity. Phospho-Aurora-A immunoprecipitation from cell extracts revealed interaction between MCAK and the phospho-active form of Aurora-A. Live-cell measurements of MT growth dynamics showed that overexpression of Aurora-A promotes long-lived MT growth similar to MCAK-KD, suggesting that Aurora-A regulates the depolymerase activity of cytoplasmic MCAK. To identify upstream activators of Aurora-A, we expressed either constitutively active- (CA-Rac1) or dominant negative-Rac1 (DN-Rac1) and measured changes in active Aurora-A via immunolabeling with a phospho-specific Aurora-A antibody. Compared to control, cells expressing CA-Rac1 displayed a 4-fold increase of phospho-active Aurora-A, while in cells expressing DN-Rac1, phospho-active Aurora-A levels were decreased by 3-fold. In addition, live-cell imaging revealed that like GFP-MCAK, GFP-Aurora-A tracks with a subset of growing MT plus-ends in CA-Rac1 cells, but

not in DN-Rac1 cells. Finally, while CA-Rac1 promoted fast and long-lived MT growth, this effect was lost by pharmacologic inhibition of Aurora-A. Together, these results suggest that Aurora-A-mediated regulation of MCAK depolymerase activity is achieved downstream of Rac1 signaling to elicit regional regulation of MT dynamics and thereby promote polarized MT growth and directional cell migration.

97

Axon injury triggers a microtubule-based pathway that protects dendrites.

L. Chen[1], M. Stone[1], J. Tao[1], M. Rolls[1]; [1]Department of Biochemistry and Molecular Biology, Pennsylvania State Univ, University Park, PA

In order for a single set of neurons to function for the entire lifetime of an animal, these cells need to be able to survive injury and repair damage. Using Drosophila dendritic arborization neurons, we have found that one unexpected response to axon injury is a global increase in the number of growing microtubules.

To understand the pathway that increases microtubule dynamics in response to injury, we performed a candidate screen of microtubule regulators. Reducing levels of microtubule nucleation by RNAi against the core nucleation protein gamma-tubulin 23C, or introducing one copy of a null allele of this gene, reduced the increase in microtubule dynamics in injured neurons but did not affect uninjured cells. Microtubule nucleation is thus required for the increase in number of growing microtubules after axon injury.

We hypothesized that the increased microtubule dynamics might be required for axon regeneration after injury. To test this hypothesis we assayed regeneration in backgrounds with reduced nucleation. No difference from control animals was found when gamma-tubulin 23C was targeted by RNAi. Thus the changes in microtubule dynamics induced by axon injury are likely to be required for an injury-response other than regeneration.

As microtubule dynamics increased in dendrites after a distant axon injury, we hypothesized that rebuilding of dendritic microtubules might act to protect dendrites from retraction or degeneration triggered by losing the axon. To test this hypothesis we made use of the finding that dendrites have an active degeneration program that clears them after they are severed from the cell body. To trigger increased microtubule dynamics we cut the axon 8 hours before dendrite severing. This resulted in a delay in dendrite degeneration. To determine whether the delay in dendrite degeneration was due to the increased microtubule dynamics, we introduced a single mutant copy of gamma-tubulin 23C or targeted the microtubule polymerase msps by RNAi. Both treatments blocked dendrite protection by prior axon injury confirming a role for microtubules in a dendrite protective pathway.

This study identifies a novel program that uses microtubules to protect dendrites after axon injury. This program likely plays an important role in maintaining intact circuits while axons attempt repair.

98

Structural Mechanism for Dynein Control by Lis1.

A. Roberts[1,2], J. Huang[1], A. Leschziner[3], S. Reck-Peterson[1]; [1]Department of Cell Biology, Harvard Medical School, Boston, MA, [2]Faculty of Biological Sciences, University of Leeds, Leeds, United Kingdom, [3]Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA

Cytoplasmic dynein, the large microtubule-based motor protein, is carefully controlled in cells, enabling it to be deployed to specific sites, collect cargoes, and transport them towards the microtubule minus end at set times. Dynein's "engine" is evolved from ring-shaped AAA+ ATPases, and its microtubule-binding domain lies at the tip of a coiled-coil stalk, but how these elements might be acted upon to achieve control remains unknown. Here, using purified proteins from *Saccharomyces cerevisiae*, we dissect how cytoplasmic dynein is controlled by two of its ubiquitous regulators: Lis1/Pac1 and Nudel/Ndl1. By single-molecule microscopy, we find that Lis1 slows dynein velocity, prolongs its encounters with microtubules, and is tethered to dynein by Nudel. High-precision analysis shows that dynein-Lis1 undergoes frequent "anchored" cycles, during which ATP is consumed without the usual microtubule release and forward motion. Unexpectedly, the structural basis for these changes involves Lis1 binding at the interface between dynein's ATPase domain and its microtubule-binding stalk. Lis1 is thus ideally situated to alter allosteric communication in cytoplasmic dynein, which could facilitate its control and function in cells. *J. Huang and A. Roberts contributed equally to this work.*

99

The crystal structure of tubulin tyrosine ligase offers insight into tubulin recognition.

A. Szyk[1], A. Deaconescu[2], G. Piszczek[3], A. Roll-Mecak[1,3]; [1]Cell Biology and Biophysics Unit, NINDS, National Institutes of Health, Bethesda, MD, [2]Brandeis University, Waltham, MA, [3]NHLBI, National Institutes of Health, Bethesda, MD

Tubulin tyrosine ligase (TTL) adds a C-terminal Tyr to alpha-tubulin as part of a tyrosination/detyrosination cycle present in most eukaryotic cells. The C-terminal tyrosine in alpha-tubulin serves as an ON/OFF signal for the recruitment of microtubule dynamics regulators. TTL loss causes morphogenic abnormalities and is associated with aggressive cancer progression and poor prognosis. We present the first crystal structure of TTL, defining the structural scaffold upon which the diverse TTL-like (TTLL) family of tubulin-modifying enzymes is built. TTL uses a bipartite strategy to recognize tubulin. It engages the tubulin tail through low-affinity, high-specificity interactions, and co-opts what is otherwise a homo-oligomerization interface in structurally related enzymes to form a tight hetero-oligomeric complex with tubulin. Small-angle X-ray scattering and functional analyses reveal that TTL forms an elongated complex with the tubulin dimer and prevents incorporation of the dimer into microtubules by capping the tubulin longitudinal interface, thereby possibly modulating the partition of tubulin between its monomeric and polymeric forms.

Symposium 5: Complex Cellular Functions: Linking Networks and Structures

100

Virtual movement of a signaling network translated into real movement of a motility network.

W. Bement[1], B. Burkel[2], H. Benink[3], E. Vaughan[4]; [1]Department of Zoology, Univ Wisconsin-Madison, Madison, WI, [2]LOCI, University of Wisconsin-Madison, [3]Promega Corp, [4]Cellular and Molecular Biology Graduate Program, University of Wisconsin-Madison

Transient contractile arrays of actin filaments (F-actin) and myosin-2 power diverse biological processes including cytokinesis, wound healing and morphogenesis. Contractile array formation is initiated by the Rho GTPases Rho and Cdc42, which stimulate myosin-2 activation and F-actin assembly in their active (GTP-bound) forms. Upon assembly, contraction itself is thought to direct movement of actomyosin arrays by myosin-2-powered shortening of the array. The relationship of contractile array movement and Rho GTPase turnover was analyzed during single cell wound repair, which entails formation and closure of a ring-like array of F-actin and myosin-2 directed by concentric zones of active Cdc42 and Rho. Remarkably, suppression of contractility prevented physical translocation of F-actin and myosin-2 and active Rho and Cdc42 without preventing closure of the actomyosin array or the Rho GTPase zones. This behavior is explained by an underlying gradient of Rho GTPase activity in which Rho and Cdc42 are preferentially activated at the leading edges of their respective zones and inactivated at their trailing edges. Contraction inhibition partially disrupts the pattern of inactivation while suppression of F-actin turnover disrupts the pattern of both activation and inactivation. The results show that differential nucleotide hydrolysis by Rho GTPases imparts directional information to contractile arrays in a manner analogous to nucleotide hydrolysis by cytoskeletal polymers and reveal unexpected roles for myosin-powered contraction and actin turnover in contractile array function and the spatial regulation of Rho GTPase activity.

101

Evolution of Epithelial Organization and the Cadherin-Catenin Complex.

J. Nelson[1]; [1]Department of Biology, Stanford University, Stanford, CA

A tube surrounded by a simple epithelium is the most basic tissue organization in metazoans. Epithelial tubes are formed by actomyosin-based constriction of the apical surface of cells in epithelial sheets. In higher animals, epithelial organization is maintained by cadherin adhesion proteins which bind β-catenin and α-catenin that in turn organizes the actin cytoskeleton. I will discuss recent structure/function studies of the catenin complex in a variety of organisms. The results show that the catenin complex plays remarkably conserved functions in the formation and functional organization of epithelial structures from mammals to slime molds.

102

Smell and the Single Neuron: Three-dimensional Reconstructions of Olfactory Neurons Offer Insights into Neuronal Morphologic Diversity and Odor Coding.

K. Baldwin[1]; [1]Department of Cell Biology, Scripps Res Inst, La Jolla, CA

Neurons are among the most morphologically diverse cell types. Neurons have been grouped into thousands of distinct subtypes based on shared functional properties and characteristic somatic morphology and location. Neurons of a particular subtype also exhibit similarities in the

gross scale structure of their axons and dendrites. In sensory neural circuits, differences in the precise connectivity of dendrites determine the information that a neuron carries, while axonal morphology controls the distribution of this information to higher brain centers. In many sensory systems, including vision, hearing and touch, neurons carrying similar sensory information project axons to closely apposed cortical targets producing spatial maps of sensory information that are similar among individuals. To address whether the sense of smell operates using similar principles, we developed long-range viral tracing tools and three dimensional neuronal reconstruction methods to characterize the entire dendritic and axonal arbors of defined olfactory bulb output neurons that carry the "same" sensory information. By reconstructing these neurons and mapping them onto a reference brain we identified unanticipated morphologic diversity among otherwise similar neurons. Neurons responding to the same odor compound project to nearly non-overlapping targets, even within the same animal. These findings have implications for odor perception and suggest a role for stochastic mechanisms in neuronal diversification.

Symposium 6: Mechanism of Multicellular Functions

103

The costs of control: Strategies and tradeoffs in robust tissue pattern formation.

A. D. Lander[1,2], W-C. Lo[3], S. Zhou[1], P. Zhang[2], F. Y. Wan[3], Q. Nie[3]; [1]Department of Developmental and Cell Biology, University of Califorina, Irvine, Irvine, CA, [2]Department of Biomedical Engineering, University of Califorina, Irvine, [3]Department of Mathematics, University of Califorina, Irvine, CA

One of the principal ways in which long-range tissue patterns are formed is through the actions of gradients of diffusible morphogens. Conserved, complex regulatory mechanisms are found in most morphogen gradient systems, nearly always including elaborate feedback and feed-forward circuits, with contributions by co-receptors, diffusible inhibitors, multiple morphogens, and regulated uptake. As such circuitry is not essential for creating or interpreting morphogen gradients, it has been hypothesized that it evolved to further "strategic" goals—-e.g. robustness, speed, noise-filtering, flexibility, adaptability, etc. Indeed, the ability of some of these mechanisms to contribute, in principle, to the robustness of patterning has been demonstrated mathematically. Yet scarce attention has been paid to the tradeoffs that such strategies incur. For example, it is straightforward to show that strategies for tolerating uncertainty in the rate of morphogen production generally interfere with strategies for overcoming cell-to-cell variability in morphogen response ("spatial noise"), and *vice versa*. One consequence of such a tradeoff between robustness and noise-tolerance is a limit on the maximum distance over which a morphogen can pattern, a constraint that is indeed observed. Recently, we have begun to systematically identify tradeoffs among strategies for achieving robustness to uncertain production rates of morphogens, receptors and co-receptors. In my talk, I will discuss the general problems of robustness and noise that confront the *decapentaplegic* (BMP) and *wingless* (Wnt) morphogen gradients that pattern the *Drosophila* wing imaginal disc, and introduce the goal of balancing such tradeoffs as a basis for understanding the peculiar regulatory machinery that exists in these gradient systems.

104

Shaping the embryo: Cellular dynamics in development.

J. Zallen[1]; [1]Developmental Biology, Sloan-Kettering Institute/HHMI, New York, NY

A major challenge in developmental biology is to understand how large-scale changes in tissue structure are generated on a cellular and molecular level. A conserved structural feature present in many multicellular animals is a body axis that is elongated from head to tail. This elongation is actively generated in the embryo through spatially regulated cell rearrangements, cell shape changes, and cell divisions. Cell rearrangements provide the driving force for axis elongation in frogs, fish, and chicks. In the fruit fly Drosophila, cell rearrangements cause the embryo to double in length from head to tail and narrow in width from back to front, creating the layout of the body plan. This process is amenable to direct live imaging approaches, which reveal a striking directionality in which large populations of cells align their movements along a common axis. To understand how genes encode the forces that drive these polarized cell behaviors and tissue remodeling, we are using cell biological approaches to identify proteins that are asymmetrically localized in intercalating cells, large-scale genetic screens to identify the molecular mechanisms that are required for elongation, and computational methods to analyze cell shape and behavior in three dimensions. We found that proteins involved in cell adhesion and contractile force generation are asymmetrically localized in intercalating cells, where they participate directly in polarized cell behavior. A polarized contractile network provides the global spatial information that guides cell movement, while differential adhesion regulates dynamic interactions between cells. Planar polarized force generation by the contractile actomyosin machinery is regulated by a combination of biochemical signals that establish cell polarity and mechanical feedback systems that coordinate dynamic events between cells. Specifically, we found that nonmuscle myosin II activity not only generates the forces that promote elongation, but myosin localization is also regulated by tension in a mechanism that recruits more myosin to the cortex and propagates contractile behavior from cell to cell. This mechanism triggers a wave of actomyosin contractility that leads to the assembly of multicellular rosette structures that form and resolve directionally, promoting elongation. Rosette behaviors have also been shown to occur in vertebrates and may represent a general mechanism linking single-cell asymmetry to global tissue reorganization.

105

Generating multicellular architecture through collective migration.

D. Gilmour[1], E. Dona[1], C. Revenu[1], G. Valentin[1], S. Streichan[4]; [1]Cell Biology and Biophysics, EMBL, Heidelberg, Germany, [4]EMBL

The collective migration of cohorts or tissues is a hallmark of organogenesis, wound repair and many invasive cancers. Cells at the leading edge of migrating collectives display many features characteristic of mesenchyme, such as highly dynamic protrusions and reduced apicobasal polarity, whereas the cells that follow become assembled into canonical epithelia. Thus, migrating collectives are generated a process that is highly similar to an epithelial-mesenchymal transition (EMT), with the exception that cell-cell junctions are maintained throughout. It is generally unclear how motility and assembly are balanced across migrating tissues. The zebrafish lateral line primordium is a migrating epithelial tissue that becomes assembled into a series of rosette-like mechanosensory organs en route. Previous genetic studies have shown that an extrinsic stripe of the chemokine SDF1 controls the behaviour of ‘leader’ cells at the tissue edge, whereas internal ‘follower’ cells are assembled into epithelial organs through the activity of an internal FGF-signaling circuit. I will present recent work addressing how cell signaling activities and dynamic cell shape changes are integrated during collective migration.

Minisymposium 17: Cell Biology of Micro-Organisms and the Evolution of the Eukaryotic Cell

106

Emergent complexity in myosin V-based organelle inheritance.

F. D. Mast[1], R. A. Rachubinski[1], J. B. Dacks[1]; [1]Cell Biology, Univ Alberta, Edmonton, AB, Canada

How is adaptability generated in complex biological systems composed of interacting cellular machineries, each with individual, separate and functionally critical jobs to perform? Organelle inheritance is one such system that requires the coordination of several robust and ancient cellular modules, including the cell cycle, cytoskeleton and organelle biogenesis/identity. Budding yeasts have emerged as powerful models to study these processes as organelles compete for access to myosin V motors that travel along polarized actin cables to vectorially deliver bound cargo to the bud. Under the direction of the cell cycle, myosin V motors are recruited to organelles by specific interactions between their carboxyl-terminal globular tail domain and organelle-specific receptors. We used comparative genomics, phylogenetics and secondary structural modeling to characterize the evolutionary history of these organelle-specific receptors. We find that while some receptors are retained widely across the animals and fungi, others are limited primarily to the Saccharomycetaceae family of budding yeast, with the emergent pattern of a conserved biogenic and inheritance factor often paired with an evolutionarily novel inheritance adaptor. We propose an evolutionary model whereby the emergence of myosin V-based organelle inheritance has utilized mechanisms of paralogy, the exploration of sequence space and the appearance of pliable, evolutionarily novel adaptor proteins. Our findings suggest an overarching evolutionary mechanism for how diverse cargoes compete for a single myosin V motor in organelle transport and detail one system's solution to obtaining evolutionary adaptability amongst constrained cellular modules. We are continuing to explore the consequences of the model with functional studies on the regulation of myosin V-based organelle inheritance.

107

Comprehensive analysis reveals dynamic and evolutionary plasticity of Rab GTPases and membrane traffic in Tetrahymena thermophila.

A. Turkewitz[1], L. Bright[1]; [1]Molecular Genetics and Cell Biology, The University of Chicago, Chicago, IL

Cellular sophistication is not exclusive to multicellular organisms, and unicellular eukaryotes can resemble differentiated animal cells in their complex network of membrane-bound structures. These comparisons can be illuminated by genome-wide surveys of key gene families. We report a systematic analysis of Rabs in a complex unicellular Ciliate, including gene prediction and phylogenetic clustering, expression profiling based on public data, and Green Fluorescent Protein (GFP) tagging. Rabs are monomeric GTPases that regulate membrane traffic. Because Rabs act as compartment-specific determinants, the number of Rabs in an organism reflects intracellular complexity. The Tetrahymena Rab family is similar in size to that in humans and includes both expansions in conserved Rab clades as well as many divergent Rabs. Importantly, more than 90% of Rabs are expressed concurrently in growing cells, while only a small subset appears specialized for other conditions. By localizing most Rabs in living cells, we could assign the majority to specific compartments. These results validated most phylogenetic assignments, but also indicated that some sequence-conserved Rabs were co-opted for novel functions. Our survey uncovered a rare example of a nuclear Rab and substantiated the

existence of a previously unrecognized core Rab clade in eukaryotes. Strikingly, several functionally conserved pathways or structures were found to be associated entirely with divergent Rabs. These pathways may have permitted rapid evolution of the associated Rabs or may have arisen independently in diverse lineages and then converged. Thus, characterizing entire gene families can provide insight into the evolutionary flexibility of fundamental cellular pathways.

108

Functional Genomics of Cell Regeneration in the Giant Ciliate *Stentor coeruleus*.

M. Slabodnick[1], W. Marshall[1]; [1]Univ California-San Francisco, San Francisco, CA

The mechanisms that specify cell shape and organization are not currently understood. Ciliates provide ideal model systems to tackle problems of cell morphology due to their complex cell organization and unique patterning. With current advances in technology along with work done in *Paramecium tetraurelia* and *Tetrahymena thermophila*, it is now possible to apply these tools to studying other organisms. *Stentor coeruleus* is a large, ~1mm long, single cell with a highly patterned cell cortex and the ability to regenerate and reorganize after surgical or chemical manipulations. The ease of surgical manipulations gives *Stentor* significant advantages over other ciliate models. Using the surgical techniques unique to *Stentor* as well as modern RNA interference (RNAi) methods, visualization techniques, and genomic sequencing I will revive *Stentor* as a model for studying cell polarity and organization. With the current state of Next Generation Sequencing it has become feasible for a lab to sequence the genome of a Eukaryotic organism. We have begun our own sequencing effort for *Stentor*'s macronuclear genome in order to facilitate the development of a better experimental toolbox. We have been able to repeat many of the surgical experiments performed by Vance Tartar, Noël de Terra and others. Using data obtained from preliminary sequences I constructed RNAi vectors that target endogenous *Stentor* genes and here I provide evidence that methodology developed for other ciliates can function in *Stentor* as well. Results for RNAi of Alpha-Tubulin and Mob1 result in dramatic changes in cell polarity and organization of the cortex and provide strong evidence that studies in *Stentor* can yield exciting and useful results. Knocking down Alpha-Tubulin, a key structural component in the cortex, results in clear cortical defects and problems with cell regeneration. This is very different from the Mob1 knockdown, which results in the drastic elongation of cells and other cortical aberrations. Using RNAi in conjunction with the unique microsurgical methods available in *Stentor*, it should be possible to restore this classical system to its previous status as a central model for addressing many important questions, including centriole structure, cell polarity, biological pattern formation, and cellular regeneration.

109

Systems-level analysis of multicellular microbial community structure.

A. M. Valm[1,2], J. L. Mark Welch[1], R. Oldenbourg[1,2], G. G. Borisy[1]; [1]Marine Biological Laboratory, Woods Hole, MA, [2]Brown University, Providence, RI

Just as the phenotypically different cells that make up multicellular organisms are distributed in tissues with structures that embody specific functions, microbial cells with different metabolic functions form unique spatial structures and coordinate their activities as multicellular units, e.g. biofilms. Fundamentally, microbial communities differ from eukaryotic tissues because their cellular constituents may be genetically distinct; in fact, up to hundreds of different species may be present in a single biofilm. Any number of probes may be designed to identify the different species present in a community; however, the ability to unambiguously distinguish more than a few different labels in a single fluorescence image has been severely hampered by the

excitation cross-talk and signal bleed-through of fluorophores with highly overlapping excitation and emission spectra.
We recently developed a fluorescence labeling, imaging, and analysis method to greatly expand the number of identifiable labels in a single image, which we call Combinatorial Labeling and Spectral Imaging (CLASI). Application of our CLASI technique to human dental plaque using fluorescence *in situ* hybridization (FISH) enabled the first quantitative analysis of the spatial distribution of 15 different taxa of microbes in a biofilm. Proximity analysis was used to determine the frequency of inter- and intrataxon cell-to-cell associations, which revealed statistically significant intertaxon pairings. Cells of the genera *Prevotella* and *Actinomyces* showed the most interspecies associations, suggesting a central role for these genera in establishing and maintaining biofilm complexity. In a proof-of-principle experiment, we further demonstrate that we can distinguish 120 differently labeled *E. coli* in a mixture labeled with binary combinations of 16 fluorophores using a novel linear unmixing algorithm constrained to identify specific combinations of fluorophores. Our results provide an initial systems-level structural analysis of biofilm organization. We believe that the CLASI approach will be useful for a systems level analysis of many complex molecular structures within cells. Supported by the Sloan Foundation and NIH Grants F31DE019576 and RC1DE20630.

110

Electrical Spiking in Escherichia coli Probed with a Fluorescent Voltage Indicating Protein.

J. Kralj[1], D. Hochbaum[2], A. Douglass[3], A. Cohen[1]; [1]Chemistry, Harvard University, Cambridge, MA, [2]Applied Physics, Harvard University, Cambridge, MA, [3]Biology, Harvard University, Cambridge, MA

Bacteria have many voltage- and ligand-gated ion channels, and population-level measurements indicate that membrane potential is important for bacterial survival. However, it has not been possible to probe voltage dynamics in an intact bacterium. Here we developed a method to measure membrane potential on a single cell which revealed electrical spiking in Escherichia coli. To probe bacterial membrane potential we engineered a voltage-sensitive fluorescent protein based on green-absorbing proteorhodopsin. Expression of the Proteorhodopsin Optical Proton Sensor (PROPS) in E. coli revealed electrical spiking at up to 1 Hz. Within a nominally homogeneous population of bacteria, cells showed a variety of voltage dynamics. Spiking was sensitive to chemical and physical perturbations, and coincided with rapid efflux of a small-molecule fluorophore, suggesting that bacterial efflux machinery may be electrically regulated.

111

Control of cell differentiation by the regulatory molecules ppGpp and inorganic polyphosphate.

C. Boutte[1], J. Henry[2], S. Crosson[1]; [1]Department of Biochemistry and Molecular Biology, University of Chicago, Chicago, IL, [2]Committee on Microbiology, University of Chicago, Chicago, IL

The molecules guanosine tetraphosphate (ppGpp) and inorganic polyphosphate (PolyP) function as global regulators of cell physiology in both prokaryotes and eukaryotes. These molecules have the capacity to directly bind and regulate the activity of a range of proteins in the cell including RNA polymerase and proteases. Our recent studies on bacterial cells have focused on understanding the molecular logic underlying regulated synthesis of ppGpp and PolyP, and the downstream control of cell development by these important signaling molecules.

We have defined the input logic and direct transcriptional targets of ppGpp in the oligotrophic bacterium, *Caulobacter crescentus*. The sole ppGpp synthase, $SpoT_{CC}$, binds to and is regulated by the ribosome, and exhibits AND-type control logic. We further demonstrate a regulatory link between the synthesis of ppGpp and PolyP and demonstrate that both molecules function to control of the timing of *Caulobacter* cell differentiation. Specifically, *Caulobacter* differentiates from a motile, foraging swarmer cell into sessile, replication-competent stalked cell during its cell cycle, akin to the G1->S transition in eukaryotic cells. This developmental transition is inhibited by nutrient deprivation to favor the motile swarmer state. Both ppGpp and PolyP inhibit this transition in rich and glucose-depleted medium. Upon exhaustion of available carbon, swarmer cells lacking the ability to synthesize ppGpp or PolyP erroneously initiate chromosome replication, proteolyze the replication inhibitor CtrA, localize the cell-fate determinant DivJ, and develop polar stalks. These results provide evidence that ppGpp and polyP function as cell-type specific developmental regulators.

Distinct Roles for Paxillin and Hic-5 in the Regulation of Tumor Cell Plasticity, Invasion and Metastasis.

N. Deakin[1], C. Turner[1]; [1]Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Individual metastatic tumor cells can exhibit two interconvertible modes of cell motility during tissue invasion that are classified as either mesenchymal or amoeboid. Indeed, this is thought to be responsible for the ineffectiveness of current invasion-targeted therapeutics. The molecular mechanisms by which invasive breast cancer cells regulate migratory plasticity have yet to be fully elucidated. Herein we show that the focal adhesion adaptor protein Paxillin, a key integrator of Rho family GTPase signaling and the closely related family member Hic-5, regulate MDA-MB-231 breast cancer cell invasion in vitro as well as lung metastasis in vivo. Furthermore, Paxillin and Hic-5 exhibit opposing but potentially integrated functions to coordinate tumor cell morphology and plasticity during 3D extracellular matrix (ECM) migration and invasion. Cells depleted of Paxillin by RNAi exhibited a highly elongated, mesenchymal phenotype, while siRNA-mediated knockdown of Hic-5 induced an amoeboid phenotype. Furthermore, Paxillin and Hic-5 over-expression results in a striking reversal of phenotypes. In evaluating associated signaling pathways, we determined that Rac1 activity was increased in cells devoid of Paxillin while Hic-5 silencing resulted in elevated RhoA activity and associated ROCK-induced non-muscle myosin II contractility. In depth analysis of adhesion dynamics during tumor cell migration through 3D ECM identified Paxillin as a key regulator of 3D adhesion assembly, stabilization and disassembly, while Hic-5 was shown to be essential for the formation of 3D adhesions. Furthermore, analysis of additional tumor cells, including melanoma, fibrosarcoma and pancreatic cancer cell lines, demonstrated a significant correlation between the relative expression of Hic-5 and Paxillin and cancer cell morphology as well as their ability to exhibit spontaneous plasticity during 3D ECM migration. This work was supported by a Susan G. Komen for the Cure Postdoctoral Fellowship (ND) and NIH grants (CT).

VASP-adhesion-mediated protrusion waves at the motile cell's leading edge.

J. Allard[1], E. Barnhart[2], J. Theriot[2], A. Mogilner[1]; [1]Univ California-Davis, Davis, CA, [2]Stanford Univ

Waves of actin received much attention recently. Fish keratocyte cells, which usually exhibit rapid and steady motility, start to exhibit traveling waves of protrusion when plated on highly adhesive surfaces. These waves are the result of oscillations in actin polymerization, not retrograde flow. Protrusion speed correlates strongly with speed of the lateral wave propagation. Inhibition of myosin contraction with blebbistatin abolishes waving. Mature adhesions co-localize with the stalled parts of the leading edge, while F-actin density is elevated at the protruding parts. We hypothesized that some molecular factor limiting actin based protrusion, such that growing actin filaments and maturing adhesions 'compete' for this factor, is responsible for the waving behavior. We further hypothesized that such factor is VASP, protein that associates with growing actin barbed ends as well as with adhesions. We developed a mathematical model of actin protrusion coupled with membrane tension and mediated by adhesion and VASP dynamics. Simulations of this model demonstrated that competition for VASP between adhesions and polymerizing actin network can lead to emergence of the protrusion waves. The model makes a great number of predictions, for example, that the amount of VASP localized to the leading edge should be reduced in waving cells, compared to smooth cells; overexpression of VASP should prevent waving, but depletion of VASP does not increase the fraction of cells that wave; VASP leading edge localization should oscillate, with VASP most enriched at the leading edge prior to initiation of protrusion. Further experiments confirmed these predictions and provided quantitative data to estimate the model parameters. We thus conclude that the oscillations are the result of competition between actin and adhesions for VASP, rather than of existence of a regulatory biochemical oscillator or mechanical tag-of-war. We hypothesize that this waving behavior contributes to adaptation of cell motility mechanisms to perturbed environment.

114

Glioblastoma motility occurs in the absence of actin polymer.

A. Panopoulos[1], M. Howell[2], R. Fotedar[1], R. Margolis[1]; [1]Sanford Burnham Medical Research Institute, La Jolla, CA, [2]The Scripps Research Institute, La Jolla, CA

In fibroblasts and keratocytes, motility is actin dependent, while microtubules play a secondary role, providing directional guidance. We demonstrate here that the motility of U87MG glioblastoma cells is exceptional, in that it can occur in cells depleted of assembled actin. Cells display persistent motility in the presence of actin inhibitors at concentrations sufficient to fully disassemble actin and to prevent cell cleavage. Such actin independent motility is characterized by the extension of cell protrusions containing abundant microtubule polymers parallel to the long axis of the protrusion. Strikingly, glioblastoma cells exhibit no motility in the presence of microtubule inhibitors, at concentrations that disassemble labile microtubule polymers and block mitotic progression. Microtubule inhibitors cause the retraction of cell protrusions, and rapid time-lapse shows microtubule inhibited cells blebbing rather than ruffling. In accord with an unconventional mode of motility, glioblastoma cells have unusual requirements for the Rho GTPases. While Rac1 is required for lamellipodial protrusions in fibroblasts, expression of dominant negative Rac1 does not suppress glioblastoma migration. Other GTPase mutants are largely without unique effect, except dominant positive Rac1-Q61L, and constitutively active rapidly cycling Rac1-F28L, which substantially suppress glioblastoma motility. In contrast, overexpression of dynamitin, which suppresses dynein, partially blocks motility. We conclude

that glioblastoma cells can display an unprecedented mode of intrinsic motility that occurs in the absence of actin polymer, and that appears to require polymerized microtubules.

115

Phosphorylation of the Arp2/3 complex: conformational changes and regulation in migrating cells.

L. LeClaire[1], A. Narayanan[2], M. Jacobson[2], D. Barber[3]; [1]Department of Biochemistry, University of Southern Alabama, [2]Department of Pharmaceutical Chemistry, University of California San Francisco, [3]Department of Cell and Tissue Biology, University of California San Francisco, San Francisco, CA

Nucleating activity of the Arp2/3 complex drives the assembly of a branched actin filament network at the leading edge of migrating cells for membrane protrusion. Arp2/3 complex binding to nucleation promoting factors (NPFs) of the WASP and WAVE families was previously thought to be sufficient to increase nucleating activity. However, we recently showed that phosphorylation of the Arp2 subunit on either Thr237/238 or Tyr202 is necessary for Arp2/3 complex activation by NPFs (LeClaire et al., JCB 182:647). We now report a structural model for how pArp2 allows reorientation of Arp2/3 subunits to an activation-competent state, and that Arp2 is a substrate for the Nck-interacting kinase NIK. Molecular dynamics simulations predict that phosphorylation of Arp2-Thr237/238 induces a ~10 Å RMSD reorientation of Arp2 relative to Arp3 toward the short pitch dimer orientation, priming the complex for activation by NPFs. Our simulations show an electrostatic network in the vicinity of Arp2-Thr237/238 that includes ARPC4-Arg105/106. The phosphate charge on pThr237/238 disrupts this network to relieve an auto-inhibited conformation. Additionally, a mutant ARPC4-R105/106A renders the complex partially active in the absence of NPFs. We also found that NIK directly phosphorylates Arp2-T237/238 and increases nucleating activity of recombinant wild-type Arp2/3 complex but not a mutant complex containing Arp2-T237A/T238A. In clonal carcinoma cells, GFP-NIK localizes with Arp2/3 at the distal margin of lamellipodia and increases Arp2 phosphorylation and actin polymerization in response to growth factors. In contrast, pArp2, actin polymerization, membrane protrusion, and cell migration are markedly attenuated in cells expressing either a kinase-inactive NIK or Arp2 (T237/238A-Y202A). Our findings suggest a revised model for Arp2/3 complex regulation where electrostatic interactions maintain an auto-inhibited inactive state. Phosphorylation of Arp2 by kinases such as NIK disrupts these interactions and induces conformational changes allowing Arp2/3 complex activation, actin polymerization, and membrane protrusion in migrating cells.

116

Arpin, a Novel Protein that Inhibits the Arp2/3 Complex, Controls Lamellipodium Protrusion and Cell Migration.

C. Sousa[1], J. Linkner[2], I. Dang[1], C. Guerin[3], M. Nemethova[4], E. Derivery[1], G. Lakisic[1], J. Small[4], L. Blanchoin[3], J. Faix[2], A. Gautreau[1]; [1]Laboratoire d'Enzymologie et Biochimie Structurales, CNRS, Gif-sur-Yvette, France, [2]Institute for Biophysical Chemistry, Hannover Medical School, Hannover, Germany, [3]LPCV / iRTSV / DSV, CEA, Grenoble, France, [4]Institute of Molecular Biotechnology, Vienna, Austria

The Arp2/3 complex is a major actin nucleator of eukaryotic cells. It generates a branched actin network that generates a pushing force. This force powers the protrusion of the plasma membrane in a structure called the lamellipodium. The Wave complex is the major Arp2/3 activator in the lamellipodium, and the small GTPase Rac activates the Wave complex, when

GTP-bound. Here we present a novel inhibitor of the Arp2/3 complex that regulates dynamics of lamellipodia and cell migration.

We interrogated public databases for proteins containing an acidic C-terminal domain and harboring a W at position -2. This characteristic motif involved in Arp2/3 binding allowed us to retrieve an uncharacterized human protein among known Arp2/3 activators. This protein indeed interacted with the Arp2/3 complex in a GST-pulldown, and inhibited its activation in a dose-dependent manner, as revealed by pyrene-actin assays and by actin filament branching monitored with TIRF microscopy. We call this protein 'Arpin' as a tribute to Monique Arpin, A.G. PhD supervisor, who retired earlier this year, and also because it is a good mnemonic for *Arp*2/3 complex *in*hibitor.

We found that Rac activity induces the interaction of Arpin with the Arp2/3 complex. Consistently, endogenous Arpin localized to the lamellipodium of migrating cells. Upon RNAi-mediated depletion of Arpin in human cell lines, lamellipodia protruded faster, consistent with its inhibitory role on Arp2/3 complex activity. Arpin depleted cells explored a larger territory than the controls, because of increased speed and directionality. A knock-out of the orthologous Arpin gene from *Dictyostelium discoideum* also resulted in faster and more directional amoeba, indicating that Arpin function is conserved from amoeba to man. Fish keratocytes are the best model for persistent migration. Microinjection of purified zebrafish Arpin into keratocytes resulted in cycles of suppression of the existing lamellipodium immediately followed by growth of a new ectopic one.

Together these results argue for an essential inhibitory role of Arpin in modulating Rac signalling toward the Arp2/3 complex. If the WAVE complex is the 'engine' of cell migration, Arpin would be a 'brake' and the 'steering wheel'.

117

Cortactin Controls Cell Motility and Lamellipodial Dynamics by Regulating ECM Secretion.

B. Sung[1], X. Zhu[2], I. Kaverina[2], A. Weaver[1]; [1]Cancer Biology, Vanderbilt University Medical Center, Nashville, TN, [2]Cell and Developmental Biology, Vanderbilt University Medical Center,

Branched actin assembly is critical for both cell motility and membrane trafficking. The branched actin regulator, cortactin, is generally considered to promote cell migration by controlling leading edge lamellipodial dynamics. However, recent reports indicate that lamellipodia are not required for cell movement, suggesting an alternate mechanism. Since cortactin also regulates membrane trafficking and adhesion dynamics, we hypothesized that altered secretion of extracellular matrix (ECM) and/or integrin trafficking might underlie motility defects of cortactin-knockdown (KD) cells. Consistent with a primary defect in ECM secretion, both motility and lamellipodial defects of cortactin-KD cells were fully rescued by plating on increasing concentrations of exogenous ECM. Furthermore, cortactin-KD cell speed defects were rescued on cell-free autocrine ECM produced by control cells but not on ECM produced by cortactin-KD cells. Investigation of the mechanism revealed that whereas endocytosed FN is redeposited at the basal cell surface by control cells, cortactin-KD cells exhibit defective FN secretion and abnormal FN retention in a late endocytic/lysosomal compartment. Cortactin-KD motility and FN deposition defects were phenocopied by KD in control cells of the lysosomal fusion regulator Synaptotagmin-7. Rescue of cortactin-KD cells by expression of cortactin binding domain mutants revealed that interaction with Arp2/3 complex and actin filaments is essential for rescue of both cell motility and autocrine ECM secretion phenotypes whereas binding of SH3 domain partners is not required. In conclusion, efficient cell motility, promoted by cortactin regulation of

branched actin networks, involves processing and resecretion of internalized ECM from a late endosomal/lysosomal compartment.

Spg20-/- mice reveal multimodal functions for Troyer syndrome protein spartin in lipid droplet maintenance, cytokinesis, and BMP signaling.

B. Renvoise[1], J. Stadler[1], R. Singh[1], J. Bakowska[2], C. Blackstone[1]; [1]Cellular Neurology Section, NIH/NINDS, Bethesda, MD, [2]Department of Pharmacology, Loyola University Chicago, Maywood, IL

Hereditary spastic paraplegias (HSPs; SPG1-48) are inherited neurological disorders characterized by lower extremity spastic weakness due to a length dependent axonopathy of corticospinal motor neurons. Loss-of-function, frame-shift mutations in the human *SPG20* gene encoding spartin cause autosomal recessive Troyer syndrome (SPG20), an HSP which has additional features of short stature, skeletal defects, cognitive decline, and distal amyotrophy. To identify cellular impairments underlying Troyer syndrome, we generated *Spg20-/-* knockout mice, which develop late-onset hind limb and gait deficits. Though central nervous system pathology appeared largely normal, cerebral cortical neurons cultured from neonatal *Spg20-/-* mice exhibited increased axon branching, a phenotype suppressed by reintroducing spartin and which required its interaction with the ESCRT-III protein IST1. Analysis of the bone morphogenetic protein (BMP) signaling pathway in *Spg20-/-* embryonic fibroblasts indicated that Smad1/5 phosphorylation is elevated, possibly due to observed alterations in BMP receptor trafficking and degradation. Cytokinesis was impaired in embryonic fibroblasts cultured from *Spg20-/-* mice, and binucleated chondrocytes were prominent in epiphyseal growth plates of bones in *Spg20-/-* mice, likely explaining the short stature of patients. Finally, adipose tissue from *Spg20-/-* animals exhibited increased lipid droplet numbers and alterations in perilipin levels, supporting a key role for spartin in lipid droplet maintenance. Taken together, our results support multimodal adaptor functions for spartin that provide important insights into HSP pathogenesis.

119

The Oculo-Cerebro-Renal Syndrome of Lowe as a Ciliopathy: Role of Ocrl1 in Primary Cilia Assembly.

B. G. Coon[1], K. Madhivanan[2], V. Hernandez[3], D. Mukherjee[1], C. B. Hanna[1], M. Lowe[4], P. Beales[3], C. Aguilar[1]; [1]Department of Biological Sciences and Purdue Center for Cancer Research, Purdue University, [2]Department of Biological Sciences and Purdue Center for Cancer Research, Purdue University, West Lafayette, IN, [3]Molecular Medicine Unit, University College London Institute of Child Health, United Kingdom, [4]Life Sciences, University of Manchester, United Kingdom

Lowe syndrome is a devastating, X-linked genetic disease characterized by the presence of congenital cataracts, profound learning disabilities and renal dysfunction. Unfortunately, children affected with Lowe Syndrome often die early of health complications including renal failure. Although this syndrome was first described in the early fifties and the affected gene, OCRL1, was identified more than 17 years ago, the mechanism by which Ocrl1 defects lead to Lowe syndrome's symptoms remains unknown.

Here we show that Lowe syndrome display some of the the characteristics of a ciliopathy. Specifically, we found that patients' cells have defects in the assembly of primary cilia and this phenotype was reproduced by knock-down of Ocrl1 in cells in culture. Importantly, this defect could be rescued by re-introduction of WT Ocrl1 in both, patient's and Ocrl1 knock-down cells. In addition, a zebrafish animal model of Lowe syndrome exhibited cilia defects and multiple morphological and anatomical abnormalities typically seen in ciliopathies. Mechanistically, we show that Ocrl1 is involved in protein trafficking to the primary cilia in a Rab8-, Appl1- and IPIP27/Ses-dependent manner via the secretory and endocytic pathways.
Taking into consideration the relevance of the signaling pathways hosted by the primary cilium, our results suggest hitherto unrecognized mechanisms by which Ocrl1 deficiency may contribute to the phenotypic characteristics of Lowe syndrome. This conceptual change in our understanding of the disease etiology may provide an alternative avenue for the development of therapies.

120

Microtubule Link between Cell Cycle and Neurotransmitter Receptor Defects in Neurodegenerative Disease.

H. Potter[1], A. Granic[2], C. Ari[2], S. Borysov[3], J. Padmanabhan[2], C. Walczak[4];
[1]Molecular Medicine, University of South Florida, Tampa, FL, [2]University of South Florida, Tampa, FL, [3]Moffitt Cancer Center, Tampa, FL, [4]Indiana University, Bloomington, IN

Microtubules serve as the highways upon which ATP driven motor proteins move key cellular components, such as proteins, vesicles, chromosomes, and large macromolecules, including microtubules themselves, from one part of the cell to another. Many neurodegenerative diseases show defects in the microtubule transport system, underlining its importance in normal cellular physiology. Our data support a unifying hypothesis stating that defects in microtubule dependent transport are induced by the key neurodegeneration-associated proteins Aβ or Tau and generate neurons with an aneuploid chromosome complement and with reduced neurotransmitter and neurotrophin cell surface expression and function. Previously, we found that mutant amyloid precursor protein and presenilin genes that cause familial AD induce chromosome mis-segregation and aneuploidy in AD patients, transgenic mice, and cultured cells. Confirmatory results from other labs showed that 30% of neurons in early AD cortex are aneuploid/hyperdiploid. We have now found that Aβ added to human cells or *Xenopus* egg extracts impairs the formation and stability of mitotic spindles and directly inhibits three microtubule motor kinesins, Eg5, KIF4A and MCAK, which are essential for the normal structure and function of the mitotic spindle. Very similar motors, and in particular Eg5 itself, are also present in neurons. Eg5 harbors polymorphisms that increase AD risk, is inhibited in neurons treated with Aβ and is almost completely inhibited in brains of the APP/PS transgenic mouse model of Alzheimer's disease. Furthermore, Aβ treatment or chemical inhibition of Eg5 results in mitotic defects and poor localization of the NMDA receptor to the plasma membrane. Like Aβ treatment, inhibition of Eg5 blocks LTP, a brain slice model of memory Most recently, we also detected aneuploid neurons in brains of patients with fronto-temporal dementia caused by mutant Tau as well as in mouse models of FTD, and are currently testing mutant cells expressing FTD mutant Tau genes. Together these data suggest that the memory impairment in AD and related disorders may derive from an inhibition of microtubule function, which can disrupt both neurogenesis and neuroplasticity.

121

RNA-binding proteins with prion-like domains in ALS and FTLD-U.

A. Gitler[1], J. Shorter[1]; [1]University of Pennsylvania, Philadelphia, PA

Amyotrophic lateral sclerosis (ALS, also known as Lou Gehrig's disease) is a debilitating, and universally fatal, neurodegenerative disease that devastates upper and lower motor neurons. The causes of ALS are poorly understood. A central role for RNA-binding proteins and RNA metabolism in ALS has recently emerged. The RNA-binding proteins, TDP-43 and FUS, are principal components of cytoplasmic inclusions found in motor neurons of ALS patients and mutations in TDP-43 and FUS are linked to familial and sporadic ALS. Pathology and genetics also connect TDP-43 and FUS with frontotemporal lobar degeneration with ubiquitin-positive inclusions (FTLD-U). It was unknown whether mechanisms of FUS aggregation and toxicity were similar or different to those of TDP-43. To address this issue, we have employed yeast models and pure protein biochemistry to define mechanisms underlying TDP-43 and FUS aggregation and toxicity, and to identify genetic modifiers relevant for human disease. We have identified prion-like domains in FUS and TDP-43 and provide evidence that these domains are required for aggregation. Our studies have defined key similarities as well as important differences between the two proteins. Collectively, however, our findings lead us to suggest that FUS and TDP-43, though similar RNA-binding proteins, likely aggregate and confer disease phenotypes via distinct mechanisms.

122

A Novel Role for N-glycans in *Drosophila* Aging.

G. Boulianne[1], M. Sarkar[2], K. Iliadi[1], H. Schachter[2]; [1]Developmental & Stem Cell Biology, The Hospital for Sick Children, Toronto, ON, Canada, [2]Molecular Structure and Function, The Hospital for Sick Children

Aging is a universal but poorly understood biological process that involves a complex interplay between environmental and genetic factors. Model organisms such as *C. elegans* and *Drosophila* have provided a unique opportunity to search for, and identify, both environmental factors and genes that can regulate the life span of these organisms. We have recently found that *N*-glycans play a novel and unexpected role in regulating *Drosophila* life span. Specifically, we have studied the role of the enzyme GnT1 (encoded by Mgat1), which is required for synthesis of paucimannose N-glycans in *Drosophila*. We have shown that null mutations in *Drosophila* Mgat1 are viable but exhibit defects in locomotion, brain abnormalities and a severely reduced life span. To further define the role of Mgat1 in organismal life span we used a combination of transgenics and RNAi technology to manipulate the expression of Mgat1 in the nervous system. We found that knock down of Mgat1 in the CNS could recapitulate the null mutant phenotype demonstrating that Mgat1 was required in the CNS. Remarkably, we also found that neuronal expression of a wild type Mgat1 transgene not only rescued the shortened life span of Mgat11 null mutants but also resulted in a dramatic increase in life span. While the wildtype control flies had a mean and maximum life span of 54 and 70 days, respectively, our rescued flies had a mean and maximum life span of 127 and 165 days, respectively. Interestingly, targeted expression of Mgat1 in the CNS of Mgat11 null mutants rendered them significantly more resistant to hydrogen peroxide than control flies demonstrating that the increase in longevity is also associated with an increase in oxidative stress resistance. Finally, we showed that while dietary restriction was not absolutely essential for the increased life span, it plays a role in the process. Altogether, these observations suggest that Mgat1-dependent N-glycosylation plays an important role in the control of *Drosophila* life span. Current studies are aimed at determining how Mgat1 and N-glycans regulate life span and whether the ability of Mgat1 to increase life span is conserved across species.

123

Molecular Mechanisms distinguishing Reproductive Aging from Somatic Aging.

S. Luo[1], C. Murphy[1]; [1]*Molecular Biology & Lewis Sigler Institute, Princeton University, Princeton, NJ*

Female reproductive cessation is the earliest aging phenotype humans experience, occurring midway through life, and is governed by declining oocyte quality. We have shown previously that C. elegans reproduction, which also persists for only half the worms' lifetime, is similarly limited by oocyte quality decline (Luo, et al. Cell 2010). Moreover, the transcriptional changes that worm oocytes undergo with age are similar to those in aging mammalian oocytes, and these changes are reversed in mutants with extended reproductive spans.
Both the TGF-b Sma/Mab and Insulin/IGF-1 signaling pathways regulate reproductive aging (Luo, et al. PLOS Genetics 2009), but IIS extends life span, as well (Kenyon, et al. 1999). We had previously identified the downstream DAF-16 targets of IIS that are responsible for long life span (Murphy, et al. Nature 2003). We wondered to what degree the mechanisms that extend reproductive span and life span are shared. In fact, very few of the terms overlap, suggesting that post-mitotic, non-proliferating tissues utilize one specific set of genes, while mitotically proliferating and cell-cycle-arrested cells utilize completely different mechanisms to keep cells youthful and functioning.

Minisymposium 20: Cilia and Centrosomes

124

Dissecting the molecular difference between MTOC-competent and non-competent centrioles.

M-F. B. Tsou[1], C. Fong[1], W-J. Wang[1], M. Kim[1], R. K. Soni[1]; [1]Memorial Sloan-Kettering Cancer Center, New York, NY

Our recent results revealed that a Plk1-dependnet modification, which occurs in early mitosis, is required to convert centrioles to centrosomes/MTOCs at late mitosis. Without such modifications, centrioles can neither organize MTOC nor duplicate regardless of their age, configuration (engaged/disengaged), or how they are formed (canonical or *de novo*). Only modified (or MTOC-competent) centrioles can duplicate in S phase, and segregate in the following mitosis through association with spindle poles. This leads to a tight coupling between duplication and segregation, i.e., only centrioles that can segregate themselves are allowed to duplicate. This mechanism, which critically maintains the homeostasis of centrioles in cycling cells, may highlight why centrioles have emerged as centrosomes/MTOCs in higher eukaryotes.

In such a regulatory scheme, centriole duplication in cycling cells inevitably generates hybrid centriole pairs, each consisting of one modified and one unmodified centriole. We propose that unmodified centrioles carry unknown inhibitory activities that locally suppress duplication. This "short-range feedback inhibition" model could nicely explain how centriole engagement blocks re-duplication. Our proteomic study in searching for molecules that associate with unmodified centrioles has generated supporting evidence for this model.

125

GCP6 is a substrate of Plk4 and required for centriole duplication.

I. Hoffmann[1], R. Bahtz[1], J. Seidler[2], U. Haselmann-Weiss[3], C. Antony[3], W-D. Lehmann[2]; [1]Cell Cycle Control and Carcinogenesis, German Cancer Research Center, Heidelberg, Germany, [2]Molecular Structure Analysis, German Cancer Research Center, Heidelberg, Germany, [3]Cell Biology and Biophysics, European Molecular Biology Laboratory, Heidelberg, Germany

Centrioles are microtubule-based structures that organize the centrosome and nucleate cilia in most eukaryotes. Centriole duplication occurs once per cell cycle and is thought to be initiated at the G1/S boundary with the formation of procentrioles at each parental centriole. A central role in the control of centriole biogenesis and duplication has been attributed to Plk4, a member of the Polo-like kinase family. Microtubule nucleation requires γ-tubulin which exists in two major protein complexes: the γ-tubulin small complex (γ-TuSC) and the γ-tubulin ring complex (γ-TuRC). GCP6 is a member of the γ-TuRC but its role in human cells and the regulation of its functions remain unclear. We find that depletion of human GCP6 prevents the assembly of the γ-TuRC and induces a high percentage of monopolar spindles. These spindles are characterized by a loss of centrosomal γ-tubulin and reduced centriole numbers. GCP6 is localized in the pericentriolar material (PCM) but also at distal portions of centrioles. In addition, GCP6 is required for centriole duplication and Plk4-induced centriole overduplication. GCP6 interacts with and is phosphorylated by Plk4. Moreover, we find that Plk4-dependent phosphorylation of GCP6 regulates centriole duplication. Our data suggest that GCP6 is a critical subunit of the the γ-TuRC and a novel target of Plk4 in centriole biogenesis.

126

The BBSome at the crossroad of signaling, trafficking and tubulin acetylation.

M. V. Nachury[1], D. K. Breslow[1], H. Jin[1], S. R. White[1], T. Shida[1], Z. Xu[1], A. Aguilar[1]; [1]Department of Molecular and Cellular Physiology, Stanford Univ Med Sch, Stanford, CA

The primary cilium exposes signaling receptors and concentrates signaling cascades to send specific molecular responses into the cell. Such remarkable signaling properties rely on the physical separation between the cilium and the rest of the cell and on molecular machines that move proteins through diffusion barriers. Our overarching goal is to reconstitute these transport activities in cell-free systems and as a first step, we have established an in vitro system that faithfully recapitulates macromolecular diffusion between ciliary lumen and cytoplasm.
Independently, our biochemical dissection of the archetypical ciliopathy Bardet-Biedl Syndrome (BBS) uncovered a complex of seven BBS proteins that we named the BBSome. We have now demonstrated that the BBSome sorts signaling receptors –such as the somatostatin receptor 3 (SSTR3)– to cilia. While initial results indicated that the BBSome functions as a coat complex akin to clathrin, COPI and COPII, we will present recent structural insights indicating that the BBSome may resemble more closely the coat adaptors that bridge membrane proteins to the lattice elements of coats. These results suggest the existence of currently unknown components the organizes the BBSome into a latticed coat.
Additionally, we discovered the long-sought α-tubulin K40 acetyltransferase TAT1 as a BBSome-associated protein. We have now uncovered an essential role for TAT1 in the maintenance of long-lived microtubules and for cell migration, thus supporting a role for stable microtubules in cell migration. Fascinatingly, acetylation takes place inside the lumen of microtubules and, utilizing TAT1 as a probe for lumen accessibility, we have found that transient openings along the microtubule sidewall allow for entry of proteins into the microtubule lumen thus suggesting the existence of a new facet of microtubule dynamicity inside the cell.

127

The importance of a single primary cilium: extra centrosomes and cilia compromise ciliary signaling.

M. Mahjoub[1], T. Stearns[2]; [1]Biology, Stanford Univ, Stanford, CA, [2]Genetics, Stanford Univ, Stanford, CA

Primary cilia perform important sensory functions, and are associated with a range of human diseases, termed ciliopathies. We show that cells with extra centrioles, a phenotype frequently observed in cancers, also form extra cilia. Such super-ciliated cells have a reduced ciliary concentration of the Sonic hedgehog pathway protein Smoothened, leading to decreased Shh pathway activation. A similar ciliary dilution phenotype was observed with the serotonin receptor Htr6, fibrocystin gene PKHD1, and GTPase Arl13b. The presence of extra cilia disrupted epithelial organization in 3-D spheroid culture. Finally, mutation of the tuberous sclerosis disease gene Tsc2 also results in super-ciliated cells and in dilution of ciliary protein. Thus, the presence of extra cilia disrupts ciliary signaling, and may contribute to ciliopathy and cancer disease phenotypes.

128

IFT25 Couples Movement of the Hedgehog Signaling Components to Intraflagellar Transport.

B. T. Keady[1], R. Samtani[2], K. Tobita[2], M. Tsuchya[2], J. T. San Agustin[1], J. A. Follit[1], J. A. Jonassen[3], R. Subramanian[2], C. Lo[2], G. Pazour[1]; [1]Molecular Medicine, Univ. of Massachusetts Medical School, Worcester, MA, [2]Dept. of Developmental Biology, University of Pittsburgh, Pittsburgh, PA, [3]Univ. of Massachusetts Medical School, Dept. of Microbiology and Physiological Systems, Worcester, MA

The intraflagellar transport (IFT) system is required for assembling primary cilia, sensory organelles that cells use to respond to their environment. IFT particles are composed of about 20 proteins and these proteins are highly conserved across ciliated species. However, IFT25 and its binding partner, IFT27, are unusual in that they are found in Chlamydomonas and mammals but not in Drosophila or Caenorhabditis even though these organisms assemble cilia. To elucidate the function of the IFT25/IFT27 module, we generated an Ift25 mutant mouse. Unlike all previously studied mice with null mutations in IFT genes, which do not assemble cilia and die at mid term, the homozygous Ift25 null mutants form cilia normally and survive through gestation. Mutant mice die at birth with multiple phenotypes indicative of Hedgehog signaling dysfunction. Loss of IFT25 leads to the depletion of IFT27 but not other IFT proteins. Cilia lacking IFT25 have defects in the dynamic transport of multiple Hedgehog signaling components, including Patched-1, Smoothened, and Gli2, and fail to activate the pathway upon stimulation. This is the first example of a null IFT mutation that perturbs Hedgehog signaling independent of ciliary architecture. Thus, IFT function is not restricted to assembling cilia where signaling occurs but also plays a direct role in signal transduction events.

An ARL3-UNC119-RP2 GTPase cycle delivers myristoylated NPHP3 to the primary cilium.

K. J. Wright[1], L. M. Baye[2], S. Mukhopadhyay[3], A. Olivier-Mason[4], L. Sang[3], M. Kwong[3], W. Wang[5], P. R. Pretorius[2], V. C. Sheffield[6,7], P. Sengupta[4], D. C. Slusarski[2], P. K. Jackson[3]; [1]Cell Regulation, Genentech, Inc., South San Francisco, CA, [2]Department of Biology, University of Iowa, Iowa City, IA, [3]Cell Regulation, Genentech, Inc., South San Francisco, CA, [4]Department of Biology, Brandeis University, Waltham, MA, [5]Structural Biology, Genentech, Inc., South San Francisco, CA, [6]Department of Pediatrics, University of Iowa, Iowa City, IA, [7]Howard Hughes Medical Institute

The membrane of the primary cilium is a highly specialized compartment that organizes proteins to achieve spatially ordered cell signaling. Disrupting ciliary organization leads to diseases called ciliopathies, with phenotypes ranging from retinal degeneration and cystic kidneys to neural tube defects. How proteins are selectively transported to and organized in the primary cilium remains unclear. Using a proteomic approach, we identify the ARL3 effector UNC119 as a binding partner of the myristoylated ciliopathy protein NPHP3. We map UNC119 binding to the N-terminal 200 residues of NPHP3 and find the interaction requires myristoylation. Creating directed mutants predicted from a structural model of the UNC119-myristate complex, we find that UNC119 binds myristoylated cargos through a highly conserved set of phenylalanines within a hydrophobic beta sandwich and identify phenylalanine residues essential for myristate binding. Further, we find ARL3, UNC119b, but not UNC119a, and the ARL3 GAP RP2 are required for NPHP3 ciliary targeting, and that targeting requires UNC119b myristoyl-binding activity. Finally, we discover a new UNC119-binding protein, C5orf30, that may regulate myristoyl-cargo binding. Our results uncover a selective, membrane-targeting GTPase cycle that delivers myristoylated proteins to the ciliary membrane, and suggest that other myristoylated proteins may be similarly targeted to specialized membrane domains.

130

Morphological and functional identity of organelles of the early plant secretory pathway.

F. Brandizzi[1]; [1]Cell Biology and Biophysics Unit, Michigan State Univ, East Lansing, MI

A fundamental question in eukaryotic cell biology is how cells maintain efficient compartmentalization and control the delivery and integration of biomolecules into specialized organelles. In our lab, we address these questions using the plant secretory pathway as a model. This pathway is vital to the inner workings of the cell and for communicating with the external environment during growth and in response to stress; it consists of several organelles that synthesize, shuttle, and store a large part of the cell's proteins, lipids, and sugars. In plants, the activities of the endoplasmic reticulum (ER) and Golgi apparatus, the initial organelles of the secretory pathway, are also fundamental for the synthesis and deposition of the building blocks of energy-rich compartments such as the cell wall and storage vacuole. Both organelles have unique architecture and functions, which are maintained despite exchange of membranes and lumenal contents with other organelles. Efforts in our lab focus on identifying the mechanisms governing the morphology and function of the ER and the Golgi and defining the extent to which their architecture influences their function. To address these questions we have carried out forward genetic screens based on confocal microscopy analyses of Arabidopsis seedlings expressing ER and Golgi markers. The screens are designed to identify mutants with aberrant distribution of the ER and Golgi markers compared to non mutagenized seedlings. Through the

characterization of these mutants we are identifying novel genes and mutations that uncover new information on the mechanisms for the integrity of the ER and the Golgi with respect to other organelles, cytoskeleton and flow of biosynthetic cargo. Our most recent findings will be presented in this talk.

131

The first 5 seconds in the life of an edocytic clathrin coated pit.

E. Cocucci[1,2], F. Aguet[1], T. Kirchhausen[1,2]; [1]Cell Biology, Harvard Medical School, Boston, MA, [2]Program in Cellular and Molecular Medicine at Children's Hospital, Boston, Boston, MA

Formation of endocytic clathrin coated pits and vesicles requires the rapid and highly orchestrated generation of a scaffold made of a very large number of interacting proteins whose assembly results in entrapment of cargoes and membrane deformation. Key for this process is the organized recruitment of clathrin triskelions and AP-2 adaptors. In order to understand the molecular events occurring at the early stages of pit formation we developed a method applicable to living cells and based on total internal reflection fluorescence microscopy that allows visualization and tracking with single-molecule sensitivity and 100 millisecond temporal resolution of clathrin and AP-2 as they are recruited during the first few seconds in the life of a coated pit. By combining this imaging method with newly developed analytical tools to cells expressing fluorescently tagged clathrin and AP-2, we established that coated pits start by the simultaneous recruitment of one clathrin triskelion and two AP-2s. This first recruitment step typically lasts ~2 s, followed by a second step of similar characteristics. We also found that there is no need to pre-cluster AP-2s at the site of coated pit formation and that the presence of the phosphoinositide PIP2 is essential for pit initiation.

132

Molecular Architecture of the Transport Channel of the Nuclear Pore Complex.

I. Melcak[1], S. Solmaz[1], R. Chauhan[1], G. Blobel[1]; [1]Laboratory of Cell Biology, Howard Hughes Medical Institute, The Rockefeller University, New York, NY

The largest and most versatile transport channel of eukaryotes is anchored in the center of the nuclear pore complex and is thought to be composed of three nucleoporins, Nup54, Nup58 and Nup62. Here, we report the crystal structures of the interacting domains between these three nucleoporins. Supported by biochemical, biophysical and mutational data we pieced together the molecular architecture of the mammalian transport channel. Located in the channel mid-plane is a Nup54·Nup58 ring that can undergo large re-arrangements yielding diameter changes from about 20 nm to 40 nm as the channel expands from inactive 'closed' to active 'open' forms, respectively. Triple α-helices of Nup62·Nup54 project alternately up and down from either side of the mid-plane ring and form nucleoplasmic and cytoplasmic entries. The channel consists of as many as 224 copies of the three nucleoporins amounting to a molar mass of 12.3 million daltons and providing 256 unstructured Phenylalanine-Glycine repeat regions for routing captured transport substrates.

133

Sedlin binds Sar1p and controls type II procollagen trafficking by modulating the cycle of COPII.

R. Venditti[1], M. Santoro[1], G. Di Tullio[2], B. Vertel[3], C. Wilson[1], A. De Matteis[1]; [1]Tigem, Telethon, Naples, Italy, [2]Consorzio Mario Negri Sud, Italy, [3]Cell Biology and Anatomy, Rosalind Franklin University, Chicago, IL

Genetic defects of sedlin, a conserved component of the TRAPP complex, cause spondyloepiphyseal dysplasia tarda (SEDT), a condition characterised by impaired chondrogenesis that results in short stature, flattening of the vertebrae and premature osteoarthritis. Prompted by the consideration that sedlin is ubiquitously expressed but that sedlin mutations cause cartilaginous-restricted dysfunctions, we hypothesized that sedlin might exert a role in the transport of chondrocyte-specific cargoes, such as type II procollagen (PCII). This hypothesis was reinforced by the fact that certain mutations in PCII give rise to autosomal dominant forms of spondyloepiphyseal dysplasia. We tested this hypothesis by analyzing the involvement of sedlin in the transport of different classes of secretory cargoes and found that sedlin is selectively required for PCII to exit the ER, while it is not essential for the ER exit of small soluble and membrane-associated cargoes. We have also identified the molecular mechanism underlying this role of sedlin in its ability to bind the GTPase Sar1 and to control the membrane-cytosol cycle of Sar1 itself and of the COPII coat complex at the level of the ER exit sites. Sedlin depletion and/or mutation in SEDT patients slows down the Sar1 cycle and prolongs the membrane association of Sar1-GTP at ER exit sites, thus inducing constriction and premature fission of nascent carriers which fail to incorporate the large PC protofibrils but are still competent for smaller secretory cargoes.

134

The Creb3l2/Sec23a/Sec24D axis in collagen secretion and cartilage morphogenesis.

D. Melville[1], D. Levic[1], S. Sarmah[2], W. Rybski[2], K. Zavalin[2], E. Knapik[2]; [1]Cell and Developmental Biology, Vanderbilt University, Nashville, TN, [2]Division of Genetic Medicine, Vanderbilt University, Nashville, TN

The COPII machinery is the primary mediator of ER-to-Golgi transport and appears to be dynamically regulated according to secretory demand, although the mechanisms of this regulation are only beginning to be elucidated. Using forward genetics coupled with a positional cloning strategy, we have identified zebrafish mutants with defects in the COPII components, *crusher/sec23a*, *bulldog/sec24d*, and *feelgood/creb3l2*, each of which leads to a malformed head skeleton. Although both early cartilage patterning and initial ECM deposition proceed normally, COPII mutant chondrocytes progressively accumulate collagen within the ER, resulting in a failure to maintain cartilage ECM and impaired chondrocyte maturation. Importantly, this trafficking deficiency appears to be collagen-specific, as shown by the normal localization of a variety of other secretory proteins, including glycosaminoglycans, integrin β1, and N-cadherin. We further identified Creb3l2 as a direct transcriptional regulator of select COPII genes, including *sec23a* and *sec24d*. This establishes Creb3l2 as the first identified transcription factor to couple the secretory activity of cells to the progression of developmental programs. Collectively, our work has shown that Creb3l2/Sec23a/Sec24D are critical for collagen secretion during the maturation stage of chondrogenesis and suggests that this secretory axis is central to a broad transcriptional regulatory network that optimizes cellular machinery to facilitate trafficking in highly secretory cell types.

135

Genome-wide siRNA screens identify novel networks regulating membrane traffic and organelle biogenesis in the secretory pathway.

R. Pepperkok[1]; [1]Cell Biology Cell Biophysics Unit, EMBL, Heidelberg, Heidelberg, Germany

The secretory pathway in mammalian cells has evolved to facilitate protein secretion and the transfer of a huge variety of cargo molecules to internal and cell surface membranes in a specific and timely manner. Extensive genetic and biochemical efforts over many years have identified and characterized much of the core machinery of this pathway. However, it is clear that regulatory components and their inter-dependence on other cellular metabolic events and pathways need to be elucidated to reach a more comprehensive understanding of the secretory pathway.
In order to identify such putative molecules involved in the regulation of the secretory pathway and organelle biogenesis, we have used high throughput/high content microscopy in intact cells to assess on a genome-wide scale the effect of knockdowns by RNAi, on processes such as constitutive protein transport, Golgi integrity and function of vesicular coat complexes. Our data reveal an unexpected relationship between secretory pathway function and genes involved in general metabolic integrity or signal transduction pathways. This provides the basis for an integrative understanding of the global cellular organization and the regulation of the secretory pathway and organelle biogenesis.

Insights into the micromechanical properties of the metaphase spindle.

Y. Shimamoto[1], Y. Maeda[2], S. Ishiwata[3], A. Libchaber[2], T. Kapoor[1]; [1]Laboratory of Chemistry and Cell Biology, Rockefeller Univ, New York, NY, [2]Laboratory of Experimental Condensed Matter Physics, Rockefeller Univ, New York, NY, [3]Department of Physics, Waseda Univ, Japan

During cell division, the microtubule-based metaphase spindle is subjected to forces that act in diverse orientations and over a wide-range of timescales. Currently, we cannot explain how this dynamic structure generates and responds to forces while maintaining overall stability, as we have a poor understanding of its micromechanical properties. Here we combine the use of force-calibrated needles, high-resolution microscopy, and biochemical perturbations to analyze the vertebrate metaphase spindle's timescale- and orientation-dependent viscoelastic properties. We find that the metaphase spindle is mechanically anisotropic, and exhibits either viscous-like or elastic-like behavior depending on the timescale of applied force. We also find that spindle viscosity depends on the dynamics of microtubule crosslinking and the density of the filament. Spindle elasticity can be linked to kinetochore and non-kinetochore microtubule rigidity, and also to spindle pole organization by kinesin-5 and dynein. These data suggest a quantitative model for the micromechanics of this cytoskeletal architecture and provide insight into how structural and functional stability is maintained in the face of forces, such as those that control spindle size and position, and can result from deformations associated with chromosome movement.

137

Spindle assembly sub-reactions without microtubule polymerization dynamics.

A. C. Groen[1,2], A. Nguyen[1,2], C. M. Field[1,2], T. J. Mitchison[1,2]; [1]Systems Biology, Harvard Medical School, Boston, MA, [2]Marine Biological Laboratory, Woods Hole, MA

Mitotic and meiotic spindles are thought to self-organize by a combination of microtubule polymerization dynamics and motor protein activity. Rapid microtubule turnover by dynamic instability is an essential part of normal spindle assembly, but it is interesting to ask, to what extent can spindles assemble in the absence of such dynamics? We addressed this question using Xenopus egg extracts that recapitulate meiosis-II spindle assembly, and high-speed supernatant (HSS) fractions derived from them. Use of HSS also addresses possible requirements for membranes and other particulate components. We used taxol and DMSO to force rapid microtubule polymerization and block subsequent polymerization dynamics. Randomly assembled microtubules were able to re-organize over time into asters, parallel bundles and, under some conditions, spindle-shaped assemblies. These arrays recruited known spindle assembly factors, such as NuMA and TPX2 to appropriate sites, and their assembly depended on dynein and Eg5. Their length scales seem to arise mostly from the initial polymerization conditions, and to a lesser extent from subsequent slow length changes. We conclude that important sub-reactions in spindle morphogenesis can occur in the absence of polymerization dynamics. These data help explain the finding that spindle-like assemblies are sometimes able to form in extracts and living cells even when key dynamics regulators are perturbed.

138

Nuclear divisions under space constraints studied in single embryo extract.

I. Telley[1], I. Gaspar[1], A. Ephrussi[1], T. Surrey[2]; [1]EMBL, Heidelberg, Germany, [2]CRUK London Research Institute, United Kingdom

Early development in the *Drosophila* embryo is governed by rapid nuclear divisions in a large syncytium. Initially at the pre-blastoderm stage nuclei divide in the interior of the embryo and later the majority migrate towards the cortex where they are tightly packed. Proper nuclear positioning is crucial at this stage as the embryo is prepared for cellularization of the blastoderm. An open question is what governs nuclear spreading through the entire embryo and the spatial relationship between the nuclei in the pre-blastoderm stage in contrast to the blastoderm stage when nuclei are anchored at the cortex. Using a novel *ex vivo* assay in which cytoplasm extracted from individual syncytial embryos is encapsulated in microchambers, we monitor nuclear divisions by confocal fluorescence microscopy. We first demonstrate that the cytoplasmic extract maintains its functionality: nuclear size, spindle morphology, cycle timing and synchrony are preserved. We find that in the absence of spatial constraints the separation of chromosomes and nuclei in pre-blastoderm extract is biphasic; fast chromosome segregation during anaphase is followed by slow separation of nuclei at telophase and early interphase, leading to even spacing of nuclei. Separation is accompanied by the formation of large centrosomal asters. Confining the extract in microchambers allowed us to test how the dynamics of nuclear divisions respond to spatial constraints. Large spindle deformations in confined pre-blastoderm extract indicate strong pushing forces generated by both the spindle midzone and the astral microtubules. The second, slow phase of separation is abolished, and instead we observe frequent spindle fusion during the next mitosis. Our results suggest that in pre-blastoderm divisions individual nuclei occupy a volume with characteristic size (radius ~15 µm). Remarkably, at this stage this length does not scale with the available space, but is an intrinsic property of the dividing nucleus, defining a domain which it occupies in the absence of membranes. This domain appears critical as two nuclei forced into the same domain collapse

and fuse. Our findings provide a conceptual framework for the rapid spreading of nuclei inside a large syncytium. This spreading of dividing nuclei within domains of constant size is distinct from the tightly packed nuclear divisions occurring at the embryo cortex, where nuclear domain size oscillates and spindle length is progressively reduced. Our novel *ex vivo* assay will allow further insight into what defines the identity of spindle domains and their biomechanical properties in a syncytium.

139

Centromere protein Q self-assembles into toroidal complexes and promotes microtubule catastrophe.

C. Samora[1], A. Straube[1], J. Bancroft[1], A. McAinsh[1]; [1]Centre for Mechanochemical Cell Biology, University of Warwick, Coventry, United Kingdom

Human kinetochores are multi-protein mechanochemical engines that form attachments to the plus-end of spindle microtubules1. By tightly controlling plus-end dynamics the kinetochore is able to coordinate the set of movements that align and segregate chromosomes during mitosis. The conserved constitutive centromere associated network (CCAN)is emerging as a key part of the machinery that regulates tubulin exchange at microtubule plus-ends with one subunit, the CENP-Q octomer, being able to bind microtubules in vitro. Here we show that purified CENP-Q octomers can self-assemble in a nucleotide-independent manner into toroidal complexes (Q-rings) that can bind to the microtubule lattice. Strikingly, CENP-Q octomers, and to a greater extent Q-rings, are able to disassemble microtubules in vitro by reducing the rate of tubulin assembly at microtubule plus-ends, thereby promoting catastrophe. Q-ring disassembly is promoted by free tubulin so that ring driven microtubule disassembly is self-limiting. Using total internal reflection microscopy we reveal that CENP-Q molecules preferentially target microtubule ends. In human cells, depletion of CENP-Q causes a reduction in the turnover of kinetochore microtubules and defects in chromosome alignment. This work identifies CENP-Q as the founding member of an entirely new class of microtubule dynamics regulator that caps and slows growth of microtubule ends. Within the kinetochore this activity is essential to control microtubule plus-end dynamics and allow accurate chromosome segregation.

140

Recruitment of the human Cdt1 replication licensing protein by the loop domain of Hec1 is required for proper kinetochore microtubule attachment.

D. Varma[1], S. Chandrasekaran[2], L. Sundin[3], D. Chasse[4], J. Deluca[3], J. Cook[2], E. Salmon[1]; [1]Department of Biology, UNC Chapel Hill, Chapel Hill, NC, [2]Department of Biochemistry and Biophysics, UNC Chapel Hill, Chapel Hill, NC, [3]Department of Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, [4]Duke Institute for Genome Sciences and Policy, Duke University, Durham, NC

The Cdt1 protein is critical for DNA replication origin licensing during G1 phase and is degraded during S phase followed by re-accumulation in G2 phase. We now provide evidence that Cdt1 has an essential function in mitosis entirely independent of its function in replication. Cdt1 localizes to kinetochores during mitosis through interaction with Hec1 (hNdc80), a member of the highly conserved Ndc80 complex that forms the core microtubule (MT) attachment site at kinetochores. G2-specific depletion of Cdt1 or injection of a function blocking anti-Cdt1 antibody into mitotic vertebrate cultured cells arrests them in late prometaphase with high levels of Mad1 at aligned kinetochores and abnormally unstable, cold-sensitive kMTs. Biochemical and cell biological analysis indicate that Cdt1 binds to a unique, flexible loop extending from the middle of the rod domain of Hec1 that we find is also required for forming robust kinetochore microtubule attachments. Mutations in the loop domain prevent Cdt1 localization to kinetochores

and arrest cells in prometaphase with high levels of Mad1 at aligned kinetochores, as observed after Cdt1 depletion. Analysis of kinetochores in control and Cdt1-depleted cells using super-resolution fluorescence microscopy indicates that Cdt1 binding to Hec1 supports a conformational change in the Ndc80 complex that is compatible with proper spindle microtubule attachment. These results show that Cdt1 is a novel regulator of Hec1 function and that Cdt1 bound to the loop domain of Hec1 has important roles in kinetochore microtubule attachment and the spindle assembly checkpoint. Because Cdt1 is actively degraded until the end of S phase to ensure once-and-only once genome duplication, we suggest that this newly recognized, essential and direct mitotic role reinforces the dependence of mitotic events on the completion of S phase.

141

System-level feedbacks during mitotic progression.

B. Novak[1]; [1]Department of Biochemistry, Univ Oxford, Oxford, England

Progression through mitosis is characterized by irreversible transitions at mitotic entry (G2/M), at metaphase-to-anaphase (M/A) and at mitotic exit (M/G1). I will argue that the irreversibility of these transitions is based on system-level feedbacks in the molecular regulatory mechanisms. In particular, positive (or double-negative) feedback circuits in these regulatory networks create one-way toggle (bistable) switches with two alternative stable steady states. The irreversibility of the G2/M transition is caused by switch-like activation of Cdk1:CycB. The M/A transition is made irreversible by the mitotic checkpoint which blocks anaphase until all chromosomes are bioriented on the mitotic spindle. The mitotic checkpoint is dependent on Cdk1:CycB activity which is down-regulated in mammalian cells before progression into anaphase, thereby blocking checkpoint re-activation during anaphase. The bistable switch created by the mitotic checkpoint is important to suppress the negative feedback loop caused by Cdk1:CycB dependent activation of APC/C (Anaphase Promoting Complex/Cyclosome) and CycB degradation. I will discuss experimental data with computational modeling in order to illustrate the sequential engagement of the bistable switches during mitotic progression.

Minisymposium 23: Nuclear Organization and Control of Gene Expression

142

The dynamics of splicing factor interactions with active genes in living cells.

N. Neufeld[1], Y. Brody[1], S. Carmi[1], I. Kanter[1], E-M. Böhnlein[2], K. Neugebauer[2], Y. Shav-Tal[1]; [1]The Mina and Everard Goodman Faculty of Life Sciences, Bar-Ilan University, Ramat Gan, Israel, [2]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

Splicing factors are co-transcriptionally recruited to the nascent transcript as it emerges from the active polymerase. Using tandem gene arrays that contain genes with introns and exons we could show that spliceosome assembly occurs at the active site of transcription. To obtain information about the recruitment kinetics of splicing factors to active genes in vivo we used live-cell microscopy in which both the splicing factors and the produced mRNAs could be fluorescently visualized. Typically, studies that have followed splicing factor diffusion dynamics

in the nucleus of living cells have utilized fluorescently-tagged splicing factors that were expressed from viral promoter-driven constructs (e.g. CMV or SV2). Overexpression of splicing factors might shift the endogenous balance of splicing factors and could influence the outcome of splicing decisions. We therefore used recombineered BACs containing GFP-splicing factor genes, i.e. these splicing factors were expressed from their endogenous promoters, leading to physiological levels of expression of the fluorescently tagged splicing factors. Each of these BACs was separately integrated into U2OS Tet-On cells already harboring the gene array. Using a combination of techniques for measuring intra-cellular kinetics, namely, fluorescence recovery after photobleaching (FRAP), fluorescence loss after photobleaching (FLIP), and fluorescence correlation spectroscopy (FCS), we measured the kinetics of a variety of splicing factors in the nucleoplasm, nuclear speckles and when engaged with the actively transcribing gene. Using computer simulations we provide measurements of the engagement times of splicing factors with active genes, and show that splicing factors exhibit different dynamics depending on their nuclear location.

143

High-Resolution Mapping Reveals Role for Three-Dimensional Chromatin Architecture During Stem Cell Differentiation.

J. E. Phillips[1], M. E. Gehring[1], A. Sanyal[2], B. Lajoie[2], T. C. McDevitt[3], J. Dekker[2], J. P. Taylor[1], V. G. Corces[1]; [1]Biology and Computer Science, Emory University, Atlanta, GA, [2]Biochemistry and Molecular Pharmacology, UMASS Worcester Medical School, Worcester, MA, [4]Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA

Chromatin structure, and the epigenetic modifications that alter this structure, are emerging as critical factors in the establishment of cellular state. High-throughput sequencing studies suggest that ES cells accumulate a multitude of epigenetic marks in response to developmental cues. Because hundreds of genome-wide epigenetic data sets now exist across multiple cell types, the challenge lies in finding combinatorial patterns that indicate how epigenetic marks are integrated into functional signals that regulate gene expression.

Genomes of higher eukaryotes are intricately packaged into several hierarchical levels of organization. Therefore, consideration of the epigenome in its native 3-D context will be critical for the discovery of patterns that may be obscured when these structural features are not taken into account. The objective of this project was to elucidate how 3-D chromatin architecture changes in a cell type-specific manner during development.

Here we report a kb-resolution analysis of higher-order chromatin structure during neural lineage commitment. We leveraged Chromosome-Conformation-Capture-Carbon-Copy (5C) technology in combination with high-throughput sequencing to generate structure maps for pluripotent ES cells, multipotent ES-derived neural progenitor cells, and mouse embryonic fibroblasts. An alternating primer design was used to query six 1-2 Mb-sized genomic regions around key developmentally regulated genes (i.e. Oct4, Sox2, Nanog, Klf4, Nestin, Olig1-Olig2) in a massively parallel and unbiased manner. These data reveal a complex chromatin interaction network in ES cells that undergoes extensive reorganization during neural lineage commitment. Furthermore, new regulatory elements and combinatorial patterns of epigenetic marks unique to looping structures were identified by the integration of structure maps with recent genome-wide ChIP-Seq and RNA-Seq data sets. Finally, an iterative process between computational and experimental approaches was used to assemble a catalogue of novel active and poised regulatory elements involved in neural differentiation. These results are significant toward understanding how the genome and the epigenome act in concert to regulate the formation of a diverse array of tissue-types during development.

144

Visualization of Eukaryotic DNA Mismatch Repair Reveals Distinct Recognition and Repair Associated Intermediates.

C. S. Campbell[1], H. Hombauer[2], C. Smith[2], A. Desai[2], R. Kolodner[2]; [1]Cellular and Molecular Medicine, Ludwig Institute for Cancer Research, San Diego, CA, [2]Ludwig Institute for Cancer Research, San Diego, CA

DNA Mismatch Repair (MMR) increases the fidelity of DNA replication by eliminating mispaired bases resulting from replication errors. MMR proteins are conserved from bacteria to humans and people with defective mismatch repair develop cancers at much higher rates due to an increased accumulation of mutations. In eukaryotes, Mispaired bases are recognized by two partially redundant heterodimer complexes, Msh2-Msh6 or Msh2-Msh3. After the mismatch recognition factors bind a mispaired base, accessory factors including the Mlh1-Pms1 complex are recruited, ultimately targeting repair to the daughter DNA strand. We used high-resolution microscopy to visualize functional fluorescent-tagged versions of the Msh2-Msh6 and Mlh1-Pms1 MMR complexes in living S. cerevisiae cells. Msh2-Msh6 forms foci in S-phase that colocalize with nuclear foci composed of the DNA replication machinery, often called replication factories. This localization was independent of mispair recognition. The association of Msh2-Msh6 with replication factories is completely dependent on the interaction of Msh6 with the DNA polymerase clamp PCNA (Pol30). Replication factory-association accounts for 10 to 15% of MMR in wild-type cells but is essential for MMR in the absence of the exonuclease Exo1. Mlh1-Pms1 forms nuclear foci that are dependent on mispair recognition by Msh2-Msh6 or Msh2-Msh3. Surprisingly, these foci rarely colocalize with Msh2-Msh6 foci. Mlh1-Pms1 foci increase in frequency in response to increased levels of mispaired bases. These foci also increase in response to the disruption of processes downstream of mispair recognition, indicating an accumulation of foci that cannot be efficiently processed. Based on these data, we conclude that Mlh1-Pms1 foci are sites of active mismatch repair; this is the first time mismatch repair intermediates have been observed in eukaryotes. These results suggest that (I) mispair recognition involves either the concentration of Msh2-Msh6 at replication factories or a second distinct pathway that depends on both Msh2-Msh6 and Exo1, and that (II) accumulation of Mlh1-Pms1 triggered by Msh2-Msh6-dependent mispair recognition defines sites of active MMR.

145

The budding yeast nuclear envelope adjacent to the nucleolus serves as a “membrane sink” during mitotic delay.

K. Witkin[1], Y. Chong[2], S. Shao[1], M. Webster[1], S. Lahiri[1], B. Lee[1], J. Koh[2], W. Prinz[1], B. Andrews[2], O. Cohen-Fix[1]; [1]NIDDK, NIH, Bethesda, MD, [2]University of Toronto, ON, Canada

To identify proteins and processes that affect nuclear structure, we conducted an automated microscopy screen of the entire budding yeast deletion collection for mutants that exhibit an abnormal nuclear shape. Prominent among those identified were mutants in DNA recombination and repair genes. The aberrant nuclei in these mutant strains had a single extension that always coincided with the nucleolus, while the morphology of the DNA mass was unchanged. We show that the alteration in nuclear shape in these mutants is an indirect consequence of a mitotic delay, as inhibiting mitotic progression by other means (e.g. nodocazole treatment, which depolymerizes microtubules and activates the spindle checkpoint, or expression of non-degradable Pds1p, which blocks anaphase initiation) also resulted in nuclei with a nucleolus-associated extension. Moreover, inactivating the DNA damage checkpoint in a DNA repair mutant reduced the occurrence of nuclei with extensions, further indicating that nuclear extensions are a consequence of a mitotic delay. In contrast, arresting cells in S phase or in G2 did not alter nuclear morphology. We also found that phospholipids continued to accumulate

during the mitotic delay, and that inhibiting phospholipid synthesis prevented the appearance of nuclear extensions during a mitotic arrest. Our data suggest that accumulation of phospholipids during a mitotic arrest leads to the accumulation of nuclear membrane that is not added evenly throughout the nuclear envelope, but is sequestered to a membrane compartment that is associated with the nucleolus. We hypothesize that in this way, cells avoid a disruption to intra-nuclear organization in the nuclear compartment containing the bulk of the DNA mass. Our findings also show that membrane addition to the nucleus during mitosis is independent of spindle-driven nuclear elongation, and suggest the existence of a mechanism that directs nuclear envelope expansion specifically in mitosis.

146

Phosphoinositide levels modulate nuclear morphogenesis.

L. Fabian[1], J. Brill[1]; [1]Cell Biology, Hosp Sick Children, Toronto, ON, Canada

Nuclear morphogenesis during sperm head formation is critical for creating functional sperm and for male fertility. During late stages of sperm development, round spermatid nuclei undergo dramatic changes in shape and volume. These changes are associated with chromatin condensation and with microtubule-dependent nuclear elongation. Chromatin condensation and remodeling involve a switch from a histone-based chromatin configuration, present in early round spermatid nuclei, to a protamine-based configuration, present in mature sperm nuclei. Concomitantly, the nucleus elongates by reorganizing the perinuclear microtubule cytoskeleton and its association with the basal body and the nuclear membrane. Here, we show that levels of phosphatidylinositol phosphates (PIPs) are critical for shaping the sperm head and for chromatin condensation during Drosophila spermiogenesis. Spermatids in which levels of phosphatidylinositol 4,5-bisphosphate (PIP2) have been reduced show profound defects in nuclear shaping; the nuclei do not mature and the males are sterile. Posttranslational modifications of histones are impaired. Protamines get incorporated into nuclei despite histones not being completely removed. Transition proteins are missing in these spermatids and repair of double-stranded DNA breaks is incomplete. We previously showed that reducing PIP2 levels in testes leads to defects in basal body docking at the nucleus and to nuclear scattering (Wei et al., J Cell Sci 2008; Fabian et al., MBoC 2010). Our present data suggest these defects could be due to absence of Klaroid, a SUN domain protein that requires normal levels of PIP2 for its localization on the inner nuclear membrane. We show that PIP2 localizes to the nucleus and along microtubules during late stages of spermatid development. Therefore, our data strongly suggest that spatially restricted PIPs control sperm head development by regulating cellular processes involved in chromatin remodeling and interactions between the nuclear membrane and nucleo-cytoskeleton.

147

Regulation of the Dbp5 nucleotide cycle by Nup159 and Gle1/IP$_6$.

K. Noble[1], S. Wente[2]; [1]Cell & Developmental Biology/ Microbiology & Immunology, Vanderbilt Univ/Meharry Med Coll, Nashville, TN, [2]Cell & Developmental Biology, Vanderbilt University, Nashville, TN

Eukaryotic gene expression is a highly regulated process that requires proper processing and transport of messenger (m) RNA-protein complexes known as messenger ribonucleoproteins (mRNPs). mRNPs are synthesized co-transcriptionally as RNA binding proteins load onto the nascent pre-mRNA transcript. The specific complement of mRNP proteins exchange throughout the mRNA's life cycle, directing downstream events such as splicing, polyadenylation, export from the nucleus, translation and degradation. One class of proteins, the DEAD-box proteins (Dbp) that function as RNA dependent ATPases, plays an integral role in the regulation of each

step in the mRNP life cycle. In *S. cerevisiae*, DEAD-box protein 5 (Dbp5) is an essential protein implicated in mRNP biosynthesis and required for mRNP export. Terminal steps in mRNP release from the nuclear pore complex (NPC) are controlled by Dbp5 interactions with another essential NPC-associated protein Gle1 and the small molecule inositol hexakisphosphate (IP_6). Both Dbp5 and Gle1 localize to the cytoplasmic side of the nuclear envelope through interactions with NPC components Nup159 and Nup42, respectively. At these cytoplasmic NPC filaments, the RNA-dependent ATPase activity of Dbp5 is stimulated by IP_6-bound Gle1 to mediate remodeling and release of proteins from mRNP complexes. To date, the model of mRNP export has assigned the role of the Dbp5-Nup159 interaction as anchoring Dbp5 at the NPC to position it close to Gle1 for activation. As such, Dbp5 is thought to be spatially controlled for remodeling mRNPs for cytoplasmic release thereby preventing re-entry into the nucleus. Utilizing *dbp5* mutants that result in dbp5 proteins that do not bind to Nup159 *in vivo* or *in vitro*, we recently showed that this binding event is not strictly required for efficient RNA export, suggesting another function for the Dbp5-Nup159 interaction. Using *in vitro* reconstitution assays to test the effect of Nup159 on other known functions of Dbp5, we determined that Nup159 promotes the release of ADP from Dbp5. Furthermore, Gle1-IP_6 promoted ATP loading onto Dbp5, thereby completing the nucleotide cycle. We propose a new model for the Dbp5 cycle during mRNA export at the NPC wherein Nup159 and Gle1-IP_6 act to promote the nucleotide cycling of Dbp5. Additionally, we suspect that along with Gle1-IP_6 regulation of Dbp5 in translation termination, a yet unidentified cytoplasmic ADP release factor works to regulate Dbp5 in translation. Overall, our work provides the first evidence for a Dbp regulated by an ADP release factor and makes light of the possibility for other Dbps to require similar co-factors.

Mechanisms regulating maintenance of stem cells and the stem cell niche.

H. Toledano[1], C. D'Alterio[1], B. Czech[2], E. Levine[3], L. Jones[4]; [1]Laboratory of Genetics, Salk Institute for Biological Studies, [2]Cold Spring Harbor Laboratory, Cold Spring Harbor, NY, [3]Department of Physics, Harvard University, Cambridge, MA, [4]Laboratory of Genetics, Salk Institute for Biological Studies, San Diego, CA

Adult stem cells support tissue homeostasis and repair throughout the life of an individual. Many stem cells lose the capacity for self-renewal when removed from their local microenvironment (“niche”), indicating that the niche plays a major role in controlling stem cell fate. Numerous intrinsic changes occur with age that result in altered stem cell behavior and reduced tissue maintenance and regeneration. However, changes to the local and systemic environments also occur that result in decreased stem cell activity or alterations in lineage commitment.
In the *Drosophila* testis, stem cells depend upon signals from the apical hub, a cluster of somatic cells that express the self-renewal factor Unpaired (Upd). Upd secretion activates the JAK-STAT pathway in adjacent stem cells to promote stem cell maintenance in young males; however, aging results in a dramatic decrease in *upd* expression, with a concomitant loss of germline stem cells (GSCs). Here we present genetic and biochemical data to demonstrate that IGF-II mRNA binding protein (Imp) counteracts endogenous small interfering RNAs to stabilize *upd* RNA and contribute to maintenance of the niche. However, Imp expression decreases in hub cells of older males, similar to *upd*, which is due to targeting of *Imp* by the heterochronic microRNA *let-7*. Therefore, in older males *upd* mRNA is unprotected and degraded. Our data reveal how small RNAs can act at multiple levels to target key self-renewal pathways, resulting in loss of stem cell niche function and decreased stem cell maintenance with age.

Understanding the mechanistic basis for aging-related changes in stem cell behavior will lead to the development of strategies to treat age-onset diseases and facilitate stem cell based therapies in older individuals.

149

The regulation of asymmetric stem cell division by centrosome orientation checkpoint.

H. Yuan[1]; [1]Life Sciences Institute, University of Michigan, Ann Arbor, MI

Adult stem cells are critical for tissue homeostasis, especially for short-lived differentiated cell populations, such as blood, skin, and sperm cells. A hallmark of stem cells is the ability to give rise to daughter cells committed to differentiation, while maintaining themselves the potential of self-renewal. Asymmetric cell division is a common strategy for stem cells to achieve the balance between self-renewal and differentiation. Perturbation of this balance can lead to either tumorigenesis by overgrowth of stem/stem-like cells, or tissue degeneration by depletion of stem cells.

Drosophila germline stem cells (GSCs) provide a useful model system in which to study the function and regulation of adult stem cells. *Drosophila* GSCs and the niche in which they reside have been identified and can be studied at single-cell resolution. *Drosophila* male germline stem cells (GSCs) always divide asymmetrically to give rise to a daughter cell that remain within the niche, maintaining stem cell identity, and the other daughter cell that is displaced away from the niche, committing to differentiation.

We have shown that the centrosome orientation in *Drosophila* male GSCs is tightly linked to the asymmetric division of the GSCs. GSCs in interphase maintain stereotypical centrosome orientation with respect to the niche component, hub cells, leading to perpendicularly oriented spindle in mitosis. Interestingly, the mother centrosome is always located close to the hub, whereas the daughter centrosome migrates to the opposite pole to set up the perpendicular orientation of mitotic spindle. However, how the precise centrosome orientation is ensured has not been investigated.

Here we show that *Drosophila* male GSCs possess a checkpoint that monitors the centrosome orientation before entering mitosis. This checkpoint delays/ arrests the cell cycle of GSCs when centrosomes are misoriented, preventing mitosis with misoriented spindle that may lead to symmetric stem cell division. Our data demonstrate that Par-1 kinase is one of the critical components of this novel centrosome orientation checkpoint. We also identified Cyclin A as the downstream target of Par-1. Cyclin A is sequestered on spectrosome, a germline specific ER-like organelle, by Par-1 till the centrosomes are correctly oriented. Interestingly, we found that the C terminal fragment of Cyclin A is required for its localization on spectrosome. We are embarking a biochemical pull-down experiment followed with mass spectrometry to identify the interacting partners with this spectrosome targeting motif/domain. This may also open new avenue for identifying other components of the centrosome orientation checkpoint. Taken together, we propose that centrosome orientation is tightly regulated and monitored in male GSCs to ensure asymmetric outcome of the cell division.

150

Measuring electrical dynamics in human iPS-derived cardiomyocytes with a fluorescent voltage-indicating protein.

J. Kralj[1], D. Hochbaum[2], D. Maclaurin[3], A. Cohen[1]; [1]Chemistry and Chemical Biology, Harvard University, Cambridge, MA, [2]Engineering and Applied Science, Harvard University, Cambridge, MA, [3]Physics, Harvard University, Cambridge, MA

Human iPS-derived cardiomyocytes are a promising platform for drug screens and studies of cardiac electrophysiology in healthy and diseased states. However, conventional patch clamp measurements are laborious, multi-electrode arrays do not probe membrane potential directly, and voltage-sensitive dyes are highly phototoxic. Here we describe a fluorescent voltage-indicating protein (VIP) based on a modified microbial rhodopsin protein, whose fluorescence sensitively and accurately reflects membrane potential. Expression of this VIP in iPS-derived cardiomyocytes yielded optical measurements of membrane potential in quantitative agreement with electrophysiological data. We used high-speed imaging to observe activation fronts propagating across and between cells with sub-millisecond temporal resolution. Co-expression of VIPs with channelrhodopsin enabled fully non-contact electrophysiology in which stimulus and response were both mediated by light. These results open the way for high-throughput and high-content optical studies of electrophysiology in human iPS-derived cardiomyocytes.

151

Characterization of blastema formation and pattern reformation during lower jaw regeneration in zebrafish.

X. Wang[1], H. He[1], W. Zheng[1], G. Chen[2], J. Yan[1]; [1]College of Fishiers and Life Sciences, Shanghai Ocean University, Shanghai, China, [2]National Human Genome Research Institute, National Institutes of Health, Bethesda, MD

Zebrafish possesses the remarkable ability to regenerate the complicated structures by formation of the characteristic blastema. It is disputed how the blastemal cells arise. Little is known about changes in gene activities that occur during the course of regeneration. To decipher the cellular and molecular processes that underlie restoration of the amputated lower jaw, we have investigated cellular transitions and transcriptional profile of the deregulated genes during the blastema formation and pattern reformation.

In the first two days, the wound epithelium is reconstituted by a stratified epidermal layer. Following complete re-epitheliation, fibroblasts, fragmented muscle cells, and cells from blood and damaged endothelium are activeated. These cells aggregate under the new formed wound epidermis, and contribute to the growing mass of mesenchymal tissue (blastema). In the following days, a large part of the blastema undergoes a transitional chondrogenesis while the rest of blastema cells are respecified to restore the original tissues including bone, muscle, pigment and connective tissue. Cell identity and selected cell marker analyses reveal that these blastemal cells possess a complex property of neural crest cell and muscle progenitor. Our observations indicate that epithelial- mesenchymal interaction and local microenvironmental cues induce transdifferentiation and dedifferentiation of pre-blastemal cells, and subsequent redifferentiation. Combing our time course-based whole transcriptome profiling, we have identified the signaling induction in relation to tissue memory of blastemal cells in the lower jaw regeneration process.

Key words: zebrafish, jaw, regeneration, blastema, cellular memory

Insights into Nuclear Reprogramming via Heterokaryon RNA Sequencing.

J. Brady[1], M. Li[1], R. Tran-Bussat[1], H. Jiang[1], W. Wong[1], H. Blau[1]; [1]Stanford University, Stanford, CA

Induced pluripotent stem cells (iPS) can be produced from virtually any somatic cell by the overexpression of a few transcription factors, a process termed “nuclear reprogramming”. At present, the molecular mechanisms underlying reprogramming are not well understood, in large part due to an inability to analyze early stages of reprogramming at the molecular level in iPS.
We hypothesized that there are as yet unidentified molecular regulators critical to the early onset of reprogramming. To identify key regulators of reprogramming we developed a synchronous, high efficiency, rapid reprogramming approach consisting of heterokaryons (interspecies multinucleate fused cells) in which activation of human pluripotency genes occurs rapidly (24hrs) and efficiently (70% of single heterokaryons), enabling early mechanistic studies.
We conducted a transcriptome-wide investigation of heterokaryon reprogramming using high throughput RNA sequencing. Heterokaryons were isolated over a three day time-course and subject to RNA sequencing to characterize the early gene expression dynamics of the mouse and human transcriptome during the early stages of nuclear reprogramming. Our results show significant changes in transcriptional output of both the mouse and human nucleus, including the induction of key human pluripotency genes and chromatin remodelers. Our results also validate using heterokaryon RNA sequencing as a discovery tool via the identification of previously published molecules known to have a role in reprogramming towards pluripotency. In conclusion, the speed and efficiency of reprogramming in the heterokaryon system provides a means to identify critical transcription factors and epigenetic regulators via RNAseq, providing temporal information and transcriptional insights into mechanisms of reprogramming and cell fate.

153

Hippo/YAP signaling in somatic stem cells.

F. Camargo[1]; [1]Deparment of Stem Cell and Regenerative Biology, Children's Hosp Boston/Harvard Univ, Boston, MA

During development and regeneration, proliferation of tissue-specific stem cells is tightly controlled and monitored to produce organs of a predetermined size. The molecular determinants of this process remain poorly understood. We are particularly interested in studying the function of the emerging highly-conserved Hippo/YAP signaling cascade, and its effects on tissue size, homeostasis and cancer. Our previous studies have demonstrated that Hippo signaling can be a very potent regulator of organ size in mice and have also provided a conceptual link between organ size regulation and stem cell activity through Hippo signals. Our work is now aimed at fully dissecting the components and the role of this cascade in somatic stem cells utilizing a variety of genetic, biochemical, and high throughput technologies. Work describing the function of the pathway in the epithelial stem cell compartments will be discussed. Insight into these processes will shed light on fundamental aspects of tissue regeneration and facilitate the development of therapeutic approaches based on cellular transplantation

Mitosis Futures: the past is prologue.

J. McIntosh[1]; [1]MCDB, Univ Colorado, Boulder, CO

The mechanisms by which spindles organize and segregate chromosomes have fascinated and frustrated many generations of cell biologists. Since the discovery of spindle microtubules, progress has been comparatively rapid, and our understanding of spindle mechanism has grown with increasing speed as the techniques of modern cell and molecular biology have been brought to bear on the problem. The discovery of spindle motor enzymes has motivated a wide range of studies on the ways these nanomachines might contribute to chromosome organization and segregation over distances as big as half a cell diameter. Modern methods for imaging, both by fluorescence microscopy of live cells and by electron microscopy of cryo-immobilized samples, have revealed the movements of spindle microtubules that underlie chromosome motion itself. Analogous methods have, however, shown that chromosome-to-pole motion in yeast cells does not require pole-directed motors enzymes, suggesting that tubulin depolymerization too can contribute to mitotic chromosome motility. To make things even more interesting, some motor enzymes can regulate tubulin dynamics, so an understanding of chromosome segregation will certainly require the evaluation of multiple contributing factors. Genetics will help, but many spindle components can be mutated without blocking mitosis, so alternative modes of experimentation are likely to be valuable. Some recent work has used the strategy of assembling isolated spindle proteins into extra-cellular devices that can duplicate aspects of spindle function under well-controlled conditions. This talk will review some recent history of mitosis research and examine current work in that context, looking forward to where the field may go in the near future.

156

Molecular motors: Where do we go from here?

J. Spudich[1]; [1]Department of Biochemistry, Stanford Univ, Stanford, CA

A mere forty years ago it was unclear what motor molecules exist in cells that could be responsible for the variety of non-muscle cell movements, including the "saltatory cytoplasmic particle movements" apparent by light microscopy. One wondered whether such cells might have a myosin-like molecule, well known to investigators of muscle. Now we know there are more than a hundred different molecular motors in eukarotic cells that drive a wealth of cell biological processes and help organize the cell’s dynamic city plan. Furthermore, *in vitro* motility assays, taken to the single molecule level using techniques of physics, have allowed detailed characterization of how these motors transduce the chemical energy of ATP hydrolysis into mechanical movement. Still, there is much to do for the eager student interested in molecular motor research.

DNA secondary structures and epigenetic determinants of cancer genome evolution.

S. De[1], F. Michor[1]; [1]Dept of Biostatistics and Computational Biology, Dana-Farber Cancer Inst, Boston, MA

An unstable genome is a hallmark of many cancers. It is unclear, however, whether some mutagenic features driving somatic alterations in cancer are encoded in the genome sequence and whether they can operate in a tissue-specific manner. We performed a genome-wide analysis of 663,446 DNA breakpoints associated with somatic copy-number alterations (SCNAs) from 2,792 cancer samples classified into 26 cancer types. Many SCNA breakpoints are spatially clustered in cancer genomes. We observed a significant enrichment for G-quadruplex sequences (G4s) in the vicinity of SCNA breakpoints and established that SCNAs show a strand bias consistent with G4-mediated structural alterations. Notably, abnormal hypomethylation near G4s-rich regions is a common signature for many SCNA breakpoint hotspots. We propose a mechanistic hypothesis that abnormal hypomethylation in genomic regions enriched for G4s acts as a mutagenic factor driving tissue-specific mutational landscapes in cancer.

158

The transcription factor ZNF217 is an oncogene that promotes an increase in progenitor cells, increases metastasis, and acts via the AKT pathway.

L. E. Littlepage[1,2], H. Kouros-Mehr[3], A. S. Adler[4], J. Chou[1,2], G. Huang[2], C. C. Collins[5,6], H. Y. Chang[4], J. W. Gray[2,7], Z. Werb[1,2]; [1]Anatomy, University of California, San Francisco, San Francisco, CA, [2]Helen Diller Family Comprehensive Cancer Center, University of California, San Francisco, San Francisco, CA, [3]University of California, San Francisco, San Francisco, CA. [4]Howard Hughes Medical Institute and Program in Epithelial Biology, Stanford University School of Medicine, Stanford, CA, [5]Helen Diller Family Comprehensive Cancer Center, University of California, San Francisco, Vancouver, BC, Canada, [6]The Prostate Centre, Vancouver General Hospital, Vancouver, BC, Canada, [7]Department of Biomedical Engineering, Oregon Health & Science University, Portland, OR

Amplification of 20q13 occurs in many cancers including 20-30% of primary human breast cancers and correlates with poor breast cancer prognosis. The transcription factor ZNF217 is a candidate oncogene within this region. In patient cohorts we found that patients expressing high ZNF217 in breast tumors had reduced survival and increased chemoresistance. To study the consequences of Znf217 overexpression we generated a transgenic mouse model with inducible Znf217 expression. Znf217 overexpression in the mammary epithelium induced premalignant and invasive lesions. In addition, Znf217 overexpression in a mouse breast cancer model generated primary tumors with increased numbers of progenitor cells that expressed markers of both the luminal and myoepithelial cells. In addition, Znf217 overexpression promoted increased motility in mouse mammary epithelial cell (MEC) lines and metastasis in vivo.

To identify an inhibitor of ZNF217 function we correlated the IC50s for drugs from the Developmental Therapeutics database with ZNF217 expression levels in NCI60 tumor cell lines and identified the AKT inhibitor triciribine. Treatment of our mouse mammary tumor models with triciribine decreased the Znf217-induced tumor burden, inhibited AKT and MAPK activation in

the tumors and inhibited progenitor cell self-renewal by mammosphere assays. ZNF217 overexpression in MECs made them resistant to the chemotherapy doxorubicin, while treatment with triciribine generated synthetic lethality with doxorubicin. Taken together, we find that ZNF217 overexpression induces multiple phenotypes required for tumor progression including increased progenitor cell phenotype, increased motility and increased resistance to cytotoxic drugs, indicating that it is an oncogene and potential drug target.

Tumor Suppressor Gene p16/INK4A Dependent Regulation of Cell Cycle Exit in a Spontaneous Canine Model of Breast Cancer.

P. Agarwal[1], P. DeInnocentes[1], M. Sandey[2], R. C. Bird[1]; [1]Dept Pathobiology, Auburn University, Auburn, Auburn, AL, [2]Scott-Ritchey Research Center, Auburn University, Auburn, AL

p16/INK4A is an important tumor suppressor gene which arrests cell cycle in early G1 phase inhibiting binding of CDK4/6 with cyclin D1 leaving the Rb tumor suppressor protein unphosphorylated and E2F bound and inactive. We have previously shown that p16 is frequently mutated in canine mammary cancer comparable to human breast cancer. Because p16 expression persists following cell cycle exit, we hypothesize that p16 has a role in exit from cell cycle that becomes defective in cancer cells and that p16 has alternate binding partners other than CDK4/CDK6 in quiescent or differentiated cells. Well characterized p16-defective canine mammary cancer cell lines (CMT28, CMT27, and CMT12), normal canine fibroblasts (NCF), and p16-transfected CMT cell clones (CMT27A, CMT27H, CMT28A, and CMT28F) exhibiting a rescued phenotype, have been used to investigate expression of p16 after serum starvation into quiescence followed by re-feeding to induce cell cycle re-entry. CMT cells lack p16 expression either at mRNA or protein expression levels, while p27, CDK4, CDK6, cyclin D1, and Rb, appear to be expressed at normal levels. We have successfully demonstrated cell cycle arrest and synchronous cell cycle re-entry in parental CMT12, CMT28 and NCF cells as well as p16 transfected CMT27A, CMT27H, CMT28A, and CMT28F cells and confirmed this by 3H-thymidine incorporation and flow cytometric analysis of cell cycle phase distribution. p16 transfected CMT27A and CMT27H exited cell cycle post serum-starvation in contrast to parental CMT27 cells. NCF, CMT27A, and CMT28F cells expressed up-regulated levels of p27 mRNA coincidently with elevated expression of p16 mRNA as cells exited cell cycle and entered quiescence. To find alternating binding partners of p16, co-immunoprecipitation was performed in quiescent CMT27A cells which resulted in unique co-immunoprecipitation of the p53-associated and putative tumor suppressor 14-3-3σ protein only in quiescent CMT27A cells in comparison to exponential cells. Levels of 14-3-3σ mRNA expression also rose along with p16 in quiescent NCF cells. Because quiescence and differentiation are associated with decreased levels of cyclin D1 and/or CDK6 our data demonstrating that p16 is up-regulated during quiescence suggests the presence of alternative binding partners for p16, such as 14-3-3σ, in promoting and maintaining the quiescent and/or differentiated phenotype (funded by NCI/NIH).

160

Mad1 upregulation causes chromosomal instability and resistance to microtubule poisons.

S. D. Ryan[1], E. M. Britigan[1], K. Witte[2], A. Audhya[2], A. Roopra[3], B. A. Weaver[1]; [1]Cell and Regenerative Biology, University of Wisconsin-Madison, WI [2]Biomolecular Chemistry, University of Wisconsin-Madison, WI [3]Neuroscience, University of Wisconsin-Madison, WI

The mitotic checkpoint ensures accurate chromosome segregation during mitosis. Reduced expression of mitotic checkpoint components causes aneuploidy, an abnormal chromosome number, and can promote tumorigenesis. Mice heterozygous for the mitotic checkpoint component Mad1 develop increased levels of spontaneous and carcinogen-induced tumors. However, at the genomic and mRNA level, Mad1 is as likely to be upregulated as downregulated in human cancers. The effects of Mad1 upregulation on mitosis, aneuploidy and transformation are currently unclear. We have found that Mad1 protein is frequently overexpressed in human breast cancers and that upregulation of Mad1 is a marker of poor prognosis. Upregulation of Mad1 causes aneuploidy and promotes transformation. Increased expression of Mad1 weakens mitotic checkpoint signaling and results in mislocalization of the Mad1 binding partner Mad2 from kinetochores, producing a mitotic checkpoint phenotype similar to that caused by reduction of Mad2. Cells overexpressing Mad1 are resistant to microtubule poisons, including those currently used to treat human cancers, and express reduced levels of the p53 tumor suppressor. These results suggest that levels of Mad1 must be tightly regulated to prevent aneuploidy and transformation.

161

Efficient Elimination of Cancer Cells by Deoxyglucose-ABT-263/737 Combination Therapy.

R. Yamaguchi[1], E. Janssen[2], G. Perkins[3], M. Ellisman[3], S. Kitada[4], J. Reed[4]; [1]Kyushu Univ Med Sch, Fukuoka, Japan, [2]Division of Molecular Immunology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, [3]Neuroscience, UCSD, La Jolla, CA, [4]Sanford-Burnham Medical Research Institute, La Jolla, CA

Genotoxin-based chemotherapies are most effective in treating tumors at early stages of development, while recently developed targeted therapies can be very effective on certain types of cancer at later stages. For most of the common cancer types, however, these targeted therapies are not available because potential targets are not even identified in most of cancer types, let alone have targeting drugs in development. Furthermore, the recent data from the Cancer Genome Atlas Project also suggested that targeting and inactivating just one protein would not be enough to kill cells in most cancer types, implying that multiple targeted drugs may be required to kill most cancer cells. Here we described a new therapy that is safe and effective in eliminating many cancer cells, including checkpoint defective, genotoxin-resistant, PTEN-deleted, late stage cancer cells.

The new therapy is based on combining 2-deoxyglucose (2DG), a glycolysis inhibitor, with ABT-263/737 (ABT), molecules targeting the anti-apoptotic Bcl-2 family of proteins. As single agents, ABT-263 and ABT-737 (ABT), molecular antagonists of the Bcl-2 family, bind tightly to Bcl-2, Bcl-xL and Bcl-w, but not to Mcl-1, and induce apoptosis only in limited cell types. The compound 2-deoxyglucose (2DG), in contrast, partially blocks glycolysis, slowing cell growth but rarely causing cell death. Injected into an animal, 2DG accumulates predominantly in tumors but does not harm other tissues. However, when cells that were highly resistant to ABT were pre-treated with 2DG for 3 hours, ABT became a potent inducer of apoptosis, rapidly releasing cytochrome c from the mitochondria and activating caspases at submicromolar concentrations in a Bak/Bax-dependent manner. Bak is normally sequestered in complexes with

Mcl-1 and Bcl-xL. 2DG primes cells by interfering with Bak-Mcl-1 association, making it easier for ABT to dissociate Bak from Bcl-xL, freeing Bak to induce apoptosis. A highly active glucose transporter and Bid, as an agent of the mitochondrial apoptotic signal amplification loop, are necessary for efficient apoptosis induction in this system. This combination treatment of cancer-bearing mice was very effective against tumor xenograft from hormone-independent highly metastasized chemo-resistant human prostate cancer cells, suggesting that the combination treatment may provide a safe and effective alternative to genotoxin-based cancer therapies.

162

Integration of Growth Factor, MAP Kinase, and DNA Damage Signaling Networks in Cancer and Cancer Treatment.

M. B. Yaffe[1], M. J. Lee[1], A. Ye[2], A. Heijink[1], A. Gardino[1], P. Sorger[2], G. MacBeath[2]; [1]Biology and Biological Engineering, MIT, Cambridge, MA, [2]Systems Biology, Harvard University, Cambridge, MA

Protein kinases and phosphoserine/threonine-binding domains such as 14-3-3 proteins, FHA domains, Polo-box domains, and BRCT domains function together within signaling networks to control growth factor responses, cell cycle progression, and the response to DNA damage. How signals from these pathways are integrated and processed to control cell phenotypic responses is unclear. To address this, we have been developing systems biology-based models of DNA damage signaling where kinase activities, protein phosphorylation, and phosphoprotein-binding events for multiple signaling pathways are quantitatively measured at densely sampled points in time, along with cellular responses such as cell cycle arrest, autophagy, and apoptosis. The resulting large dataset of signals and responses are then related to each other mathematically using partial least squares regression, principal components analysis, and time-interval stepwise regression. We have used this approach to examine the response of breast cancer and osteosarcoma cells to DNA damaging chemotherapy and gamma radiation in the presence or absence of small molecule inhibitors of growth factor signaling pathways. The resulting models, built from thousands of signaling measurements and hundreds of cellular response assays, reveals surprisingly paradoxical context-dependent roles for several well-established protein kinase signaling pathways in controlling cell cycle arrest, apoptosis and senescence after DNA damage. Furthermore, the analysis has identified novel therapeutic approaches that can therapeutically re-wire signaling pathways within tumor cells to dramatically improve tumor cell killing by conventional clinical agents.

163

Transcriptional control of mRNA export and low expressing genes: New clues from single molecules.

A. Senecal[1], F. Mueller[1,2], E. Bazyuk[3], V. Ruda[1], S. Causse[1], O. Collin[1], E. Bertrand[3], C. Zimmer[2], X. Darzacq[1]; [1]Functional Genomics, IBENS, Paris, France; [1]Functional Imaging of Transcription, Ecole Normale Supérieure CNRS IBENS, Paris, France, [2]Institut Pasteur, Groupe Imagerie et Modélisation, CNRS, URA 2582, Paris, France, [3]Institut de Génétique Moléculaire de Montpellier, UMR 5535 CNRS, Université Montpellier I and II, Montpellier, France

Some of the most important genes controlling key processes in cellular regulation are expressed in low amounts virtually undetectable; yet their function is absolutely necessary for normal cell function. Here we report new methods to study gene expression at the single molecule level devoted to quantify mRNAs expressed in populations at levels far below one molecule per cell. We will also show how these approaches bring new clues on the link in between Transcription and mRNA physiology.
We found that different promoter architectures enabling equal loading and initiation rates of polymerases on a gene yielded notably different elongation rates. Moreover, we found that properly spliced mRNAs transcribed from a same gene under different activating conditions can have drastically different fates, one being exported and translated while the other is retained in the nucleus where it accumulates in nuclear SC35 domains (speckles).

164

Characterization of the Enlargement of Speckles of SF2/ASF due to Loss of Function of Smu1 in the Mammalian Temperature-Sensitive Mutant.

K. Sugaya[1], Y. Ishihara[1], K. Sugaya[1]; [1]National Institute of Radiological Sciences, Chiba, Japan

A temperature-sensitive (ts) CHO-K1 mutant cell line, tsTM18, exhibits chromosomal instability with decreased DNA synthesis at the nonpermissive temperature, 39°C. An amino acid substitution in Smu1 underlying the ts phenotypes of tsTM18 cells was identified previously. We also found a ts defect in splicing of the *unc52/perlecan* gene. In the present study, we have generated cell lines expressing Smu1 tagged with green fluorescent protein (GFP) to study the dynamics of Smu1 in living cells. The hybrids complement deficiencies in tsTM18 cells and allow them to grow normally at 39°C. GFP-tagged Smu1 is found in speckles in many discrete nucleoplasmic sites, and most of these also contained SF2/ASF. SF2/ASF is a member of the serine/arginine (SR)-rich splicing group of factors that are necessary for spliceosome assembly and can influence alternative splicing. SF2/ASF is also involved in the integrity of genome maintenance. In tsTM18 cells cultured at 39°C, the Smu1 ts defect appears to alter SF2/ASF localization, suggesting a physiological association of Smu1 with SF2/ASF. The significant decrease of Smu1 may lead the enlargement of speckles of SF2/ASF. These data show the importance of Smu1 as a regulator of splicing and genome maintenance.

165

β-actin mRNA compartmentalization by ZBP1 controls focal adhesion stability and directed cell motility.

Z. B. Katz[1], A. L. Wells[1], B. Wu[1], H. Y. Park[1], S. M. Shenoy[1], R. H. Singer[1]; [1]Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Localization of β-actin mRNA is facilitated by the zipcode binding protein, ZBP1. Binding to the cognate zipcode within the 3'UTR of β-actin mRNA enables ZBP1 to asymmetrically distribute mRNA and control translation of its target, a process known to be necessary for directed cell motility. This study utilized a ZBP1 KO fibroblast cell line to compare β-actin mRNA dynamics to wild-type cells. TIRF microscopy and mRNA particle tracking in live cells enabled us to discover a specific compartment near focal adhesions where β-actin mRNA dwells for periods greater than one minute. In ZBP1 KO fibroblasts, the probability of tracking β-actin mRNA within the adhesion environment is significantly reduced. Consequently, adhesion lifetimes are reduced in ZBP1 KO cells. This supports the hypothesis that ZBP1 facilitates mRNA localization to strengthen focal adhesions and therefore direct cell migration. To test directly whether mRNA localization to adhesions can alter adhesion dynamics and cell motility we utilized a novel mRNA tethering technique. We tethered β-actin mRNA to focal adhesion complexes through MS2 stem loops in the 3'UTR of β-actin mRNA and the MS2 coat protein fused to vinculin. This produced a significant increase in adhesion lifetime and adhesion size in cells expressing MS2-β-actin mRNA. Additionally, cell velocity was significantly reduced in cells with tethered β-actin mRNA. These experimental results lead us to conclude that β-actin mRNA compartmentalization to adhesions, mediated by ZBP1, strengthen adhesions and therefore produce an asymmetric force distribution within the cell to control its directionality.

Test driving the 60S subunit during ribosome biogenesis.

C. Bussiere[1], Y. Hashem[2], S. Arora[1], J. Frank[2,3], A. W. Johnson[1]; [1]Molecular Genetics and Microbiology, UT Austin, Austin, TX, [2]Department of Biochemistry and Molecular Biophysics, Columbia University, New York, NY, [3]Howard Hughes Medical Institute

In eukaryotic cells, ribosomes are largely preassembled in the nucleus. When the large (60S) ribosomal subunit enters the cytoplasm, it is functionally inactive and requires the release of export and assembly factors and the addition of ribosomal proteins to generate functionally active subunits. We recently delineated the order of these maturation events and found that assembly of the ribosome stalk was a prerequisite for the release of the subunit anti-association factor Tif6 followed by release of the nuclear export adapter Nmd3. Because we had previously found that the ribosomal protein Rpl10 was required for the release of Nmd3, we asked if Rpl10 was also required for the release of Tif6. Rpl10 is located in a cleft between the central protuberance and the GTPase stalk and contains an internal loop that embraces the P-site tRNA. Deletion of the P-site loop of Rpl10 trapped Tif6 in the cytoplasm, indicating a novel role for Rpl10 in release of Tif6, prior to its role in Nmd3 release. Mutagenesis of the P-site loop yielded mutants that specifically affect 60S biogenesis. The release of Tif6 is known to require the GTPase Efl1, a paralog of the translation translocation factor eEF2. Surprisingly, these rpl10 mutants could be suppressed by a mutant allele of Tif6 that has weakened affinity for the ribosome and can bypass the need for Efl1. Because Efl1 is normally required for the release of Tif6, this result implicates Efl1 in signaling between Rpl10 and Tif6. Indeed, we identified mutations in Efl1 that bypass P-site loop mutations in Rpl10. Based on the crystal structure for eEF2, the suppressing mutations in Efl1 map to domain interfaces of eEF2 that are important for the conformational changes in eEF2 that drive translocation. Molecular dynamics simulations of

these mutants show that one cluster of suppressing mutations disrupt the hydrophobic core of a critical subunit interface, suggesting that they facilitate a conformational change in ribosome biogenesis that mimics the changes eEF2 undergoes during translocation. These results suggest that during maturation, the 60S subunit undergoes a "test drive" that assesses the correct assembly and ability of the subunit to support the conformational dynamics required during translation. We suggest that this assessment of 60S assembly by Efl1 is multi-faceted, monitoring assembly of the stalk, correct folding of the sarcin-ricin loop and the correct assembly of the P-site of the ribosome. We propose that interrogation of the P-site of the ribosome represents a quasi-functional quality control check of the large subunit, prior to its first round of *bona fide* translation.

167

The human enhancer of mRNA decapping, Hedls, regulates the decapping enzyme, Dcp2, protein levels and activity.

S. Erickson[1], E. Corpuz[1], C. Fillman[2], J. Maloy[1], J. Lykke-Andersen[1]; [1]UCSD, La Jolla, CA, [2]University of Colorado at Boulder, Boulder, CO

mRNA decay is a key step in the regulation of gene expression. A critical step in several mRNA decay pathways is decapping. A major decapping complex consists of the decapping enzyme Dcp2 as well as several decapping enhancers. An outstanding question is what role does each of these enhancers play in regulating the activity of Dcp2. We have identified a role for the metazoan specific decapping enhancer Hedls (also called Ge-1/Edc4) in the regulation of Dcp2 protein stability and activity. We observed that knockdown of Hedls results in the accumulation of deadenylated mRNA using a beta globin reporter containing the AU-rich element from the 3'UTR of granulocyte-macrophage colony-stimulating factor mRNA. This suggests that Hedls is required for the efficient 5'-3' decay of the message following deadenylation. We also observed that endogenous Dcp2 levels were reduced dramatically upon Hedls depletion. In addition exogenously expressed Dcp2 protein is highly unstable but can be stabilized by Hedls co-expression or by deletion of or five point mutations within the C-terminal Hedls interaction domain of Dcp2. Thus Hedls promotes Dcp2 activity at least in part by interacting with and preventing the activity of a C-terminal Dcp2 instability domain. These results provide novel insights into the regulation of mRNA decay mediated by the Dcp2 decapping complex.

The Chp1-Tas3 core is a multifunctional platform critical for gene silencing by RITS.

T. Schalch[1], G. Job[2], S. Shanker[2], J. Partridge[2], L. Joshua-Tor[3]; [1]Keck Structural Biology Laboratory, Cold Spring Harbor Laboratory, Cold Spring Harbor, NY, [2]Department of Biochemistry, St Jude Children's Research Hospital, Memphis, TN, [3]W.M. Keck Structural Biology Laboratory, Cold Spring Harbor Lab/HHMI, Cold Spring, NY

In the fission yeast *S. pombe*, the RNAi machinery regulates heterochromatin in coordination with chromatin regulators. The RNA-induced Initiation of Transcriptional gene Silencing (RITS) complex is at the center of this process, integrating the two pathways and directing heterochromatin formation and maintenance. Within the RITS complex the GW protein Tas3 links the large chromodomain protein Chp1 to the RNAi effector protein Ago1. Current evidence suggests that small RNAs loaded into Ago1 act cooperatively with the high affinity for histone H3K9 methyl marks of Chp1's chromodomain to target the RITS complex to specific genomic regions where recruitment of the histone methyltransferase Clr4 and the RNA dependent RNA polymerase Rdp1 result in a self enforcing process of heterochromatin formation and gene silencing.

We have solved the crystal structure of the complex between Chp1 and Tas3, forming the core of the RITS complex. The structure reveals a very intimate and unusual interaction between the two proteins with the Tas3 N-terminal fragment being engulfed by two domains of Chp1. We furthermore identified a third domain in Chp1 that shares strong similarity with PIN domains of proteins involved in RNA decay and telomere silencing. Deletion of the Chp1 PIN domain in *S. pombe* compromises specifically the silencing of subtelomeric transcripts, thereby revealing that Chp1 and Tas3 provide a heterochromatin bound platform with roles that extend beyond recruitment of Ago1.

Minisymposium 27: Cell Cycle Dynamics and Checkpoints

169

A forward genetic screen for cell cycle control genes in the plant kingdom.

F. R. Cross[1], F. Tulin[1]; [1]Laboratory of Cell Cycle Genetics, Rockefeller Univ, New York, NY

Current evolutionary analysis, predominantly based on molecular systematics, indicates that fungi and animals diverged more recently from each other than from all other eukaryotic branches, including plants. This has the implication that intense research over the past decades into cell cycle control in fungi and animals may mistake fungal/animal (‘opisthokont’) control principles for features of a ‘universal’ eukaryotic cell cycle control system. A forward, unbiased exploration of cell cycle control in other branches of the eukaryotic family is necessary both for direct understanding of cell cycle control in that branch, and for allowing the possibility of deducing truly universal features of eukaryotic cell cycle control. For these reasons, and because of the fundamental importance of plants for life on earth, we have initiated a forward genetic screen for cell cycle control genes in the green alga Chlamydomonas reinhardtii, a member of the plant kingdom (Viridiplantae). Our approach integrates classical genetic methodologies with resequencing of mutant genomes, with the aim of obtaining both a comprehensive ‘parts list’ and initial functional understanding of cell cycle control in Viridiplantae.

170

Entry into mitosis is linked to membrane growth in budding yeast.

S. Anastasia[1], D. Nguyen[1], M. Meloy[1], D. Kellogg[1]; [1]Molecular, Cell and Developmental Biology, Univ. of California, Santa Cruz, Santa Cruz, CA

Addition of new membrane to the cell surface by vesicle transport is a key mechanism of cell growth. Here, we report that blocking transport of vesicles to the site of cell growth causes a checkpoint arrest before entry into mitosis in budding yeast. The arrest is enforced via coordinated control of the budding yeast homologs of Wee1 and Cdc25. We discovered a signaling pathway that acts upstream of Wee1 and Cdc25 to relay signals regarding the status of vesicle transport. Signaling via this pathway is dependent upon vesicle transport and appears to be proportional to membrane growth. We hypothesize that transport of vesicles to the site of cell growth generates a signal that is proportional to membrane growth, and that the strength of the signal is read by downstream components to determine when sufficient growth has occurred to allow entry into mitosis. Thus, growth-dependent signaling could represent a new mechanism by which growth is integrated with cell cycle progression. In addition, a growth-dependent signaling model for mitotic checkpoint function could reconcile different views of the checkpoint as functioning to control cell size or morphogenesis.

171

A quantitative approach to exploring spindle assembly checkpoint signaling.

S. Hauf[1], S. Heinrich[1], E-M. Geissen[2], J. Kamenz[1], S. Trautmann[4], N. Hustedt[1], M. Knop[3], N. Radde[2]; [1]Friedrich Miescher Laboratory, Max Planck Society, Tuebingen, Germany, [2]IST, University of Stuttgart, Germany, [3]EMBL Heidelberg, Germany

The spindle assembly checkpoint (SAC) is a crucial surveillance mechanism within the eukaryotic cell cycle that ensures proper chromosome segregation. Despite a wealth of cell biological and biochemical data about the SAC, its complex in vivo dynamics are still only fragmentarily understood. To obtain insight into this intricate signaling mechanism, we have combined mathematical modeling with quantitative experiments in fission yeast. As an accurate foundation for our mathematical models, we have quantified the abundance of SAC proteins in vivo in single cells. Furthermore, we have modulated the protein abundance of single SAC proteins in steps between 0 and about 200 % of the endogenous level. This enabled us to determine the range of SAC protein abundance that allows checkpoint activity, and enabled us to test models for the signaling mechanism. We find that the range of expression that allows SAC activity varies greatly between different SAC proteins. Interestingly, subtle reduction of some SAC proteins leads to a bimodal distribution of the SAC response. This implies the presence of an ultrasensitive step in the signaling mechanism, which could explain how the SAC can robustly respond to even a single misattached chromosome.

172

A novel cyclin dependent kinase couples cell size to cell division.

Y. Li[1], B. Olson[1], J. G. Umen[2]; [1]Plant Biology Laboratory, The Salk Institute, La Jolla, CA, [2]Donald Danforth Plant Science Center, St. Louis, MO

Cell size is coupled to the cell division cycle in diverse eukaryotes, but size checkpoint control is relatively unexplored. The unicellular green alga *Chlamydomonas reinhardtii* divides by multiple fission where mother cells undergo repeated rounds of S and M phase in rapid succession. A sizer mechanism couples mother cell size to division number such that larger mother cells undergo more S/M cycles than smaller mother cells, thus ensuring a uniform daughter size distribution. We identified a sizer protein, CDKG1, that is a D cyclin dependent kinase which phosphorylates the retinoblastoma-related protein MAT3 as its key substrate. Loss of CDKG1 causes inadequate division and results in large daughters, while misexpression of CDKG1 causes supernumary divisions and results in small daughters. CDKG1 is nuclear-localized and is produced in mother cells just prior to division. It is then diluted during successive rounds of S/M and eliminated upon reentry into G0 or G1 phase. The concentration of CDKG1 in pre-mitotic cells is set by mother cell size, and provides a link between cell size and the extent of cell division. Cell-size-dependent accumulation of rate-limiting cell cycle regulators such as CDKG1 is a potentially general mechanism for size control.

173

Mps1/Mph1 kinase recruits SAC components to kinetohores through phosphorylation of KNL1/Spc7.

Y. Yamagishi[1], Y. Watanabe[1]; [1]Institute of Molecular and Cellular Biosciences, University of Tokyo, Tokyo, Japan

The spindle assembly checkpoint (SAC) delays anaphase onset in the presence of unattached kinetochores. Bub1 is a well conserved SAC protein and temporarily recruited to kinetochores in mitosis. In addition to SAC function, kinetochore associated Bub1 has a role in proper chromosome segregation in part through recruiting shugoshin proteins to centromeres.The

kinetochore localization of Bub1 requires its binding partner Bub3 as well as another SAC protein kinase Mps1/Mph1. But how Mps1/Mph1 regulates the kinetohore localization of Bub1 is unknown. Here, we show that Mph1 promotes the interaction of the Bub1-Bub3 complex with the kinetochore protein KNL1/Spc7 through phosphorylation of Spc7 in fission yeast. Mph1 phosphorylates Spc7 at multiple sites containing conserved MELT repeats in vitro. In cells expressing the non-phosphorylatable spc7-12A mutant, the kinetochore localization of Bub1 and Bub3 are abolished, resulting in impaired chromosome segregation and SAC. Moreover, artificial targeting of Mph1 to kinetochores or expression of the phospho-mimetic mutant spc7-12E causes ectopic localization of Bub1 and Bub3 at kinetohores in interphase. Our results suggest that Spc7 is a hitherto unknown critical target of Mph1 in both chromosome segregation and SAC.

174

Regulation of mitosis in Giardia, a divergent eukaryote, is independent of the Anaphase-Promoting Complex or Ubiquitination.

S. Gourguechon[1], W. Cande[1]; [1]Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Giardia intestinalis, a human parasite responsible for diarrheal disease, is a member of the Diplomonads, potentially one of the most highly divergent lineages in the eukaryotic kingdom. We investigated the role of *Giardia* cell cycle proteins including cyclin B, aurora kinase and polo-like kinase to determine whether their regulation differs from those in other eukaryotes. In every eukaryote studied to date, cyclin B is targeted by the Anaphase Promoting Complex (APC) for proteasome-mediated degradation prior to the onset of anaphase by ubiquitin conjugation. There are no APC subunits in *Giardia*, and the *Gardia* cyclin B (*Gi* cyclin B) lacks the conserved sequences required for recognition by the APC in other eukaryotes. Overexpression of *Gi* cyclin B in fission yeast leads to mitotic arrest, a phenotype similar to that observed when N-terminal mutants of yeast mitotic cyclins are expressed. This phenotype can be suppressed by fusing the yeast degradation sequence to *Gi* cyclin B. One of the endogenous gene copies of cyclin B in *Giardia* was tagged with a 3HA epitope and experiments using morpholino-mediated gene knockdown show that *Gi* cyclin B is essential for mitotic entry in *Giardia*. Using immunofluorescence and quantification assays we showed that cyclin B is degraded before the cells return to G1. Both *in vivo* experiments using proteasomal inhibitors and *in vitro* ubiquitination experiments using recombinant ubiquitin show that, though *Giardia* ubiquitin can be effectively conjugated to substrates, *Gi* cyclin B and other APC substrates such as aurora kinase and polo-like kinase are not ubiquitinated. In addition cells treated with proteasomal inhibitors do not arrest in the cell cycle. This is the first example of a mitosis that is not regulated by the APC, or ubiquinitination by an E3 ligase and it may reflect an evolutionary ancient form of cell cycle regulation. To further improve our understanding of cell cycle regulation in *Giardia* we have isolated by affinity purification proteins interacting with aurora and polo-like kinase from *Giardia*. Work is in progress to identify these proteins and their contribution to cell cycle regulation.

The Chlamydial Toxin CPAF Promotes Early Exit from Mitosis in Infected Cells.

H. Brown[1], A. Knowlton[1], S. Grieshaber[1]; [1]Oral Biology, University of Florida, Gainesville, FL

Chlamydia trachomatis has been epidemiologically linked to cervical cancer in patients with a prior human papilomavirus (HPV) infection. *Chlamydia* causes multinucleation of the host cell, a potential pathway for chromosomal instability. Two mechanisms that are known to initiate multinucleation are cell fusion and cytokinesis failure. Our studies ruled out cell fusion and demonstrated that multinucleation is caused by cytokinesis failure. From this data, we aimed to determine the mechanism of cytokinesis failure due to *Chlamydia* infection. We have previously reported that chlamydial infection of the host cell overrides the Spindle Assembly Checkpoint (SAC) causing mitosis to be shortened. Our findings demonstrate that the Chlamydial Protease-like Activity Factor (CPAF) functionally inactivates cyclin B1 and cyclin dependent kinase 1 (Cdk1) through cleavage, effectively bypassing the SAC. This checkpoint is necessary for an organized cell division. In this study we demonstrate that premature entry into anaphase causes a increased rate of DNA tangles that results in cytokinesis failure of chlamydial infected cells.

176

Brush border microvilli-derived vesicles detoxify bacterial products and regulate epithelial-microbial interactions.

D. Shifrin[1], R. McConnell[2], R. Nambiar[1], J. Higginbotham[3], R. Coffey[3], M. Tyska[1]; [1]Department of Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN, [2]Department of Biology, Massachusetts Institute of Technology, Cambridge, MA, [3]Department of Medicine, Vanderbilt University Medical Center, Nashville, TN

The continuous monolayer of intestinal epithelial cells (IECs) that lines the gut lumen functions as the site of nutrient absorption and as a physical barrier that prevents the translocation of microbes and associated toxic compounds into the peripheral vasculature. IECs also express host defense proteins such as intestinal alkaline phosphatase (IAP), which detoxify bacterial products and prevent intestinal inflammation. Our laboratory recently showed that IAP is enriched on vesicles that are released from the tips of IEC microvilli and accumulate in the intestinal lumen (McConnell et al, 2007; McConnell et al, 2009). Here, we show that these native ‘lumenal vesicles’ (LVs): (i) contain catalytically active IAP that can dephosphorylate lipopolysaccharide (LPS), (ii) cluster on the surface of native lumenal bacteria, (iii) prevent the adherence of enteropathogenic E. coli (EPEC) to epithelial monolayers, and (iv) limit bacterial growth. We also find that IECs upregulate LV production in response to EPEC and defects in LV production are associated with significant changes in the intestinal microbiota. Together these results suggest that microvillar vesicle shedding represents a novel mechanism for distributing host defense machinery into the intestinal lumen, and that microvillus-derived LVs modulate epithelial-microbial interactions and exert a direct effect on the lumenal microbiome.

177

Mitochondrial dynamics in *Listeria monocytogenes* infection.

F. Stavru[1], F. Bouillaud[2], A. Sartori[3], D. Ricquier[2], P. Cossart[4]; [1]Bacteria Cell Interactions, Institut Pasteur, Paris, France, [2]Mitochondria, bioenergetic, metabolism and signaling, Institut Cochin, Paris, France, [3]PFMU - Imagopole, Institut Pasteur, Paris, France, [4]Bacteria Cell Interactions, Institut Pasteur, Paris, France

Mitochondria are dynamic organelles central to energy production and several other cellular processes, such as calcium buffering and apoptosis. As such, they are targeted by pathogens to subvert cellular function. We studied the effects of infection by the intracellular pathogen *Listeria monocytogenes* on mitochondrial dynamics and function and could recently show that it profoundly alters mitochondrial dynamics, causing transient fragmentation of the mitochondrial network. Such mitochondrial fragmentation occurs early during infection, is specific to pathogenic *L. monocytogenes*, and is not observed upon infection with several other intracellular pathogens. The relevance of mitochondrial dynamics for *L. monocytogenes* infection is highlighted by the finding that siRNA-mediated inhibition of mitochondrial fusion or fission alters infection efficiency. We identified the secreted pore-forming toxin listeriolysin O as the main bacterial factor responsible for disruption of the mitochondrial network and for mitochondrial function modulation. Our work suggests that transient disruption of mitochondrial dynamics and function represents a novel strategy used by pathogenic bacteria to interfere with cellular physiology at the onset of infection, which opens new avenues to study mitochondrial dynamics and function.

178

Dynamics of ESCRT protein recruitment during retroviral assembly.

N. Jouvenet[1], P. Bieniasz[1,2], S. M. Simon[3]; [1]Aaron Diamond Aids Research, New York, NY, [2]Lab of Retrovirology, Rockefeller University, New York, NY, [3]Rockefeller University, New York, NY

The assembly of retroviruses is the dependent upon the interaction of various components encoded both by the virus and the host cell. The separation of retroviral particles from host membranes is promoted by the cellular ESCRT (Endosomal Sorting Complex Required for Transport) complexes and associated proteins. The ESCRT complexes and associated proteins mediate other membrane scission reactions, such as multi-vesicular body formation and the terminal stages of cytokinesis. These proteins are believed to be sequentially recruited to the site of membrane scission, and then complexes are disassembled by the ATPase Vps4A. However these events have never been observed in living cells and their dynamics are unknown. Characterizing the relative time course of these molecules is complicated in cells where each virion is in a different state of assembly. To characterize the dynamics of these molecules, we studied the assembly of individual virions. By quantifying the recruitment of several ESCRT and associated proteins during the assembly of two retroviruses, EIAV and HIV-1, we show that Alix progressively accumulated at viral assembly sites, coincident with the accumulation of the major viral structural protein, Gag, and was not recycled after assembly. In contrast, ESCRT-III and Vps4A were only transiently recruited when the accumulation of Gag was complete. These data suggest that the rapid and transient recruitment of proteins that act late in the ESCRT pathway and carry out membrane fission is triggered by prior and progressive accumulation of proteins that bridge viral proteins and the late-acting ESCRT proteins.

179

Salmonella enterica and epithelial cells: life in a vacuole or the cytosol?

L. Knodler[1], O. Steele-Mortimer[1]; [1]Laboratory of Intracellular Parasites, Rocky Mountain Laboratories, NIH/NIAID, Hamilton, MT

Salmonella enterica is an intracellular bacterial pathogen that resides and proliferates within a membrane-bound vacuole in phagocytic and non-phagocytic cells of its mammalian hosts. Although essential to disease, how Salmonella escapes from its intracellular niche and spreads to secondary cells within the same host, or to a new host, is not known. We recently described that a subpopulation of Salmonella are released from the Salmonella-containing vacuole and hyper-replicate in the cytosol of epithelial cells. These bacteria are transcriptionally distinct from intravacuolar Salmonella. They are induced for the invasion-associated type III secretion system and possess flagella; hence, they are primed for invasion. Epithelial cells laden with these cytosolic bacteria undergo inflammatory programmed cell death and are extruded out of the monolayer, releasing invasion-primed and -competent Salmonella into the lumen, allowing for completion of the infectious cycle. To distinguish cytosolic from vacuolar Salmonella, we have developed a drug-based assay that we are using to define bacterial factors that contribute to vacuole lysis and cytosolic replication in epithelial cells.

180

Viral interior design: Rewiring the host to generate organelle platforms for replication.

N-Y. Hsu[1], N. Altan-Bonnet[1]; [1]Department of Biological Sciences, Rutgers Univ, Newark, NJ

RNA viruses manipulate multiple host components of the secretory pathway to generate organelles that are specialized for replication and are distinct in protein and lipid composition from the host cell. We show that specific picornaviral proteins promote recruitment of host phosphatidylinositol-4-kinases to membranes, while suppressing recruitment of host membrane coat proteins. This results in the biogenesis of uncoated membrane platforms that are highly enriched in phosphatidylinositol-4-phosphate (PI4P) lipids and contain a specific subset of host endocytic and secretory proteins. We find that the PI4P-rich lipid microenvironment is essential for viral RNA replication in both picorna- and flavivirus families; and that this unique lipid microenvironment may regulate the recruitment and assembly of viral replication machinery including viral RNA polymerases which we show have a specific novel binding site for PI4P lipids. Our findings reveal how RNA viruses can selectively exploit specific elements of the host to form specialized organelles, and identify host phosphatidylinositol-4-kinases and PI4P lipids as key panviral regulators of viral RNA replication and hence potential targets for the development of novel panviral therapeutics.

Minisymposium 29: Collective Cell Behavior and Morphogenesis in Development

181

Regulation of collective cell movements and morphogenetic diversity *in vivo*.

D. Montell[1], D. Cai[1], L. He[2], X. Wang[1], J. Sawyer[1], W. Yoon[1], A. Cho[1], J-H. Kim[1], J. Jensen[1]; [1]Department of Biological Chemistry, Johns Hopkins School of Medicine, Baltimore, MD, [2]Johns Hopkins School of Medicine, Baltimore, MD

Morphogenetic cell movements are very diverse and many cells travel in groups. We study the similarities and differences between the mechanisms of collective cell migrations and those of

single cells. We would also like to understand how cells self-organize into tissues. We use ovarian development in the fruit fly as our major experimental model. Border cell migration serves as a genetically tractable, in vivo model for collective cell migration. We have identified signals that regulate when, where and which cells migrate and invade. Recent studies suggest that E-cadherin plays diverse and central roles both in organizing the cluster as well as in guidance and movement of the cells, in contrast to the general notion that E-cadherin inhibits cell motility. We have also discovered a novel role for Src in cell motility in vivo. On the other hand, using a photo-activatable form of the small GTPase Rac, we have shown that local activation of Rac in one cell can guide the whole cluster in a new direction. This is very similar to the function of Rac in single cells. In addition to promoting protrusion locally, focal Rac activation inhibits protrusion of other cells in the cluster. We are exploring the mechanism by which activation or inactivation of Rac in one cell affects the behavior of other cells in the cluster. Taken together our results support the hypothesis that morphogenetic diversity arises from combinatorial use of modular mechanical properties including cell-cell and cell-matrix adhesion, myosin-mediated contractility, and Rac-mediated protrusion.

182

Actin turnover balances forces between cells during epithelial invagination.

M. Tworoger[1], A. Martin[1]; [1]Biology, Massachusetts Institute of Technology, Cambridge, MA

Embryonic development requires that coordinated cell shape changes collectively deform tissues to generate organs with diverse forms and functions. Cell shape changes result from forces generated by actin networks that are coupled to adhesive complexes. During Drosophila gastrulation, pulsed contraction of an apical actin and myosin II network coupled to adherens junctions drives apical constriction of mesoderm cells, which is important for epithelial invagination. While the role of actin turnover is well established for individual cell migration, the importance of actin turnover for the coordinated movement of an epithelial sheet is not known. To examine the importance of actin turnover, we titrated the rate of actin polymerization by injecting different concentrations of cytochalasin D, which blocks barbed end growth, and imaged cell and cytoskeletal dynamics in live embryos. We observed a transition from a general disruption of contractility in all cells with high doses of cytochalasin D to a mesoderm specific disruption in cell-cell connections at low doses. At low cytochalasin D neighboring actomyosin networks continually lost and reformed connections, resulting in an unbalanced ‘tug-of-war’ between cells of the mesoderm. A similar phenotype was observed in mutants for the formin, dia, suggesting that formin mediated actin polymerization is required to maintain cell-cell connections. Live imaging of F-actin in wild-type embryos demonstrates that pulsed contractions generate transient holes in the actin meshwork across the apical surface. We propose that rapid actin turnover is required to fill holes generated by network contraction in order to balance forces across adhesive contacts.

183

Angular morphomechanics in the establishment of multicellular architecture.

K. Tanner[1], M. Bissell[1]; [1]Life Sciences, LBNL, Berkeley, CA

We report a novel type of human cell motility in which cells undergo coherent angular motion to assemble into polarized multicellular spherical structures (acini) when placed in a 3D basement membrane surrogate gel. We visualize the complete evolution from the single cell to an acinus. We address a fundamental question: what are the physical laws that govern the geometry of acinar structures? We link the functional relevance of this distinct coherent angular motion (CAMo) to the ability to attain the resultant architecture, and determine the relevance of adhesion and tissue polarity to the outcome. CAMo is conserved from primary human cells to

established breast cell lines where the final realized geometry is spherical. Cancer cells do not display CAMo motility but random motility. Upon 'phenotypic reversion' of malignant cells, both CAMo motility and correct architecture are restored.

184

Self-organizing and stochastic behaviors during the regeneration of a large population of hair stem cells.

C. Chuong[1], M. Plikus[2], C. Chen[3], D. de la Cruz[2], R. Widelitz[2]; [1]Pathology, University of Southern California, Los Angeles, CA, [2]University of Southern California, Los Angeles, CA, [3]Yang Ming University, China

The hair follicle undergoes cyclic degeneration and regeneration cycle throughout life. The length of growing (anagen) and resting phase (telogen) can determine the hair length. Long resting phase mean shorter or no hair, i.e., alopecia. We have developed ways to visualize hair stem cell activation over entire skin in living mice. With this, we found cyclic BMP signaling from subcutaneous adipose layer regulates stem cell activation during hair regeneration (Plikus et al. 2008, Nature. 451:340-344. Cyclic dermal BMP signaling regulates stem cell activation during hair regeneration). More molecular analyses showed wnt serves as activators and hair growth patterns are governed by simple rules based on a pair of activator/inhibitor signaling. Regeneration in a population of hair follicles spreads like chain reaction, forming diverse wave patterns (Plikus et al. 2011, Science 332:586-589. Self organizing and stochastic behaviors during the regeneration of hair stem cells). Mathematical modeling reveals unexpected self-organizing and stochastic nature of this novel stem cell behavior, which emerge only at higher organ population level, allowing hair regeneration to become a very adaptable trait. These variations are seen among different animal species with different needs for hairs: robust spreading in rabbits, gradual wave spreading in mice, and random growth with loss of coupling among follicles in human skin. The hair wave can also vary under different physiological conditions of a same individual, such as in puberty, pregnancy and aging. We show that change in macro-environment is one major factor that contributes to alopecia in aging mice. We have developed ways to modify macro-environment for hair follicles, and hence can stimulate many more resting phase hair follicles to re-enter growing phase.

185

Par-1 Controls Non-Muscle Myosin II Activity and Dynamics to Regulate Collective Cell Migration.

P. Majumder[1], G. Aranjuez[1,2], J. McDonald[1,2]; [1]Molecular Genetics, Cleveland Clinic Lerner Research Institute, Cleveland, OH, [2]Genetics, Case Western Reserve University School of Medicine, Cleveland, OH

Many cells migrate in collective groups during tissue morphogenesis, wound healing and tumor invasion and metastasis. In single migrating cells, localized actomyosin contraction couples with actin polymerization and cell-matrix adhesion to regulate cell protrusions and retract trailing cell edges. In contrast, we have only a limited understanding of mechanisms that coordinate actomyosin dynamics in collective cell migration. We study the migration of *Drosophila* border cells, which move as a cohesive group of 6-10 epithelial-derived cells during late oogenesis. We previously observed that mutants of the cell polarity protein Par-1 (MARK), a serine-threonine kinase, result in defective border cell delamination and migration. We now show that these defects are caused by perturbations in cytoskeletal dynamics due to disruption of a previously unknown signaling pathway between Par-1 and non-muscle myosin-II (Myo-II). Using live time-lapse imaging, we show that Myo-II is required for two critical features of border cell migration: initial detachment of the border cells from the surrounding epithelium, and extension of cell

protrusions of normal length and direction. We identified a robust genetic interaction between the myosin regulatory light chain (MRLC) homolog *spaghetti squash* (*sqh*) and *par-1* and, remarkably, found that active Sqh/MRLC strongly suppresses par-1-dependent mutant phenotypes. We show that Par-1 regulates dynamic subcellular localization of Sqh/MRLC in live border cells, and, furthermore, that Par-1 regulates the activity of Myo-II. We have discovered that Par-1 phosphorylates and inactivates myosin phosphatase, thus promoting phosphorylation of Sqh/MRLC and increasing Myo-II activity. Finally, while myosin phosphatase is distributed uniformly in the border cell cluster, we find that Par-1 localizes to the cluster rear along with active Myo-II; in the absence of Par-1, spatially distinct active Myo-II is lost. Our study reveals that Par-1 kinase is a principal regulator of polarized Myo-II activity within the border cell cluster through localized inhibition of myosin phosphatase. Polarity proteins such as Par-1, which intrinsically localize, can thus directly modulate the spatiotemporal actomyosin dynamics required for proper collective cell migration.

186

Spatiotemporal regulation of somitogenesis by the oscillator networks of the segmentation clock.

R. Kageyama[1]; [1]Institute for Virus Research, Kyoto Univ, Kyoto, Japan

A bilateral pair of somites forms periodically by segmentation of the anterior ends of the presomitic mesoderm (PSM). This periodic event in time and space is regulated by a biological clock called the segmentation clock, which involves cyclic gene expression. In mice, Hes7 expression oscillates by negative feedback, and mathematical models have been used to generate and test hypotheses to aide elucidation of the role of negative feedback in regulating oscillatory expression. Hes7 induces coupled oscillations of Notch and Fgf signaling in the posterior PSM, while Notch and Fgf signaling cooperatively regulate Hes7 oscillation, indicating that Hes7 and Notch and Fgf signaling form the oscillator networks. Oscillations in Notch signaling generate traveling waves, thereby periodically segregating a group of synchronized cells. Notch signaling activates, but Fgf signaling represses, expression of the master regulator for somitogenesis Mesp2, and coupled oscillations in Notch and Fgf signaling dissociate in the anterior PSM, which allows Notch signaling-induced synchronized cells to express Mesp2 after these cells are freed from Fgf signaling. These results indicate that Notch signaling periodically defines the prospective somite region (spatial periodicity), while Fgf signaling regulates the pace of segmentation (temporal periodicity).

Molecular organization and function of the Golgi stacks.

Y. Xiang[1], X. Zhang[1], Y. Wang[1]; [1]University of Michigan, Ann Arbor, MI

The unique structure of the Golgi in almost all eukaryotic cells is a stack of flattened cisternal membranes, but how this structure is formed at the molecular level and why its formation is important for cellular functions remain elusive. We have developed an in vitro system to reconstitute the process of mitotic Golgi disassembly and post-mitotic reassembly in mammalian cells, which allowed us to reveal the molecular mechanism of the Golgi biogenesis during cell division. Mitotic Golgi fragmentation involves membrane vesiculation coupled with cisternal unstacking; post-mitotic Golgi reassembly is mediated by membrane fusion to form single cisternae and stack formation. Stack formation directly involves the Golgi stacking protein

GRASP65 and GRASP55, which play complementary and essential roles in Golgi cisternal stacking by forming mitotically regulated trans-oligomers. By depletion of GRASP65/55 we are able to manipulate Golgi stack formation and thus determine the biological significance of stacking. We demonstrate that Golgi cisternal unstacking stimulates COPI vesicle budding and thus enhances protein transport. Golgi fragmentation, however, impairs protein sorting and alters the glycosylation of cell surface proteins and reduces cell adhesion. Subsequently, cell adhesion and migration were reduced when the Golgi was unstacked, which was probably the result of reduced ¦Á5/¦Â1 integrin expression. Furthermore, total protein synthesis and the proliferation of cells with unstacked Golgi were enhanced. Inhibition of Golgi disassembly at the onset of mitosis also affects cell cycle progression. We propose that Golgi stack formation is a flux regulator for protein trafficking and thereby functions as a quality control mechanism for protein sorting and modification. Structural and functional Golgi defects in disease models are explored in this study.

188

ER tubules mark sites of mitochondrial division.

J. Friedman[1], L. Lackner[2], M. West[1], J. DiBenedetto[1], J. Nunnari[2], G. Voeltz[1]; [1]University of Colorado, Boulder, Boulder, CO, [2]University of California, Davis, CA

Mitochondrial structure and distribution are regulated by division and fusion events. Mitochondrial division is regulated by Dnm1/Drp1, a dynamin-related protein that forms helices around mitochondria to mediate fission. Little is known about what determines sites of mitochondrial fission within the mitochondrial network. Given that ER and mitochondria exhibit tightly coupled dynamics and have extensive contacts, we tested whether ER plays a role in mitochondrial division. We show that mitochondrial division occurs at positions where ER tubules contact mitochondria and mediate constriction prior to Drp1 recruitment. These data demonstrate that ER tubules play an active role in defining the position of mitochondrial division sites.

189

Coordinating Mitochondrial Biogenesis and Redistribution to Achieve Proper Inheritance of Mitochondrial Content in Budding Yeast.

S. Rafelski[1], M. Viana[2], L. Costa[2], W. Marshall[1]; [1]Biochemistry, UC San Francisco, San Francisco, CA, [2]Inst. de Fisica de Sao Carlos, USP, Sao Carlos, Brazil

Mitochondria must grow with the growing cell to ensure proper cellular physiology and inheritance upon division. But it is unknown how mitochondrial content scales with cell size during asymmetric cell growth and division. Is the same mitochondrial to cell size ratio maintained uniformly throughout the growing cell to produce identical mother and daughter cells? Or is there an asymmetry in the inheritance of mitochondrial content? We previously developed a novel computational method that quantifies mitochondrial networks as 3D mathematical graphs to measure the physical size of the mitochondrial network. Using this method, we found mitochondrial inheritance to be very asymmetric. Regardless of mother size or mitochondrial content, all buds attained the same average mitochondrial to cell size ratio with the same kinetics during budding. In contrast, aging mothers experienced a continued decrease in their mitochondrial to cell size ratio over successive generations. The proper mitochondrial volume ratio in the bud must is generated by a combination of net biogenesis (sum of new synthesis and turnover) in each, and net redistribution (sum of all movement and retention of tubules) between, mother and bud compartments. We calculated the relative contributions of net biogenesis and redistribution to the mitochondrial content in the bud. We found that redistribution dominated during the first half of budding and biogenesis in the bud took over

during the second half. A final 60-75% of the mitochondria inherited by the buds originated in their mothers. Mitochondrial biogenesis in the mothers could not keep up with the required redistribution into their buds. In the youngest, first generation mothers decreased redistribution was compensated for by increased biogenesis in their buds to achieve the same volume ratio as the rest of the population. We delayed or sped up mitochondrial inheritance with deletion or overexpression of Ypt11p and Mmr1p, representing two of the three mitochondrial inheritance pathways. In both cases the kinetics of mitochondrial inheritance were significantly altered but buds still reached the proper mitochondrial volume ratio in time for division. We conclude that cells actively regulate the mitochondrial volume ratio in their buds by regulating both redistribution and biogenesis to ensure proper inheritance of mitochondrial content.

mTORC1 Senses Amino Acids Through a Lysosomal Inside-Out Mechanism that Requires the Vacuolar H+-ATPase.

R. Zoncu[1], L. Bar Peled[1], A. Efeyan[1], S. Wang[1], Y. Sancak[1], D. Sabatini[1]; [1]Whitehead Institute for Biomedical Research, Cambridge, MA

The mTOR Complex 1 (mTORC1) kinase is a master growth regulator that senses amino acids through a poorly understood mechanism. A key event is the amino acid-induced activation of the Rag GTPases, which promotes the translocation of mTORC1 to the lysosomal surface, the site of mTORC1 activation. A central question is where in the cell amino acids are sensed and how their sensing leads to Rag activation. Here, we identify the vacuolar H+-ATPase (v-ATPase) as necessary for amino acid signaling to mTORC1. The v-ATPase functions upstream of the Rag GTPases and promotes amino acid-mediated recruitment of mTORC1 to the lysosomal surface. Using an assay that recapitulates amino acid signaling to mTORC1 in a cell-free system, we show that the catalytic movement of the v-ATPase, but not the lysosomal pH gradient, is necessary for amino acids to regulate the Rag GTPases and promote mTORC1 translocation. Moreover, using this system we implicate the lysosomal lumen as the site where amino acid signaling initiates. These results identify the v-ATPase as a new component of the mTOR pathway and delineate a lysosome-associated machinery for amino acid sensing.

191

The interaction of MiT/TFE transcription factors with lysosomes contributes to regulation of lysosomal homeostasis.

A. Roczniak-Ferguson[1], C. Petit[1], S. Qian[1], S. Ferguson[1]; [1]Department of Cell Biology, Yale University, New Haven, CT

The MiT/TFE family of transcription factors (MITF, TFEB, TFE3) regulates expression of many genes encoding proteins involved in autophagy and the biogenesis of lysosomes and lysosome-related organelles. In this study, we show that the regulation of MiT/TFE transcription factor abundance in the nucleus is tightly linked to autophagy-inducing stimuli and overall lysosomal status and that this regulation depends on a physical interaction of these transcription factors with lysosomes via a conserved region at their amino terminus. This lysosomal recruitment promotes MiT/TFE phosphorylation within a motif that confers a phosphorylation-dependent interaction with 14-3-3 proteins. This interaction retains MiT/TFE proteins mostly in the cytoplasm under basal conditions. In response to specific autophagy-inducing stimuli and/or perturbation of lysosomal function, phosphorylation of the14-3-3 binding site is attenuated, the interaction with 14-3-3 proteins is lost and the MiT/TFE proteins accumulate in the nucleus. Building on the previously established ability of these transcription factors to up-regulate the expression of genes within the autophagy-lysosomal pathway, our data suggests a novel homeostatic feedback mechanism that couples demand for lysosomal activity to the

transcriptional control of the expression of genes encoding proteins critical for the function of this organelle.

192

The PX-BAR protein SNX18 is required for autophagy.

H. Knævelsrud[1], K. Søreng[1], K. Håberg[2], F. Rasmuson[2], C. Raiborg[3], K. Liestøl[3], H. Stenmark[3], S. Carlsson[2], A. Simonsen[1]; [1]Institute of Basic Medical Sciences, University of Oslo, Oslo, Norway, [2]Department of Medical Biochemistry and Biophysics, Umeå university, Sweden, [3]Centre for Cancer Biomedicine, University of Oslo, Oslo, Norway

Autophagy is a catabolic pathway targeting cytoplasmic material for lysosomal degradation, thereby protecting cells from accumulation of toxic components and enabling cells to survive scarce nutrient supplies. Macroautophagy is characterized by the formation of double-membraned vesicles, but the membrane remodeling events required for formation of autophagic vesicles are still not completely understood. However, the class III PI3K/Vps34 complex and phosphoinositol-3-phosphate are of core importance to induction of autophagy. Since PX domain proteins are known to bind PI3P and other phosphoinositides and mediate membrane remodeling and trafficking events, we performed an imaging-based siRNA screen targeting all human PX domain proteins using GFP-LC3 autophagosome formation as a read-out and found depletion of the PX-BAR protein SNX18 to strongly inhibit autophagosome formation. Consequently, overexpression of SNX18 increases LC3 lipidation and GFP-LC3 spot formation and we demonstrate that membrane binding of SNX18 is required for efficient autophagosome formation. Moreover, SNX18 colocalizes with and interacts with the autophagy-associated proteins LC3 and TBK1. In conclusion, our study identified the PX-BAR protein SNX18 to be involved in membrane events required for autophagosome formation.

Minisymposium 31: Signal Transduction Networks

193

Exploring the design principles of signaling circuits in space and time.

W. Lim[1]; [1]Cellular & Molecular Pharmacology, Univ California-San Francisco/HHMI, San Francisco, CA

Living cells are able to carry out diverse information processing tasks and to control complex spatiotemporal behaviors using molecular signal transduction networks. To understand the design principles of such networks, we are complementing traditional analytical approaches with synthetic approaches of trying to build novel or systematically modified networks that can carry out target functional behaviors. Using modular components that control phosphorylation and GTPase signaling, we are exploring the construction of synthetic spatial self-organizing circuits, as well as circuits with complex dynamical responses. We are also using parallel enumeration based computational approaches to explore the space of networks that can robustly execute such tasks. We hope to gain a deeper understanding between network structure and function through such studies. We also hope to gain a better understanding of the evolutionary landscape through which such behaviors emerge.

194

Spatio-temporal control of intracellular ROS concentration in PDGF signaling revealed by single Eu^{3+}-doped nanoparticle imaging.

C. Bouzigues[1], T-L. Nguyen[1], R. Ramodiharilafy[1], P-L. Tharaux[2], A. Alexandrou[1]; [1]Laboratoire Optique et Biosciences, Ecole Polytechnique, Palaiseau, France, [2]PARCC, HEGP, Paris, France

For many cell functions, notably those requiring an asymmetric response, such as directed migration, spatio-temporal organization of signaling pathways is important for the cell response regulation. PDGF (Platelet Derived Growth Factor) induces migration in numerous contexts, such as reparation of vascular lesions or metastasis formation, inducing ROS (Reactive Oxygen Species) production as second messenger. The potential lethality of concentrated ROS and the importance of intracellular organization for migration require a tight control of their concentration. However, the dynamics of ROS production and organization is so far mostly unknown. By imaging single Eu^{3+}-doped nanoparticles[1], we probed the intracellular ROS response with high temporal and spatial resolution. We thus measured the absolute ROS concentration in normal or tumoral cells and revealed specific temporal patterns of ROS production under PDGF stimulation. We measured an integration time of several minutes required for the ROS response formation. This response formation is shorter for tumoral cells. We satisfyingly explained this fact by modeling the diffusion-limited dimerization of PDGFRs. This may constitute a temporal filtering mechanism for preventing cell responses to transient signals and its impairment in tumoral cells could be of great physiological relevance for the metastatic transition. We moreover quantitatively measured a transactivation of EGFR by PDGF stimulation and revealed its role in the dynamics of the cell response. By using a microfluidic system, we furthermore apply spatially controlled PDGF stimulation and displayed the maintenance of asymmetric ROS concentration in the cell under a PDGF gradient. This likely relies on a balance between ROS diffusion and degradation. This balance controls the local ROS concentration and thus the cell response. Altogether, our results reveal the tight regulation of the ROS spatio-temporal organization by the cell, which illustrates how the spatio-temporal control of transduction pathways is crucial for the buildup of the cell response.

Dynamics: SH2 domain binding/unbinding on EGFR.

D. Oh[1], K. Machida[1], M. Ogiue-Ikeda[1] , J. A. Jadwin[1], B. J. Mayer[1], J. Yu[1]; [1]CCAM, University of Connecticut Health Center, Farmington, CT

Epidermal growth factor (EGF) stimulation triggers downstream signaling cascades through binding of Src homology 2 (SH2) domain containing proteins to the phosphorylated tyrosine (p-Tyr) residues of the EGF receptor (EGFR). This signaling plays a crucial role in cell proliferation, metastasis, survival, tumorigenesis, etc. However the dynamics of bindings of SH2 domain to p-Tyr on the EGFR are not well quantified. Applying novel single-particle-tracking photoactivated localization microscopy (spt-PALM) techniques combined with the total internal reflection (TIR) optics, we quantified kinetic parameters for following tyrosine phosphorylation rate and dissociation rate between EGFR and tdEos- fused SH2 domains of several signaling molecules (Grb2, Plc□1, Shp2, Src, Nck1, Crk, Jak2, ShcA, CblA) in live cell. We mapped the progression of the EGFR-SH2 complexes over the EGF induction time and measured binding kinetics. Our data shows each SH2 domain produced a different binding curve as a function of time after EGF stimulation, suggesting phosphorylation rates are different for different tyrosine residues on EGFR and each SH2 domain has binding specificity. Analyzing multiple exponential distributions of an individual binding time of SH2 domain, we obtained the dissociation rate from

0.05 to 10 S^{-1}. This finding implies that there exist multiple states of EGFR-SH2 complex such as transient, monomer or clustering binding states. The clustering of EGFR-SH2 complex developed as a function of EGF stimulation time was confirmed by tracking approximately 1-5 $x10^4$ individual complexes with the time-course PALM imaging. Interestingly, a negative correlation between binding time of SH2 domain on EGFR and their mobility was observed. This result, along with PALM analysis, suggests that downstream signaling may require stable clustering of EGFR-SH2 complexes. In conclusion, our analyses not only confirmed binding specificity of SH2 domains, but also suggested that each specific p-Tyr residue on the receptor has a specific phosphorylation rate.

196

Targeted Proteomics Analysis of Signalling Dynamics: a View of the Adaptor Protein GRB2 mediated events.

N. Bisson[1], A. James[1], G. Ivosev[2], S. Tate[2], L. Taylor[1], T. Pawson[1]; [1]Samuel Lunenfeld Res Inst, Toronto, ON, Canada, [2]AB Sciex

Signalling pathways are commonly organized through inducible protein-protein interactions, mediated by adaptor proteins that link activated receptors to cytoplasmic effectors. However, we have little quantitative data regarding the kinetics with which such networks assemble and dissolve to generate a specific cellular response. We have identified 90 proteins and 36 phosphorylation sites associated with the GRB2 adaptor protein in human cells. We have found that GRB2 nucleates a remarkably diverse set of protein complexes, involved in multiple aspects of cellular function. To comprehensively and quantitatively investigate changes in GRB2-based protein interactions in growth factor stimulated cells, we have designed a targeted mass spectrometry method, AP-SRM (affinity purification-selected reaction monitoring). The data define context-specific and time-dependent networks that form around GRB2 following stimulation, and reveal core and growth factor-selective interaction subsets. These results illustrate the reliability of AP-SRM in the quantitative analysis of dynamic signalling networks. They also suggest that capturing a key hub protein and dissecting its interactions by SRM is an approach that can be broadly applied to quantify signalling dynamics.

197

KLF5 acetylation, which is induced by TGFbeta but interrupted by oncogenic signaling, underlies the dual functions of TGFbeta in gene regulation and cell proliferation control.

J-T. Dong[1], P. Guo[1]; [1]Winship Cancer Institute, Emory University School of Medicine, Atlanta, GA

During epithelial homeostasis, stem cells divide to produce progenitor cells, which not only proliferate to generate the cell mass but also respond to cellular signaling to transition from a proliferative state to a differentiation state. Such a transition involves functional alterations of transcriptional factors, yet the underlying molecular mechanisms are poorly understood. In addressing this question, we found that the pro-proliferative factor KLF5 becomes anti-proliferative upon TGFbeta-mediated acetylation in an in vitro model of epithelial homeostasis. KLF5 is not only essential for cell proliferation, it is also indispensable for TGFbeta-induced anti-proliferation in epithelial cells. Without TGFbeta, KLF5 inhibits p15 expression and induces Myc expression, but when TGF-¦Â is present, KLF5 becomes a cofactor of TGFbeta to induce p15 and suppress Myc expression in the same cells. Mechanistically, TGFbeta recruits acetylase p300 to acetylate KLF5, and acetylation in turn induces the assembly of KLF5 with other TGFbeta transcriptinoal effectors including Smad2-4 and Miz-1 and their binding to p15 and Myc promoters, resulting in the reversal of KLF5 function. Failure in KLF5 acetylation prevents TGFbeta-assemblled p300-KLF5-Smads complex on gene promoters, reversing the function of

TGFbeta in gene regulation and proliferation control. It was reported that TGFbeta and KLF5 have dual roles in tumoirigenesis, and that Ras oncogenic signaling converts TGFbeta from a tumor suppressor to a tumor promoter. We therefore also examined whether Ras signaling modulates TGFbeta function by interrupting TGFbeta-induced KLF5 acetylation and the assembly of the p300-KLF5-Smads transcriptional complex. We found that Ras inhibited TGFbeta-induced KLF5 acetylation and interfered with TGFbeta in p15 induction and Myc repression. In addition, TGFbeta-induced Smad3 phosphorylation at the C-terminal region was necessary for TGFbeta to induce KLF5 acetylation, and Ras interrupted this phosphorylation. Ras signaling further interrupted the interactions among p300, KLF5 and Smads, as well as the binding of the p300-KLF5-Smads complex onto the TGFbeta-responsive promoter elements for both p15 and Myc. Our findings suggest that 1) TGFbeta-induced KLF5 acetylation is a "switch" that that turns on differentiation in proliferating progenitor cells; 2) deacetylation of KLF5 underlies the reversal of TGFbeta function in gene regulation and cell proliferation control; and 3) oncogenic signaling reverses TGFbeta function by interrupting KLF5 acetylation.

198

Cross-talk and information transfer in mammalian and bacterial signaling.

S. Lyons[1], A. Prasad[2]; [1]School of Biomedical Engineering, Colorado State University, Fort Collins, CO, [2]Chemical and Biological Engineering, Colorado State University, Fort Collins, CO

In both mammalian cells and bacteria, simple phosphorylation circuits play a very important role in cellular function. Bacteria have hundreds of two-component signaling systems that involve phosphotransfer between a receptor kinase and a response regulator. In mammalian cells a similar pathway is the crucial TGF-beta signaling pathway, where extracellular levels of TGF-beta family ligands lead to activation of cell surface receptors that phosphorylate Smad proteins, which in turn activate many genes. In TGF-beta signaling the multiplicity of external ligands begs the question as to how cells are able to distinguish signals coming from different extra-cellular ligands, but transduced through a small set of Smads. Here we use information theory with stochastic simulations of simple networks to address this question. We find that when signals are transduced through the same Smad, the cell cannot distinguish between different levels of the external ligands. Increasing the number of Smads from one to two significantly improves information transmission as well as the ability to discriminate between different external ligands. Surprisingly, both total information transmitted through the channel and the capacity to discriminate between the external ligands are quite insensitive to the cross-talk between the two Smads as long as they are not nearly identical. In sharp contrast, we find that two-component systems in bacteria show a significantly sharper decline in information transfer in the presence of cross-talk. This suggests that mammalian signal transduction can tolerate a high amount of cross-talk. This may have played a role in the evolution of new functionalities from small mutations in signaling pathways and allowed for the development of cross-regulation. Insensitivity to cross-talk also could increase robustness due to redundancy in signaling pathways. On the other hand, bacterial two component systems are much less robust against cross-talk which may provide an explanation for the lack of cross-regulation in most two component systems.

Symposium 7: Design Principles of Cells and Tissues

199

Inside of the cell, meet the extracellular universe: merging tissue engineering and systems biology.

L. G. Griffith[1]; [1]Biological and Mechanical Engineering, Massachusetts Inst Technol, Cambridge, MA

Tissue engineering is the process of creating functional 3D tissues using cells combined with scaffolds or devices that facilitate cell growth, organization and differentiation. At its inception, the major vision of the field was on building clinical therapies to replace human heart, liver, cartilage and other tissues, by combining cells with polymer scaffolds. The vision for clinical therapies has arguably evolved to include more emphasis on regenerative medicine approaches that harness endogenous pathways. Further, an important new direction has emerged – creation of models of human tissues that capture 3D physiology for use in applications ranging from drug development to studies of disease pathophysiology. For both application areas, an integration of design principles from molecular to macroscopic length scales is required, using (or developing) mathematical models of cell behavior. For example, at the molecular level, presenting adhesion ligands in a clustered compared to random format enhances cell adhesion and influences migration in a manner predicted by a mathematical model of migration; at a macroscopic level, the density of cells in an implanted scaffold is limited by nutrient diffusion, and this constraint influences the strategies for cell transplantation therapies for tissue defects such as bone. An emerging frontier is in linking the networks of extracellular cues that stimulate cells from the microenvironment to the intracellular signaling networks that dictate downstream phenotypic responses. Comprehensive analysis of intracellular protein kinase signaling networks, coupled with mathematical analysis, have begun to yield rules for cell fate decisions as a function of cell state and the temporal evolution of cell state. These systems biology approaches offer new insight into design of extracellular microenvironments to influence cell fate. At the same time, incorporation of macroscopic design principles through design of 3D environments enhances investigation of cell fate, as exemplified by use of tissue-engineered systems for predicting liver toxicology in drug development.

200

The Flagellar Length Control System.

W. Ludington[1], K. Wemmer[1], B. Engel[1], E. Kannegaard[1], W. Marshall[2]; [1]UCSF, San Francisco, CA, [2]Department of Biochemistry and Biophysics, Univ California-San Francisco, San Francisco, CA

One of the most fundamental engineering problems faced by a cell is how to control the size of its organelles. Cilia and flagella of eukaryotic cells provide an excellent model system in which to explore the design principles of size control systems, due to their simple one-dimensional geometry and easy visibility. Moreover, since flagella are motile structures, their size can be directly related to their function and to the evolutionary fitness of the organism. We will present a simple model for length control based on quantitative measurements of transport within flagella, and show tests of this model using length-altering mutations and analysis of intraflagellar transport and length fluctuations in living cells of the unicellular green alga Chlamydomonas reinhardtii.

Actin and Actin-Associated Proteins I

201

Distributed deconvolution analysis of fluorescence images reveals a regulatory mechanism for thin filament lengths in human skeletal muscle.

S. A. Lewis[1], N. E. Kim[1], D. S. Gokhin[1], V. M. Fowler[1]; [1]Department of Cell Biology, The Scripps Research Institute, La Jolla, CA

Skeletal muscle is striated and consists of arrays of repeating sarcomere units, which contain interdigitating thin (actin) filaments and thick (myosin) filaments. The lengths and regulation of each of these filament systems are important since the amount of overlap between the thin and thick filaments dictates the force that can be produced by the muscle. This study aims to determine if human thin filament lengths are regulated by nebulin via a ruler mechanism, as is commonly thought, or by some other mechanism, potentially involving tropomodulin (Tmod). Pectoralis major and deltoid muscle biopsies were obtained from human patients, and cryosections were immunostained using Tmod, nebulin, and α-actinin antibodies as well as phalloidin and imaged by confocal fluorescence microscopy. Line scans of myofibrils from images of the samples were analyzed using distributed deconvolution to accurately determine lengths associated with each thin filament component. Across all patients and muscle biopsies, it was found that Tmod and phallodin lengths were comparable (Tmod: 1.27±0.09 μm, n=1091 myofibrils; phalloidin: 1.24±0.06 μm, n=1146 myofibrils), confirming that Tmod localizes to the pointed ends of the thin filaments. However, Tmod lengths were found to be significantly greater than the lengths associated with the nebulin N-terminus (0.90±0.07 μm, n=1214 myofibrils) for all samples, with an average difference from the Tmod lengths of 0.37±0.11 μm, suggesting the existence of a nebulin-free pointed-end extension. Based on these findings, nebulin cannot be a ruler that dictates human thin filament lengths. Rather, human thin filaments extend past the nebulin N-terminus and up to, but not past, Tmod. These data complement previous studies showing that thin filament lengths are not regulated via a nebulin ruler mechanism in mouse and rabbit muscles. The existence of nebulin-free pointed-end extensions in human thin filaments suggests a unifying mechanism for thin filament length regulation across mammalian species.

202

Heterogeneity of thin filament lengths in human skeletal muscles: implications for biomechanical function.

D. S. Gokhin[1], N. E. Kim[1], S. A. Lewis[1], H. R. Hoenecke[2], D. D. D'Lima[2], V. M. Fowler[1];
[1]Department of Cell Biology, The Scripps Research Institute, La Jolla, CA, [2]Shiley Center for Orthopaedic Research and Education, Scripps Clinic, La Jolla, CA

During skeletal muscle contraction, force is produced when actin (thin) filaments slide past myosin (thick) filaments, resulting in sarcomere shortening. The degree of force production is proportional to the amount of overlap between the thin and thick filaments, which, in turn, depends on their lengths. Both thin and thick filament lengths are precisely regulated and uniform within a muscle fiber. While thick filament lengths are essentially constant across muscles and species (~1.65 μm), thin filament lengths are highly variable both across species and across muscles of a single species, depending on the dynamic activities of specific combinations of tropomodulin (Tmod), tropomyosin, and nebulin isoforms. However, thin filament length heterogeneity has not been assessed in humans. Here, we used a high-resolution immunofluorescence and image analysis technique (distributed deconvolution) to

directly test the hypothesis that human thin filament lengths vary across muscles and individuals. Using deltoid and pectoralis major muscle biopsies from patients undergoing shoulder replacement surgery, we identified substantial intra- and inter-patient thin filament length variability. Thin filament lengths ranged from 1.19±0.08 μm to 1.37±0.04 μm, based on Tmod localization with respect to the Z-line, corresponding to optimum sarcomere lengths of 2.38-2.58 μm to 2.74-2.94 μm, respectively. Tmod localized 0.28 μm to 0.47 μm further from the Z-line than the N-terminus of nebulin, confirming that human thin filaments have nebulin-free pointed-end extensions whose lengths are modulated by Tmod and comprise up to 34% of total thin filament length. Thin filament length was negatively correlated with the percentage of type-2X myosin heavy chain within the biopsy, establishing the existence of a relationship between thin filament lengths and fiber types in human muscle. Together, these data challenge the widely held assumption that human thin filament lengths are constant. Our results also have broad relevance to musculoskeletal modeling, surgical reattachment of muscles, and orthopaedic rehabilitation.

203

The Limch1, a novel microfilament associated protein, associated with to the sarcomeric type stress fiber.

Y-H. Lin[1], Y-Y. Zhen[2], L-M. Pai[1,2]; [1]Department of biochemistry and molecular biology, Chang Gung University, TaoYuan, Taiwan, [2]Molecular medicine research center, Chang Gung University, TaoYuan, Taiwan

Limch1 as a novel protein engaged in cell migration was identified in systematic screening of misexpressing proteins in border cell migration in Drosophila oogenesis. This novel protein comprises an N-terminal calponin homologous (CH) domain, and a C-terminal LIM domain flanking its central undefined coiled coil stretch. Immunofluorescence microscopy investigation in subcellular localization indicated Limch1 mainly distributes on stress fibers. The CH domain and LIM domain of Limch1 both are capable of localizing the Limch1 to stress fibers by domain characterization with overexpression of GFP tagged CH domain or LIM domain either in the U2OS cells, in contrast, the GFP fused central coiled coil stretch randomly mislocalized in cytoplasmics. Indeed, the Limch1 is associated with the sarcomeric type stress fiber (SSF). The association of Limch1 with SSF was dissected by a costaining with α-actinin as a Z-disc marker as in the sarcomere of skeletal muscle myofibrils and the SSF in non-muscle cells. Subsequently, the ROCK inhibitor administration was performed to examine the biological role of Limch1 implicated in physiological function of SSF. While the inhabiting ROCK activity leads to Limch1 disassociated from the SSF, it suggested Limch1 might be a downstream effector of ROCK signaling. The ROCK is, however, a crucial regulator involved in SSF assembly, and mediated actomyosin contraction. The treatment of ROCK inhibitor caused Limch1 detached from SSF may imply that Limch1 likely plays an important role in the contractile SSF assembly and function. Furthermore, SSF contraction is an essential force generator in migratory cell. Take together, the misexpression of Limch1 in Drosophila delayed the border cell migration during oogenesis, it hinted that association of Limch1 with SSF may manage contractile SSF assembly, and operate SSF dependent force generation for cell migration.

205

A novel actin filament class that regulates glucose uptake and GLUT4 trafficking.

A. Kee[1], C. Lucas[1], R. Szokolai[1], L. Yang[1], N. Martel[2], G. Leong[2], G. Muscat[2], W. Hughes[3], D. James[3], P. Gunning[4], E. Hardeman[1]; [1]Neuromuscular and Regenerative Medicine Unit, School of Medical Science, University of New South Wales, Sydney, Australia, [2]Institute for Molecular Biosciences, University of Queensland, Australia, [3]Diabetes and Obesity Program, Garvan Institute of Medical Research, Australia, [4]Oncology Research Unit, School of Medical Science, University of New South Wales, Sydney, Australia

A primary defect in Type 2 diabetes is alterations to glucose uptake in skeletal muscle and adipose tissue. Insulin-stimulated glucose uptake requires the trafficking of GLUT4-containing vesicles from intracellular stores to the cell surface. We have identified a novel population of actin filaments defined by the cytoskeletal tropomyosin (Tm) isoform Tm5NM1. Analysis of Tm5NM1 transgenic (Tg) mice suggests these filaments play a role in glucose uptake. In Tm5NM1 Tg mice, whole body glucose clearance and insulin-stimulated glucose uptake into white adipose tissue (WAT), skeletal muscle and heart was increased. This was specific to Tm5NM1, as glucose clearance was unaltered in mice expressing an alternative Tm, Tm3. Gene expression profiling (Illumina microarray), quantitative RT-PCR and Western blot analysis of WAT from the Tm5NM1 Tg mice detected an increase in genes involved in actin filament turnover and GLUT4 trafficking, including myosin motors (Myolc, $P<0.05$) and components of the exocyst complex (Sec8, $P<0.005$). In keeping with Tm5NM1's reported role in stabilising actin filaments, there was a 30% increase ($P=0.019$) in filamentous actin (detected by phalloidin staining) in Tg WAT. In 3T3L1 adipocytes, insulin-stimulation (30 min.) resulted in a shift in Tm5NM1 localisation to the plasma membrane, consistent with a role in GLUT4 trafficking. This effect was specific to Tm5NM1, as insulin had little impact on the localisation of other Tm isoforms. Finally, in 3T3-L1 adipocytes stably expressing Tm5NM1, there was an increase in insulin-stimulated GLUT4 movement to the plasma membrane compared to vector control cells. We propose that Tm5NM1 actin filaments promoterecruitment of GLUT4 trafficking machinery that in turn results in enhanced insulin-stimulated GLUT4 translocation to the plasma membrane and glucose uptake.

Progression of hepatitis C virus infection to hepatocellular carcinoma is associated with increased expression and co-localization of filamin A and angiogenic markers.

S. Ghosh[1], C. A. Stump[2,3], W. A. Ahrens[1], T. Narang[1], J. Parsons[1], L. W. Schrum[1,4], H. L. Bonkovsky[1,5]; [1]Liver-Biliary-Pancreatic Center, Carolinas Medical Center; UNC School of Medicine, Charlotte, NC, [2]Wingate University, Charlotte, NC, [3]Carolinas Medical Center; UNC School of Medicine, [4]UNCC, [5]UNC School of Medicine

Background: Around 80% of hepatitis C virus (HCV) infected patients develop chronic HCV infection. HCV-infected patients have a high risk for developing HCC but mechanisms leading to the increased risk for liver cancer are still unclear. Angiogenesis, a physiological process involving the formation of new capillaries from pre-existing vessels, plays a pivotal role in majority of malignancies favoring growth and metastasis of several types of cancer including HCC. Our recent study showed an increase in expression of filamin A (fila), an actin-binding protein in HCV expressing cell lines compared to parental cell line. Fila is a regulator of R-ras which is a precursor of RAF/MEK/ERK pathway, is one of the main mediators of angiogenesis. The objective of this study was to investigate whether increased liver angiogenesis could be a predictor of HCC occurrence in patients with HCV-related cirrhosis. Furthermore we determined the association between fila and angiogenic markers in HCV induced cirrhosis and progression

to HCC. Methods: Expression profile and co-localization of fila and angiogenic markers in livers of human subjects with HCV infection, HCV with HCC, and HCC VS. control was determined. HCV replicon cell (Con1) and parental cell (Huh7.5) lines were treated with either IFN-a or sorafenib (soraf), an antitumor drug targeting towards VEGF receptors (R2 and R3) and c-Raf or in combination for 24 hours and 48 hours to asses the effect on fila and HCV proteins. Results: The result showed higher expression of fila, VEGF, R2 and R3 with the progression of the disease from HCV to HCC. Cells treated with either IFN-α or soraf showed a dose and time-dependent decrease of fila and HCV proteins. The combination treatment showed synergistic effects on fila. Conclusions: A positive association and co-localization was found between higher expression of fila and angiogenic markers with progression of HCV infection to HCC in both human subjects and cell lines. This study suggests that the interaction between fila and angiogenic markers in hepatocytes may contribute to the progression of the HCV to HCC and can be used as a potential target for development of new therapy in the treatment of HCV with HCC.

The Microtubule Plus End Tracking Protein EB1 Binds to Actin and Promotes Actin Polymerization.

Z. C. Zhu[1], H. Su[2], B. A. Paulson[1], K. K. Gupta[1], J. M. Schober[3], D. R. Kovar[4], H. V. Goodson[1]; [1]Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN, [2]Wadsworth Center, New York State Department of Health, Albany, NY, [3]Pharmaceutical Sciences, Southern Illinois University Edwardsville, Edwardsville, IL, [4]Departments of Molecular Genetics and Cell Biology and of Biochemistry and Molecular Biology, University of Chicago, Chicago, IL

Coordination between the actin and microtubule cytoskeletons is vital for complex processes such as cell division and multicellular development, but the mechanisms of this cross-talk remain mysterious. We show that the microtubule plus-end tracking protein (+TIP) EB1 binds to actin filaments directly, and it promotes actin polymerization both in vitro and in vivo. EB1 also colocalizes with actin under certain conditions in a variety of cell types. EB1 plays a pivotal role in the MT cytoskeleton because it the structural core of the +TIP network, a web of interacting proteins that are master regulators of MT dynamics. The observation that EB1 binds to actin suggests that EB1 plays a direct and perhaps central role in the process of actin-MT coordination.

208

Filamin is required for maintenance of F-actin and calcium signaling in *C. elegans.*

I. Kovacevic[1], E. J. Cram[1]; [1]Biology, Northeastern University, Boston, MA

We are using *C. elegans* as a model system to study how cells respond to mechanical forces *in vivo*. The spermatheca—a simple myoepithelial tube—experiences dramatic stretching forces caused by oocytes during ovulation. We hypothesize that the stretching of the spermatheca initiates a signaling cascade to release the oocyte from the spermatheca into the uterus. We identified filamin, a mechanosensitive scaffold protein, as being required for the release of oocytes from the spermatheca. The *C. elegans* filamin ortholog, FLN-1, has a well-conserved overall structure, including an actin-binding domain, and a series of 20 immunoglobulin-like repeats. FLN-1 is expressed in the somatic gonad, and colocalizes with F-actin. Analysis of a deletion allele indicates filamin is required to maintain the actin cytoskeleton in the spermatheca and uterus. Filamin-deficient animals accumulate embryos in the spermatheca, and consequently lay damaged eggs and exhibit reduced brood sizes. PLC-1/phospholipase C is also required for the exit of embryos from the spermatheca, and analysis of double mutant animals suggests that PLC-1 and FLN-1 act in the same pathway. Because PLC-1 is thought to

be upstream of intracellular calcium release, we used GCaMP—a genetically encoded calcium indicator—to image calcium during ovulation and spermathecal transit. Using worms expressing GCaMP we show that entry of an oocyte into the spermatheca initiates a distinctive series of autonomous calcium transients, which likely result in spermathecal constriction that propels the fertilized oocyte into the uterus. Loss of filamin results in drastically delayed onset of calcium signaling, followed by abnormal calcium oscillations. Importantly, mutations that enhance IP_3 signaling increased Ca^{2+} signaling and partially rescued the filamin defect. As expected, loss of PLC-1 abolished the calcium transients. The calcium pulses likely modulate actomyosin contraction to constrict the spermatheca, pushing the oocyte into the uterus. Given the effect on calcium signaling and the known mechanosensory role of filamin, we hypothesize that filamin is required in the spermatheca to respond to increased tissue tension, and to initiate calcium signaling. Understanding how cells sense and respond to mechanical forces has implications for development, cancer metastasis, and normal organ function.

209

The distinct roles of nucleo-cytoskeleton connections in three-dimensional cell motility.

S. B. Khatau[1,2], R. J. Bloom[1], S. Bajpai[1,3], D. Razafsky[4], S. Zang[4], A. Celedon[3,5], C. M. Hale[1,3], D. Hodzic[4], D. Wirtz[1,3]; [1]Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, [2]Johns Hopkins Physical Science-Oncology Center, Baltimore, MD, [3]Johns Hopkins Physical Science-Oncology Center, [4]Ophthalmology, Washington University, [5]Mechanical Engineering, Pontificia Universidad Católica de Chile

The role of actin filament organization in motility on conventional flat substrates has been studied extensively. However, cells often migrate in vivo in an extracellular matrix milieu that is intrinsically three-dimensional (3D) and the role of actin filament architecture in 3D cell motility is less well understood. Here we use quantitative functional live-cell assays to show that, while recently identified linkers of nucleoskeleton to cytoskeleton (LINC) complexes play a minimal role in conventional 2D migration, they play a critical role in regulating actin architecture in cells in 3D matrix and mediate protrusion dynamics, which in turn drive matrix remodeling and migration. LINC complex molecules Nesprin 2 giant and Nesprin 3 differentially modulate 3D motility by directly regulating the organization of a subset of actin filament bundles connected to the nucleus. A simple mechanical model explains why nucleo-cytoskeleton connections play no significant role in 2D motility, but are essential in 3D motility.

210

Architecture and dynamics of F-actin in somatic nuclei.

B. J. Belin[1], R. D. Mullins[1]; [1]Cellular & Molecular Pharmacology, UCSF, San Francisco, CA

Actin filaments have been suggested to participate in a number of processes in eukaryotic nucleus, including transcription, chromatin remodeling and active gene transport. Studies in oocyte systems have revealed an extensive nuclear F-actin network that plays crucial roles in nuclear integrity and chromosome segregation, but the architecture and precise functions of actin in somatic nuclei are unknown. We have developed a novel utrophin-based reporter construct for the detection of actin filaments in somatic nuclei. Expression of this reporter in HeLa and U2OS cells reveals a pool of small (<0.5 um diameter) discrete nuclear F-actin puncta. These nuclear F-actin puncta are highly mobile and are resistant to latrunculin B, suggesting a low turnover rate. Surprisingly, nuclear F-actin puncta are excluded from chromatin and do not localize to known nuclear landmarks. These results indicate that nuclear F-actin puncta are unlikely to participate directly in chromatin-based processes, and may instead serve as scaffolds in the interchromatin space.

211

Interaction of Telomeres and the Nucleoskeleton.

B. Cimini[1], B. Belin[1], D. Mullins[1], E. Blackburn[1]; [1]Biochemistry, Univ California-San Francisco, San Francisco, CA

The mammalian telomere consists of several kilobases of ‘TTAGGG’ repeats bound by the 6-protein ‘shelterin’ complex. Telomere maintenance is very important for long-term cell replenishment and genomic stability; more than 90% of human cancers have high telomerase levels, while haploisufficiency for the telomerase enzyme or mutations in telomere-associated proteins cause crippling premature aging syndromes in humans. We set out to examine the interaction between telomeres and nucleoskeletal components to determine if their interaction was modulated by telomere damage. After introducing fluorescently tagged versions of a telomere binding protein, an actin binding domain, and a DNA-damage sensing section of 53BP1 into cancer cells, we induced telomere damage by overexpressing a mutant telomerase template and quantified changes in signal and relative localization of all of the components. In addition to the expected increase in colocalization between telomeres and 53BP1, we saw an increased association between telomeres and nuclear actin foci after induction of telomere damage. These associations were modulated by inhibition of the DNA damage response protein ATM, which is known to be important in sensing telomere damage. We therefore hypothesize that a functional interaction between telomeres and the nucleoskeleton represents one of several control systems important to recognition and/or repair of damaged telomeres.

212

Mechanical Characterization of the Actomyosin Cortex in Single Cell C. elegans Embryos.

C. W. Harland[1,2], M. Gardel[2,3], E. Munro[1]; [1]Cellular and Molecular Biology, University of Chicago, Chicago, Il, [2]Physics, University of Chicago, Chicago, Il, [3]Institue for Biophysical Dynamics, University of Chicago, Chicago, Il

Polarization of the one-cell C. elegans embryo (zygote) is essential for proper development. Polarity is established in response to a transient symmetry-breaking cue and then maintained for many minutes prior to the first asymmetric division. During maintenance, the anterior cortex is highly enriched in ARP2/3 mediated branched actin and non-muscle Myosin II. While underlying genetic and biochemical mechanisms have been much explored, little is understood about the mechanics of polarity maintenance – in particular about how the zygote maintains a stably positioned anterior-posterior (AP) boundary despite the asymmetric distribution of force generating elements. More generally, the zygote cortex offers an attractive platform for developing microrheological techniques to probe mechanisms underlying actomyosin-based contraction and force transmission in animal cells.

Here, we combine video rate fluorescence microscopy and particle tracking to characterize spatiotemporal dynamics of actin filaments. We use phalloidin-conjugated quantum dots to report local motions of filamentous actin (F-actin). We mapped the trajectories of quantum dots at 30 fames per second at the zygote cortex during maintenance phase. In wild type (WT) embryos, the mean squared displacement (MSD) of actin bound quantum dots appears diffusive at long times with an apparent diffusion coefficient of 0.02 um^2/s and 0.03 um^2/s in the anterior and posterior halves respectively. In embryos that lack cortical myosin during maintenance, the MSD is again diffusive at long times with apparent diffusion coefficients reduced by a factor of four compared to WT. We find that the distribution of actin bound quantum dot displacements at 30 Hz is not Gaussian indicating that cortical actin filaments experience heterogeneous microenvironments that may result from variations in actin density,

actin turnover, actin architecture, or myosin force generation. Significantly, posterior bound quantum dots, which experience lower densities of both branched actin and Myosin II, show a higher occurrence of large and rapid (5 – 11 um/s) displacements compared to anterior. These differences are abrogated in embryos lacking cortical myosin, suggesting that myosin drives the large fluctuations. Moreover, reduced fluctuations in the anterior, where Myosin II is highly enriched, suggest that myosin-driven fluctuations are suppressed in the presence of ARP2/3-dependent (branched) actin, perhaps because branched actin networks are an unsuitable substrate for myosin force generation. Displacement distributions in both anterior and posterior halves become Gaussian at longer times indicating that inhomogeneities in cortex microenvironments and/or driving forces have randomized.

213

Cyclase-associated Protein 1 (CAS-1) Promotes Actin Filament Turnover in Cooperation with ADF/Cofilin And Is Essential for Muscle Actin Organization in C. elegans.

K. Nomura[1], K. Ono[1], S. Ono[1]; [1]Department of Pathology, Emory University, Atlanta, GA

Cyclase associated protein (CAP) is a conserved multi-domain protein that binds to monomeric actin. At high concentrations, CAP inhibits actin polymerization, while it also catalytically promotes actin filament turnover in cooperation with ADF/cofilin and regulates actin dynamics in yeast, fruit fly, Dictyostelium, and mammalian cultured cells. However, little is known about the role of CAP in a morphogenetic process of highly differentiated cytoskeletal structures. In the nematode C. elegans, the cyclase-associated protein-1 (cas-1) gene encodes a CAP protein. Here, we report that CAS-1 promotes actin filament turnover in cooperation with UNC-60B (a muscle-specific ADF/cofilin) and is essential for actin filament organization in the body wall muscle. We generated recombinant full-length CAS-1, an N-terminal half (CAS-1N) containing the helical-folded domain, and a C-terminal half (CAS-1C) containing the proline-rich motif, the WASP-homology 2 domain, and the ß-sheet domain for in vitro studies. In the presence of UNC-60B, full-length CAS-1 enhanced the rate of actin filament turnover as determined by the rate of phosphate release. While CAS-1N and CAS-1C independently bound to G-actin, either fragment failed to enhance actin filament turnover in the presence of UNC-60B, indicating that both N- and C-terminal domains are required for this activity. Full-length CAS-1 strongly enhanced exchange of G-actin-bound ATP even in the presence of UNC-60B that inhibits exchange of ATP. However, CAS-1N and CAS-1C did not enhance exchange of G-actin-bound ATP, indicating again that both N- and C-terminal domains are required for this activity. We generated a specific antibody against CAS-1 and found that CAS-1 was specifically expressed in the body wall muscle and localized to the M-line and a part of the thin filaments within sarcomeres. A cas-1-null mutant was homozygous lethal, and most of the mutant worms die in larval stages. The cas-1-null mutants showed disorganized actin filaments in the body wall muscle. In wild-type, UNC-60B localized to the thin filaments, while it mislocalized to the center of actin aggregates in the cas-1-null mutants. On the other hand, localization of CAS-1 was largely unaffected in unc-60B mutants, indicating that CAS-1 localizes to sarcomeres independently of UNC-60B. These results suggest that cooperative effects of CAS-1 and UNC-60B on actin filament turnover are essential for sarcomeric actin organization in striated muscle.

214

Remodeling of Actin Filaments by Cofilin and Phalloidin.

V. E. Galkin[1], A. Orlova[1], D. Kudryashov[2], A. Soloduhin[1], E. Reisler[3], G. Schröder[4], E. H. Egelman[1]; [1]University of Virginia, Charlottesville, VA, [2]Ohio State University, [3]University of California, [4]Institute of Structural Biology and Biophysics, Germany

Cofilin/ADF proteins play key roles in the dynamics of actin, one of the most abundant and highly conserved eukaryotic proteins. We used cryo-electron microscopy to show that the cofilin induced change in the filament twist is due to a unique conformation of the actin molecule unrelated to any previously observed state. The changes between the actin protomer in naked F-actin and in the actin-cofilin filament are greater than the conformational changes between G- and F-actin. This illustrates the structural plasticity of actin and suggests that other actin-binding molecules may also induce large but different conformational changes. We used cryo electron microscopy to reveal the structure of F-actin decorated with phalloidin - a small polypeptide widely used to stabilize actin filaments in in vitro experiments including the motility assay. We show that phalloidin and cofilin impose very different structural states on F-actin. In contrast to the previously accepted notion that phalloidin stabilizes a particular structural state of the actin filament we show that multiple structural states of F-actin exist in the filaments saturated with phalloidin. Our results suggest that the plasticity of actin-phalloidin filaments may explain their ability to support acto-myosin motility.

215

Dynamic modes of F-actin and its D-loop and their modulation by cofilin.

Z. Durer[1], M. McSunas[1], C. Altenbach[1,2], D. Kudryashov[1], W. Hubbell[1,2], E. Reisler[1,3]; Chemistry and Biochemistry, Univ California-Los Angeles, Los Angeles, CA, [2]Jules Stein Eye Institute, Univ California-Los Angeles, Los Angeles, CA, [3]The Molecular Biology Institute, Univ California-Los Angeles, Los Angeles, CA

Conformational dynamics of filamentous actin (F-actin) is essential for its regulation by actin binding proteins that modulate the actin cytoskeleton. Previous solution studies showed that the plasticity of the DNase I binding loop (D-loop; residues 40–50) on subdomain 2 of actin, and its contacts with the hydrophobic loop (H-loop), the C-terminus, and the W-loop at the interprotomer space create multiple filament states, including the destabilized ones. Here, we explored the nucleotide dependence of D-loop states via site directed fluorescence or electron paramagnetic resonance (EPR) spin probing of cysteine mutants of a.a. 40-50. Neither the reactivity towards fluorescent label acrylodan nor the spectral analysis of spin labeled D-loop mutants show any residue dependent helical periodicity, suggesting a highly mobile and disordered D-loop irrespective of the bound nucleotide. EPR spectra of spin-labeled mutants indicate the presence of multiple D-loop conformers in F-actin. These conformers provide greater versatility of actin binding surfaces and can be selectively stabilized by the binding partners. Focusing on cofilin, we show by site directed fluorescence and spin labeling that cofilin changes the emission properties of acrylodan and the mobility of spin labels attached to D-loop cysteine mutants. Furthermore, the kinetics of copper-catalyzed disulfide cross-linking in equimolar copolymers of D-loop cysteine mutants with either wildtype (C374) actin or mutant S265C/C374A (on the H-loop) or mutant F169C/C374A (on the W-loop) is altered in the presence of cofilin, favoring the unstable conformers of F-actin. These polymerization impaired oligomers of actin, created by such disulfide traps, can be rescued by cofilin, as detected by light scattering and electron microscopy imaging. Overall, our results emphasize the importance of F-actin dynamics and structural modes and their functional role in actin interactions with its binding proteins.

216

Investigating actin binding sites and bundling behavior of TRIOBP-4.

E. Bielski[1,2], S. Chakraborty[1], S. Kitajiri[3], T. Sakamoto[1];
[1]Department of Physics and Astronomy, Wayne State University, Detroit, MI, [2]Wayne State University, [3]Department of Otolaryngology, Heand and Neck Surgery, Kyouto University, Kyoto, Japan

TRIOBP is an actin-bundling protein that helps form resilient rootlets of hair cell stereocilia in the inner ear. TRIOBP binds to actin filaments and forms highly dense F-actin bundles. The formation mechanisms of the actin bundles are very unique, because TRIOBP may be able to wrap around actin filaments, instead of connecting between the actin filaments. TRIOBP has three isoforms: TRIOBP-1, -4, and -5. In TRIOBP-4/5 knockout mice, stereocilia rootlets failed to develop and hair cells subsequently degenerated resulting in profound deafness. We have been investigating the structural basis of TRIOBP function. We are determining the number and sequence of the actin binding sites in TRIOBP-4, and their interaction with actin filaments using in vitro biochemical assays and cell biological methods. TRIOBP-4 has two repeated domains, R1 and R2 and we hypothesized that these would be the binding sites to F-actin. To test this, we purified TRIOBP-4 mutants with either the R1 or R2 domain removed. These deletion mutants of TRIOBP-4 were still able to form F-actin bundles. F-actin bundle dynamics were visualized by TIRF microscopy in real time. Localization and actin dynamics in the cells were observed. We found that the repeat sequences, R1 and R2, have different mechanisms for actin bundling formations.

217

Optimising models to examine the specificity of anti-tropomyosin compounds for Tm5NM1.

T. T. Bonello[1], J. Stehn[1], S. Hitchcock-DeGregori[2], I. Dixon[3], P. Gunning[1]; [1]Department of Pharmacology, University of New South Wales, Sydney, NSW, Australia, Sydney, Australia, [2]Department of Neuroscience and Cell Biology, Robert Wood Johnson Medical School, Piscataway, NJ, Piscataway, NJ, [3]Genscreen Pty Ltd, Melbourne, VIC, Australia, Melbourne, Australia

Disrupting the actin cytoskeleton of cancer cells represents an attractive chemotherapeutic strategy. However given the critical role of actin in all cellular functions, a more refined approach is necessary to prevent excessive toxicity. The actin cytoskeleton is organised into functionally distinct compartments by a repertoire of low and high molecular weight (LMW/HMW) tropomyosin isoforms. Malignant cells demonstrate an increased reliance on a subset of LMW tropomyosins. Importantly, these isoforms are distinct from muscle tropomyosins regulating sarcomeric contraction. Using a novel class of anti-tropomyosin compounds we have demonstrated preferential disruption of endogenous LMW tropomyosin-containing actin filaments in SHEP neuroblastoma and SK-MEL-28 melanoma cells. Ascertaining the specificity of the compounds for Tm5NM1 has proven more challenging given that Tm5NM1 is a structural protein with no simple functional readout by which to assess activity. OBJECTIVE: We aim to optimise assays which will allow us to investigate the nature and specificity of the Tm5NM1-compound interaction. SUMMARY OF RESULTS: Drug-induced changes to the alpha-helical structure of LMW isoform Tm5NM1 were measured by circular dichroism (CD). Preliminary CD findings revealed a more stable secondary structure of Tm5NM1 model peptides in the presence of drug. We next sought to investigate the effect of drug binding on the function of Tm5NM1 as a regulator of the actin filament. While the compounds tested did not alter the affinity of Tm5NM1 for filamentous actin, Tm5NM1 bound with greater cooperativity in the presence of the drug. Further to this, the slowed rate of actin filament elongation seen with Tm5NM1 saturation was reversed in the presence of compound. Therefore, we postulate that

Tm5NM1 targeting compounds may act to alter actin filament dynamics. Tm5NM1 has also been shown to enhance actin-activated myosin II ATPase activity. The effect of Tm5NM1 targeting compounds on the actomyosin II ATPase activity is the focus of further investigation. CONCLUSIONS: We have described a novel class of compounds which modulate the activity of Tm5NM1 and may serve as a valuable tool for dissecting the role of Tm5NM1-containing actin filaments in cellular models. These findings have significant clinical implications for targeting distinct actin filament populations involved in tumour cell function.

218

Correlation between tropomyosin-binding and actin-capping abilities of tropomodulin.

N. Moroz[1], R. Azevedo[1], A. Kostyukova[1,2]; [1]Neuroscience & Cell Biology, RWJMS, Piscataway, NJ, [2]School of Chemical Engineering & Bioengineering, WSU, Pullman, WA

Tropomodulin (Tmod) is an actin-capping protein that binds two tropomyosins (TM) at the pointed end of the actin filament in order to prevent further actin polymerization and depolymerization. Capping ability is highly influenced by TM and is 1000 fold greater in its presence. There are four Tmod isoforms (Tmod1-4), three of which, Tmod1, Tmod3 and Tmod4, are expressed in skeletal muscles. Earlier studies revealed that Tmod/TM interactions are isoform-specific. It was found that the affinity of Tmod1 to skeletal striated αTM (stTM) is higher than that of Tmod3 and Tmod4. In this study, we used synthetic peptides corresponding to the first and second TM-binding sites of Tmod1 to measure affinities by circular dichroism. We showed that mutations R11K, D12N and Q144K in TM-binding sites of Tmod1 decreased the affinity of Tmod1 to stTM and made it similar to that of Tmod3 and Tmod4. To find out if these mutations affect actin-capping properties, they were introduced into full length Tmod1. TM-dependent actin-capping ability of Tmod1, wild type and mutants, was tested using a pyrene-actin polymerization assay. We showed a significant decrease of inhibition of actin pointed-end polymerization in the presence of Tmod1 [R11K/D12N/Q144K] as compared with wild type Tmod1. This indicates a direct correlation between TM-binding and actin-capping abilities of Tmod. We suggest that actin-capping ability of Tmods depends on their TM-binding affinity and therefore preferential binding of Tmod isoform to actin filament should depend on TM isoform, associated with these filaments.

219

Identification and Functional Analysis of Conserved Residues in Fission Yeast Tropomyosin.

M. Pamula[1], Y. Hong[2], B. Barua[3], B. Desai[3], R. Trent[4], N. Walworth[5], S. Hitchcock-DeGregori[3]; [1]Molecular Biology & Biochemistry, Rutgers University, Piscataway, NJ, [2]Genetics, Rutgers University, [3]Neuroscience & Cell Biology, Robert Wood Johnson Medical School, Piscataway, NJ, [4]Rutgers University, [5]Pharmacology, Robert Wood Johnson Medical School

Tropomyosin (Tm) is a global regulator of actin filament function. We have taken a bioinformatics approach in a structure-function analysis of this protein in Schizosaccharomyces pombe. S. pombe has a single, essential Tm gene (cdc8) that is required for required for growth, formation of the contractile ring and actin cables, for normal transport of actin-containing dots on the cables, and for normal conjugation. S. pombe Tm, like its vertebrate counterparts, regulates formin function, inhibits actin crosslinking and severing proteins, and can inhibit or activate myosin activity, depending on the myosin isoform. Our objective is to identify the regions and residues required for these universal functions. We posit that that mutation of specific conserved residues in tropomyosin will affect these, and have unanticipated effects in this model system. First, we constructed a phylogenetic tree of 30 fungal protein sequences from 27 species using maximum-likelihood and Bayesian analyses. Then, the substitution rates

at individual codon sites was determined using PAML to identify the most conserved residues. Many of the conserved codons are also conserved in animal Tm sequences, even though the fungal sequences are shorter, spanning the length of four or five actin subunits, compared to six or seven for animal Tms. We have screened a series of mutants of 22 conserved residues (amino acid residues 6, 16, 23, 30, 41, 58, 82, 86, 93, 96, 103, 104, 107, 110, 114, 117, 118, 121, 131, 138, 139, 153) in 16 mutants for the ability to rescue growth of a cdc8-ts mutant (cdc8-27) at the restrictive temperature (35 oC) when overexpressed in a pREP41 vector. Most of the mutated residues are in the surface positions of the Tm coiled coil, those most likely to be available for interacting with other proteins. While all except two of the mutants rescue growth at 35 oC, we have observed subtle differences when monitoring the nuclear number (DAPI staining), actin cytoskeleton (phalloidin staining) and septum formation (Calcofluor staining) with time after transfer to the restrictive temperature. These differences include the position and number of nuclei, cellular shape and length distribution, position and organization of the septum and contractile rings, and the frequency of abnormal cell divisions. The results will give insights into Tm-dependent cellular functions that can be corroborated by genetic experiments as well as in vitro analysis of purified proteins. Supported by MDA, NIH, Aresty Research Center for Undergraduates at Rutgers University.

Multiple nonmuscle tropomyosin isoforms perform overlapping but distinct functions in *Drosophila.*

L. Goins[1], R. D. Mullins[1]; [1]Cellular and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA

Nonmuscle tropomyosin (Tm) is an actin-binding protein, which is implicated in many cellular processes, including locomotion, intracellular trafficking, and cytokinesis. Metazoans typically express multiple non-muscle isoforms of Tm (up to 40 isoforms from four different genes in humans). Although previous studies indicated that *Drosophila melanogaster* expresses only one nonmuscle isoform (Tm1PA) from two different genes, we have discovered that *Drosophila* S2 cells express at least two additional nonmuscle Tm isoforms, using a combination of immunoblotting, RT-PCR, and RNAi. Using double-stranded RNAs targeting specific isoforms, we found that different isoforms may perform overlapping but distinct cellular functions. Knockdown of a subset of Tm isoforms results in aberrant cell spreading and increased adhesion, while knockdown of a different subset of Tm isoforms alters the structure and dynamics of the actin cytoskeleton at the leading edge of interphase cells. Knockdown of all known isoforms from both Tm genes perturbs cytokinesis in S2 cells. Given the diversity of phenotypes, we are currently exploring how these Tm isoforms play different roles in the actin cytoskeleton. We have found that fluorescently tagged Tm isoforms exhibit different localization patterns and retrograde flow rates in S2 cells, which may indicate the presence of two distinct Tm bound actin networks. Our preliminary results suggest that the isoforms are differentially regulated by acetylation, and that this may affect their affinity for filamentous actin. We speculate that differences in their affinities for filamentous actin and their effects on actin regulatory factors (such as cofilin and myosin II) underlie the functional differences between the different isoforms.

Higher-Order Actin-Based Structures

Entrapment of Intracytosolic Bacteria by Septin Cage-Like Structures.

S. Mostowy[1], P. Cossart[1]; [1]Bacteria Cell Interactions, Institut Pasteur, Paris, France

Actin-based motility is used by various pathogens for dissemination within and between cells. Yet host factors restricting this process have not been identified. Septins are GTP-binding proteins that assemble as filaments and are essential for cell division. However their role during interphase has remained elusive. We have discovered that septin assemblies are recruited to different bacteria that polymerize actin. We observed that intracytosolic *Shigella* either become compartmentalized in septin cage-like structures or form actin tails. Inactivation of septin caging increases the number of *Shigella* with actin tails and enhances cell-to-cell spread. TNF-α, a host cytokine produced upon *Shigella* infection, stimulates septin caging and restricts actin-tail formation and cell-to-cell spread. Finally we show that septin cages entrap bacteria targeted to autophagy. Together these results reveal an unsuspected mechanism of host defense that restricts dissemination of invasive pathogens, and highlight the septins as a novel and unconventional component of the cytoskeleton.

222

The Shs1p C-terminus is required for septin ring geometry and cell morphology.

R. A. Meseroll[1], A. S. Gladfelter[1]; [1]Department of Biological Sciences, Dartmouth College, Hanover, NH

Septins are a class of conserved GTP-binding proteins that function in diverse cellular processes. Individual septin proteins assemble into hetero-oligomeric complexes, which can further polymerize into nonpolar filaments. These filaments complex to form higher-order structures, including rings and bundled filaments, that function in cytokinesis and act as membrane barriers. Although *in vitro* analyses have unveiled the composition and arrangement of individual septin filaments, the mechanisms of septin assembly into the higher-order structures seen *in vivo* are not well understood. The filamentous fungus *Ashbya gossypii* expresses five septins (Cdc3p, Cdc10p, Cdc11p, Cdc12p, and Sep7/Shs1p) that localize to hyphal tips and form cortically-attached rings throughout the hyphae. These rings maintain a persistent but dynamic association with the plasma membrane over many hours of growth. We have shown that the kinases Elm1p and Gin4p regulate the stable association of septin structures with the cell cortex. A possible kinase target is the C-terminus of Shs1p, a region containing nine phosphorylation sites that we have identified by mass spectrometry. Additionally, the Shs1p C-terminus harbors a predicted coiled-coil domain, which may play a role in septin-septin interactions. Expression of Shs1p lacking the C-terminus as the only Shs1p in *Ashbya* results in aberrant formation of a specific subset of septin rings that arise at hyphal branch points. Branch rings containing Shs1ΔC-GFP assemble extra cortical filamentous extensions adjacent to otherwise normal-appearing rings. Shs1ΔC-GFP immunoprecipitates with the other four septins, indicating that a loss of septin complex association is not the cause of the aberrant branch ring phenotype. Time-lapse microscopy reveals that the extensions appear concurrently with the septin ring formation, suggesting that loss of the C-terminus of Shs1p leads to misregulation of the septin assembly process, specifically an inability to scale the ring properly at assembly. In addition to septin abnormalities, these cells display increased hyphal branching frequency, suggesting that either the C-terminus of Shs1p is required for normal cell morphology and/or that aberrantly scaled septin rings can alter sites of polarity. We hypothesize that the phosphorylation sites and/or the coiled-coil domain of Shs1p may be

responsible for the inability of Shs1ΔC-GFP to grow and form septin rings properly and are currently analyzing alleles containing point mutations in the phosphorylation sites. This work illuminates the role of specific septin domains in higher-order septin structure regulation.

Self-Organization of Cytoplasmic Actin-Myosin-Formin Network.

W. Luo[1], A. Mogilner[2], A. Bershadsky[3], M. Sheetz[4]; [1]Mechanobiology Institute, National University of Singapore, Singapore, Singapore, Singapore, [2]Department of Neurobiology, Physiology and Behavior and Department of Mathematics, University of California at Davis, USA, [3]Mechanobiology Institute, National University of Singapore, Singapore and Weizmann Institute of Science, Rehovot, Israel, Singapore, Singapore, [4]Mechanobiology Institute, National University of Singapore, Singapore and Columbia University, New York, USA, Singapore, Singapore

In eukaryotic cells, specialized actomyosin structures such as stress fibers and cytokinetic contractile ring are well known, but there is very limited understanding of the cytoplasmic actomyosin network. To elucidate this actomyosin network organization, we perturb it using Latrunculin A (LA). This treatment led to emergence of asters with diameter of 0.5-1.2μm, visualized by fluorescently tagged Lifeact or beta-actin in regions of cytoplasm not associated with remaining stress fiber or focal adhesions. These asters were very dynamic moving vigorously, often fusing with each other. Using dual color TIRF microscopy live imaging, myosin clusters were found either between or co-localized with actin aster centers, while filamin A and formin protein DAAM1 co-localized with the centers. Notably, PALM microscopy revealed that even in non-treated cells DAAM1 was localized in patches spaced similarly to the asters that emerged after the LA treatment. Actin aster movements induced by LA can be stopped by adding blebbistatin, a myosin II inhibitor, or largely reduced by treatment with formin inhibitor SMIFH2. On the other hand, in filamin A-/- cells, LA treatment resulted in formation of asters moving more rapidly and fusing and splitting more frequently than in control cells. Re-introduction of filamin A into the knockout cells decreased the asters' dynamics significantly. Increasing the level of filamin A in the control cells caused the reduced velocity or complete block of the aster motility. We developed a computational model which, in agreement with these data, suggests that myosin motors slide actin filaments into the multiple asters with centers stabilized by cross-linkers and reinforced by formin-mediated nucleation, while myosin is stabilized at the edges between the asters where its contractile action causes aster movements. Modeling suggests that the dynamic-aster mode of self-organization is optimal for mechanical connectedness of the cytoplasm in perturbed actin networks.

224

Actin Assembly Kinetics Determine the Architecture of α-Actinin Crosslinked F-actin Networks.

T. Falzone[1], M. Lenz[2], D. Kovar[3], M. Gardel[4]; [1]Biophysics Graduate Program, Institute for Biophysical Dynamics, University of Chicago, Chicago, IL, [2]James Franck Institute and Department of Physics, University of Chicago, [3]Department of Molecular Genetics & Cell Biology, Department of Biochemistry & Molecular Biology, University of Chicago, [4]Institute for Biophysical Dynamics, James Franck Institute and Department of Physics, University of Chicago

The spatial and temporal regulation of the actin cytoskeleton is required for numerous aspects of eukaryotic cell physiology including adhesion, polarity, migration, division, endocytosis, and intracellular trafficking. In concert with actin regulatory proteins, actin filaments (F-actin) are organized into bundles of axially aligned filaments or meshworks cross-linked at high angles.

Understanding the biochemical and physical processes regulating the assembly of actin filaments into meshworks or bundles is central to developing a quantitative and predictive understanding of cytoskeletal organization. Here we show that the kinetics of actin polymerization play a crucial role in controlling the morphology of *in vitro* filament networks assembled with α-actinin by a combination of quantitative imaging, microrheology and computational modeling approaches. Cross-link mediated bundle formation only occurs in dilute solutions of actin filaments with a predominately viscous microenvironment facilitating rotational and translational diffusion of actin filaments. During the time period of high filament mobility, α-actinin concentration and filament density controls the rate of bundle formation. Furthermore, we show that the network morphology can be modulated from a highly bundled network to an isotropic meshwork that by altering only nucleation kinetics. Thus, the morphology of cross-linked F-actin networks reflects a metastable state determined by the kinetics of filament nucleation, elongation and α-actinin mediated aggregation. These results underscore the importance of physical constraints in regulation of actin cytoskeletal organization into higher ordered structures in a dense and crowded cytoplasm.

225

In-vivo measurement of stress fiber contraction dynamics with high resolution and dynamics range.

B. Axelrod[1], A. Tadmor[2], M. Roukes[3]; [1]Physics, California Inst Technol, Pasadena, CA, [2]Biochemistry and Molecular Biophysics, California Inst Technol, [3]Physics, Applied Physics and Bioengineering, California Inst Technol

Force generation is critical to the regulation of many fundamental cellular processes including stem cell differentiation, tissue development, and tumor progression. Stress fibers, the principle generators of contractile forces, are linear chains of bundles of actin filaments of opposing polarity that are pulled together by bipolar myosin filaments in a manner similar, though less ordered, to muscle myofibrils. Though force was not directly measured, recent experiments suggest a surprising richness in how stress fiber dynamics regulate force and mechanotransduction.

We present a high resolution, high dynamic range Nano-Electro-Mechanical Systems (NEMS) based force measurement tool with wide applicability to measure forces generated by individual adherent cells. Which we demonstrate here with measurement of the force from a single stress fiber within a cell as the cell is perturbed by Cytochalasin D (CD) and recovers after CD removal. We measure a contraction upon initial exposure to CD of ~4nN, force steps during both CD induced force collapse and post-CD force recovery of ~1nN, and small force oscillations, ~400pN peak-peak, with frequency linearly dependent upon the cell generated force throughout.

The data validate a two part model – steady state and kinetic – of stress fiber force generation. The steady state model, adapted from recent work that features actin treadmilling and polymerization forces in addition to actomyosin contraction, describes the initial contraction and force steps. The kinetic model is based upon stochastic, abrupt failure and activation of sarcomere like units within the stress fiber and describes the overall force-time response.

This work demonstrates the ability of high performance NEMS to connect quantitative biophysical modeling with specific cell level function. With these capabilities we confirm the importance of actin polymerization dynamics in understanding stress fiber response and present a detailed mechanism by which cytochalasins reversibly disrupt cellular force generation.

226

In silico myosin motors and contractile networks.

J. Alberts[1], E. Munro[2], M. Gardel[3]; [1]Biology, University of Washington, Friday Harbor, WA, [2]Cell and Molecular Biology, University of Chicago, Chicago, IL, [3]Physics, University of Chicago, Chicago, IL

Motor proteins are critical to cells in processes such as cellular contractility, motility, cell division, and intracellular transportation and compartmentalization. Thus detailed simulations of these processes require motor representations that can be "benchmarked" to encapsulate key features of the biochemical and mechanical motor characteristics.

A biological myosin molecule is continuously flexible (with distinct regions of differing rigidity) and mechanical models might vary from molecular dynamics approaches (i.e. representation of each molecule and the various force fields of interaction) to multiple rigid bodies connected by springs, to simple elastic representations. Ever more detailed and physically realistic models of a motor protein have the potential to capture finer facets of motor behavior, but at a computationally cost.

Our eventual goal with this model is to simulate very large networks of actin filaments, myosin motors, and crosslinkers. Thus a very simple and computationally inexpensive motor representation is appropriate. We propose a two-spring myosin motor for 2-dimensional simulations. One spring is co-linear with the actin filament —this spring has the stiffness measured for a myosin crossbridge and a bi-modal rest length to enact a powerstroke— while an orthogonal spring keeps the filament and motor from drifting apart.

Each single motor is encoded through Monte Carlo methods to exhibit the measured transition rates between biochemical states (i.e. the state of the bound nucleotide). The ADP-release rate is modulated by force-state, as indicated by experiment. The model prescribes a 5.5nm step-size and a measured value for crossbridge stiffness, which guarantees appropriate force interaction between filament and myosin with each powerstroke.

We show that groups of motors exhibit the expected average duty-ratios. In *in silico* gliding filament assays filaments demonstrate appropriate speed dependence and eventual saturation with increasing myosin density. And under resisting loads these model motors can reproduce the expected concave force-speed curve.

As an element in networks with filaments and crosslinkers we demonstrate how these motors can lead to filament buckling and different contractile topologies, dependent on motor heterogeneity and density.

227

Actin pattern formation in reconstituted actomyosin cortices.

S. K. Vogel[1], P. Schwille[1]; [1]Institute of Biophysics, BIOTEC/TU Dresden, Dresden, Germany

In eukaryotic systems the actomyosin cortex is involved in fundamental processes such as cytokinesis, cell migration and cell polarization. Actomyosin contractility is involved in the generation of cortical flows helping cells to polarize, which is essential for asymmetric cell division and hence for the development of multicellular organisms. In *Caenorhabditis elegans* zygotes cortical flows are accompanied by the formation of dynamic actomyosin networks. However, the physical relation between actomyosin contractility, network formation and cortical flows are not well understood.

We therefore set out to build minimal *in vitro* systems, namely consisting of membrane bound actin filaments and myosin (filaments) motors in order to reconstitute and mimic general features of contractile actomyosin cortices present in model organisms. In particular, we aim to understand the behavior of motor filaments and the role of the membrane during actomyosin network formation.
By imaging fluorescently labeled actin and myosin filaments with TIRF microscopy we show that the addition of myosin filaments to the membrane bound actin layer leads to the formation of interconnected actin clusters. By varying the density of the membrane bound actin layer we obtain different morphologies of the actin pattern after addition of the motors. We demonstrate that similar to active gels in bulk solution, the process of actin pattern formation depends on the concentration of ATP. At saturating ATP concentration actin pattern formation is inhibited, while lowering the ATP concentration to a critical level leads to the formation of actin clusters. This process is reversible by the addition of ATP to actomyosin clusters thereby resuming the original morphology of the actin meshwork. However, addition of the crosslinker Fascin at ATP saturating conditions leads to pattern formation, although more slowly. This indicates that crosslinking is necessary for the contraction of the actin filament layer. Visualization and tracking the motion of individual fluorescently labeled myosin filaments revealed that the processivity of the motor filaments increases when the ATP concentration is lowered. We propose that upon ATP depletion some myosin filaments start to function as crosslinkers inducing the actin meshwork contraction. We hypothesize that the concomitant overall increase of the processivity of myosin filaments further accelerates the contraction of the actin filaments into actomyosin clusters.

228

Thickness and dynamics of the actomyosin cortex.

A. G. Clark[1], K. Dierkes[2], S. Simmert[1], E. Paluch[1]; [1]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, [2]Max Planck Institute for the Physics of Complex Systems, Dresden, Germany

Cellular shape changes are, in essence, mechanical processes that are governed by the physical properties of the cell. One physical property in particular that has been implicated in cell shape change is tension, which is controlled by the actomyosin cortex, a thin layer of proteins that directly underlies the plasma membrane. Cell tension arises from two major properties of the cortex: (1) the amount of stress generated by myosin motors within the cortex and (2) cortex thickness. In order to further understand the regulation of cortical tension, we have developed an assay to measure cortex thickness in living cells that relies on a precise, quantitative analysis of fluorescence images of the cortex and the plasma membrane. In this assay, we measure cortex thickness by determining the spatial separation between the cortex and the plasma membrane, and we have used this technique to track changes in thickness during dynamic cell shape changes, including bleb retraction and cell division. Furthermore, we have used a similar image analysis approach, combined with the use of photoactivatable probes, to investigate the dynamics and spatial regulation of actin assembly in the steady-state cortical network. By interpreting these photoactivation data through a simple geometrical description of the cortex, we are not only able to more precisely extract information about the spatial dynamics of actin assembly, but we also attain an independent measurement of cortex thickness that is consistent with our thickness measurements using cortex and membrane peak separation. Comparing the results of these experiments with photobleaching data, we are further trying to understand the regulation of actin dynamics and thickness at different stages of the cell cycle, both in order to uncover the underlying mechanisms involved in previously observed changes in cells' physical properties and shape throughout the cell cycle and also to more generally determine the relationship between cortical actin dynamics and cortex thickness.

The understanding of such relationships and of the basic principles of cortical actin dynamics are essential in understanding how the coordinated actions of these proteins contribute to larger-scale physical properties.

229

Actin network architecture determines myosin motor activity.

A-C. Reymann[1], R. Boujemaa-Paterski[1], J-L. Martiel[1], W. Cao[2], H. Chin[2], E. De La Cruz[2], M. Théry[1], L. Blanchoin[1]; [1]Institut de Recherches en Technologies et Sciences pour le Vivant, CNRS/CEA/INRA/UJF, Grenoble, France, [2]Department of Molecular Biophysics and Biochemistry,Yale University, New Haven, CT

The organization of actin filaments into higher-ordered networks governs overall eukaryotic cell shape, mechanical integrity and directed movement. The global architecture of the actin cytoskeleton is determined by coordinated actions of a large number of actin regulatory proteins that modulate filament assembly and disassembly dynamics. Myosin motors also plays a critical role in these processes and reorganize filament structures through sliding (e.g. contractility) and/ or depolymerization. Understanding the molecular mechanism of such complex spatiotemporal orchestration is extremely challenging in cells, where hundreds of different proteins act simultaneously on overlapping actin sub-structures. Here, we use geometrically controlled and polarized in vitro actin networks to evaluate how myosin motors influences filament architecture. Direct visualization of filaments indicates that myosins selectively disassemble randomly-oriented and anti-parallel actin filament structures while parallel actin filament bundles are unaffected by myosin contractility. This “orientation selection” reveals how the overall organization and dynamics of the actin cytoskeleton is controlled by actomyosin contractility. General principles governing the spatial organization of actin filaments in cells emerge from this work.

230

Spatial structure of actin cytoskeletons associated with nuclear membrane.

J. Usukura[1], S. Minakata[2]; [1]EcoTopia Science Institute, Nagoya University, Nagoya, Japan, [2]School of Engineering, Nagoya University, Nagoya, Japan

Current study aims to elucidate the spatial organization of cytoskeletal actin filaments in the cytoplasm with special reference to the association with nuclear membrane and its alternations during cell cycle. Cytoskeletal actin filaments in living cell have been investigated so far exclusively with fluorescent light microscopy in conjunction with GFP tag method. However, fine structural changes with time were not detected well. Observation was restricted on the stress fiber with relatively strong fluorescence and at ventral side of the cell. We compared live cell images with electron microscopic images in a strict sense. In order to detect real spatial structure of cytoskeleton, high voltage TEM (1000 KV), high resolution SEM and immune-freeze etching technique were applied to unroofed whole cells in addition to light microscopic live cell imaging . Our innovative methods arrested incredibly more abundant actin filaments besides the stress fibers than in fluorescent microscopy. Remarkable amount of fine actin filaments occupying the whole cytoplasm extended in all directions with aggregation and dispersion to form meshwork, and eventually divided cytoplasmic space into several domains. Furthermore many stress fibers as well as non-bundled actin filaments attached onto the nuclear membrane while associating with intermediate filaments. On closing to the M phase, stress fibers were disappeared together with the nuclear membrane for a short time (within one minute). Therefore, stress fibers seem to play an important role to disperse the nuclear envelope, though mesh work formed by fine actin filaments was not changed significantly. Then, restoration of

nuclear envelope took a long time more than 20 minutes after mitosis, when stress fibers were formed again gradually.

231

Retinoic acid controls cultured and harvested epithelial cell sheet's shrinkage via the regulation of actomyosin contraction.

M. Kondo[1], M. Yamato[2], D. Murakami[3], R. Takagi[2], K. Nishida[4], T. Takenawa[3], H. Namiki[1], T. Okano[2]; [1]Graduate School of Advanced Science and Engineering, Bioscience and Biomedical Engineering, Waseda University, Tokyo, Japan, [2]Institute of Advanced Biomedical Engineering and Science, and Global Center of Excellence (COE) prog, Tokyo Women's Medical University, Tokyo, Japan, [3]Graduate School of Medicine, Kobe University, Kobe, Japan, [4]Graduate School of Medicine, Osaka University, Osaka, Japan

Primary oral mucosal epithelial cells show a self-stratification similarly to those in vivo under optimum culture condition supplemented with serum. After being incubated in 20 ºC for 30 min, confluent cells on a poly(*N*-isopropylacrylamide)-grafted temperature-responsive cell culture insert spontaneously detached themselves as a contiguous cell sheet. Interestingly, the harvested cell sheets shrank to approximately 30% of their initial size. By utilizing the culture insert, stratified epithelium-like cell sheets were also harvested even without serum, and the harvested cell sheets failed to show any shrinkage. In addition, the cell adhesion ability to culture substratum was significantly weak under serum-free culture condition. Therefore, we hypothesized that these differences depend on cell cytoskeleton and attempted to investigate cytoskeletal organization of cell sheets.
Several cytoskeletal inhibitors were added in a serum-containing cell sheet culture system. Shrinkage of each harvested cell sheet was inhibited when actin polymerization, Rho kinase, myosin light chain kinase, and myosin ATPase were inhibited for 24 h before the cell sheet harvest, while intermediate filament or microtubule inhibition showed no effect. In addition, ATP synthesis inhibitor NaN_3 also inhibited the shrinkage. These results strongly indicate that cell sheet shrinkage was controlled by an actomyosin contraction. HE staining showed the thickness of harvested cell sheet in serum-free condition was thinner than that of serum-containing culture. Lysophosphatidic acid and thrombin, which are known as Rho activating factors, showed no effect on the cell sheet shrinkage. Furthermore, the receptor antagonists of these receptors were added in serum-containing culture, but no shrinkage was inhibited. Retinoic acid, an epidermal proliferation and differentiation regulator contained in serum, was added to oral mucosal epithelial cell culture, resulting in shrinkage similar to the serum-containing condition. Moreover, the shrinkage was suppressed by the actomyosin specific inhibition.
In conclusion, the cell sheet shrinkage was found to depend on cytoskeleton organization, especially on actomyosin contraction, and the cell sheet shrinkage via actomyosin contraction was regulated by retinoic acid.

232

Supervillin couples myosin-dependent contractility to podosomes and enables their turnover.

R. Bhuwania[1], S. Cornfine[1], T. Smith[2], Z. Fang[2], M. Krüger[3], E. Luna[2], S. Linder[1]; [1]University Medical Center Eppendorf, Hamburg, Germany, [2]University of Massachusetts Medical School, Worcester, MA, [3]Max-Planck-Institute for Heart and Lung Research, Bad Nauheim

Podosomes are actin-rich adhesion and invasion structures. Especially in macrophages, podosomes exist in two subpopulations, large precursors at the cell periphery and smaller podosomes (successors) in the inner cell regions. To date, the mechanisms that differentially regulate these subpopulations are largely unknown. Here, we show that the membrane-

associated protein supervillin localizes preferentially to successor podosomes and becomes enriched at precursors immediately prior to their dissolution. Consistently, podosome numbers are inversely regulated by supervillin protein levels. Using deletion constructs, we find that the myosin II-regulatory N-terminus of supervillin (SV 1-174) is crucial for these effects. Moreover, phosphorylated myosin light chain (MLC) localizes at supervillin-positive podosomes, and time-lapse analyses show that enrichment of EGFP-supervillin at podosomes coincides with their coupling to contractile myosin IIA-positive cables. Because supervillin binds only to activated myosin IIA, and a dysregulated N-terminal construct (SV 1-830) enhances phospho-MLC levels at podosomes, preferential recruitment of supervillin to podosome subpopulations may both require and induce actomyosin contractility. Importantly, using siRNA-treated cells, we demonstrate that supervillin and myosin IIA cooperate to regulate podosome life time, podosomal matrix degradation and cell polarization. In sum, we show here that podosome subpopulations differ in their molecular composition and identify supervillin, in cooperation with myosin IIA, as a critical factor in the regulation of podosome turnover and function.

233

The scaffolding protein EPB50 is a highly dynamic and essential component of microvilli regulated by its PDZ interactions.

D. Garbett[1], A. Bretscher[1]; [1]Molecular Biology and Genetics, Cornell University, Ithaca, NY

Most cells are or have the potential to be polarized. Polarity requires the ability to control the protein composition of the plasma membrane in time, in location, and in response to signaling pathways. A well-studied example is epithelial cells that have distinct apical and basolateral domains. Microvilli, which define the apical surface of epithelial cells, are dynamic finger-like protrusions of the apical membrane supported by bundled filamentous-actin (F-actin) cores. Despite their abundance on many cell types, the regulation of microvilli remains poorly understood. One regulator is Ezrin Binding Phosphoprotein of 50 kD (EBP50), a microvillar scaffolding protein with two PDZ domains followed by a C-terminal ezrin binding domain. We have shown that both the first PDZ and ezrin binding domains of EBP50 are required for microvillar formation, and that phosphorylation regulates its ability to engage multiple PDZ ligands simultaneously. Because of the dynamic nature of microvilli, we are currently investigating the dynamics of microvillar components using both FRAP and photo-activation in live epithelial cells. We were surprised to find that EBP50 is extremely dynamic compared to other microvillar proteins. Of particular interest is how EBP50 can exhibit such high turnover compared to ezrin, which binds to EBP50 with 1-3nM affinity in vitro. Surprisingly, we also find that mutation of either of EBP50's PDZ domains results in reduced turnover in microvilli and that this is due to an increased association with ezrin, a much less dynamic regulator of microvilli. These unexpected results require dramatic revision to current models of microvillar regulation and rethinking as to how a cytoskeletal scaffolding protein is able carry out its structural function amid such rapid molecular turmoil.

234

PKC phosphorylation of cortactin is implicated in the regulation of actin dynamics.

H. Yamada[1], T. Abe[1], T. Masumoto[2], M. Sei[1], T. Kikuchi[1], K. Tomizawa[3], S. Ikeda[1], H. Matsui[2], K. Takei[1]; [1]Neuroscience, Okayama University, Okayama, Japan, [2]Cell Physiology, Okayama University, Okayama, Japan, [3]Molecular Physiology, Kumamoto University

Actin bundle formation is essential for variety of cellular events including the formation of neuronal growth cones. Recently we have reported that dynamin 1-cortactin ring complexes bundle actin filaments in growth cone filopodia (Takei et al., 2010, 50th ASCB meeting). In the present study, we show that PKC phosphorylation of cortactin is implicated in the actin

dynamics in the growth cone. Cortactin was rapidly phosphorylated in metabolically ^{32}P-labeled NG108-15, a human neuroblastoma cell line, during growth cone collapse by LPA. The phosphorylation was inhibited by Ro-31-8220, a PKC inhibitor, indicating that cortactin is a substrate for phosphorylation by PKC. By double immunofluorescence of SH-SY5Y, cortactin colocalized with PKCα, an isoform enriched in SH-SY5Y, along the growth cone filopodia. Cortactin and PKCƒ¿ interacted as confirmed by immuneprecipitation. Treatment of SH-SY5Y with phorbol 12-myristate 13-acetate (PMA), a protein kinase C activator, increased cortactin-PKCα interaction simultaneously with PMA-induced growth cone collapse. Consistently, cortactin-dependent actin bundle formation in vitro was reduced by cortactin phosphorylation via PKCα. MALDI-MS analysis revealed multiple PKC phosphorylation sites of cortactin. Taken together these results strongly suggest that PKC phosphorylation of cortactin represents a mechanism involved in the regulation of actin dynamics in growth cones.

235

The Role of Protocadherin 24 in Enterocyte Brush Border Assembly.

S. W. Crawley[1], S. Mao[1], J. E. Heuser[2], M. J. Tyska[1]; [1]Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN, [2]Cell Biology and Physiology, Washington University School of Medicine, St. Louis, MO

Intestinal epithelial cells (IECs) possess a highly ordered apical array of actin-based, membrane protrusions known as microvilli. Collectively, these microvilli form the brush border, which is known to play a key role in both nutrient absorption and host-cell defense. A mature, functional brush border is characterized by ~1000 tightly packed microvilli, which extend into the gut lumen to a near identical length. Despite playing a critical role in gut function, little is known about the molecular mechanisms underlying brush border assembly during enterocyte differentiation. Using the CACO-2_{BBE} cell culture model system, we observed that microvilli cluster together during enterocyte differentiation, interacting with each other at their distal tips to form ‘tepee’-shaped structures. High magnification images of these clusters revealed that microvilli are physically connected to one another by thread-like links. Similarly, quick-freeze deep-etch electron microscopy of native intestinal tissue revealed an extensive network of inter-microvillar links that exists within a mature brush border. Towards the goal of identifying the constituent(s) of these links, we have identified and characterized the functional role of a cadherin superfamily member, protocadherin-24 (PCDH24), which exhibits striking enrichment at the tips of microvilli of both CACO-2_{BBE} cells and native intestinal tissue. PCDH24 is composed of 8 extracellular cadherin domains, a single-pass transmembrane spanning region and a short cytoplasmic tail. Over-expression of PCDH24 in CACO-2_{BBE} cells was correlated with microvillar clustering, while knockdown resulted in an abnormal brush border assembly, in which cells lost the ability to form a tightly packed brush border, with microvilli of uniform length. Pull-down analysis using a tagged PCDH24 cytoplasmic domain incubated in CACO-2_{BBE} cell lysates demonstrated an interaction with the molecular scaffold protein harmonin-a. Harmonin-a colocalized with PCDH24 at the tips of microvilli of CACO-2_{BBE} cells and native tissue. A yeast-two-hybrid screen identified an interaction of harmonin-a with the motor protein, Myo7b. Similar to PCDH24 and harmonin-a, Myo7b was found to localize to the distal tips of microvilli in CACO-2_{BBE} cells and native tissue. We propose that PCDH24, harmonin-a and Myo7b form a complex, which localizes to the distal tips of microvilli and functions to promote the tight packing and uniform length of microvilli during brush border assembly.

236

Regulation of Macrophage Podosome Patterning by Proline-Serine-Threonine Phosphatase Interacting Protein 1 (PSTPIP1).

T. W. Starnes[1], A. Huttenlocher[1,2]; [1]Medical Microbiology and Immunology, University of Wisconsin, Madison, WI, [2]Pediatrics, University of Wisconsin

The autoinflammatory disease, pyogenic sterile arthritis, pyoderma gangrenosum and acne (PAPA) syndrome, results from mutations that appear to activate PSTPIP1. PAPA syndrome patients suffer from uncontrolled, phagocyte-mediated inflammation in the skin and joints, but the reason for this accumulation has remained unclear. PSTPIP1 is a member of the F-bar family of proteins and has important interactions with the actin nucleating protein, WASp, features which suggested that it could play a role in cytoskeletal regulation. We therefore tested the hypothesis that PSTPIP1 would regulate the function of macrophage podosomes, which are actin-based structures that mediate adhesion, chemotaxis, and ECM degradation in myeloid-lineage cells. Lentiviral transduction of shRNA targeting PSTPIP1 resulted in an approximately 90% decrease in PSTPIP1 expression in the human monocyte cell line, THP-1. Differentiation of the THP-1 cells on fibrinogen-coated cover slips and staining for actin and vinculin revealed that PSTPIP1 deficiency caused increased formation of highly-organized podosome rosettes. One of the unique functions of podosomes, as compared to other adhesion types, is the ability to degrade extracellular matrix. We found that PSTPIP1 deficient THP-1 macrophages had an increased ability to degrade a fluorescent-gelatin extracellular matrix as compared to controls. Preliminary data suggest that rescuing the PSTPIP1 knockdown with a form mutated in PAPA syndrome results in reduced podosome number, organization, and degradative capacity as compared to controls. These results suggest that the normal function of PSTPIP1 is to inhibit podosome organization, and that this inhibitory feature is amplified in PSTPIP1 mutants. The correlation of increased podosome organization and degradative capacity is consistent with studies in osteoclasts that demonstrate the necessity of podosome rosette formation prior to degrading bone matrix. Preliminary data also show that PSTPIP1 deficiency also results in decreased chemotaxis of THP-1 monocytes to CCL2. These findings imply that PSTPIP1 is important for podosome patterning and chemotaxis in macrophages. Additionally, they suggest that a potential mechanism underlying phagocyte accumulation in the skin and joints of PAPA syndrome patients is the altered interaction of macrophages with the ECM via dysregulation of podosomes.

237

Extraction and Analysis of 3D Cytoskeletal Networks Based on Open Active Contour Models.

T. Xu[1], H. Li[1], T. Shen[1], D. Vavylonis[2], X. Huang[1]; [1]Department of Computer Science and Engineering, Lehigh University, Bethlehem, PA, [2]Department of Physics, Lehigh University, Bethlehem, PA

Network structures formed by actin and microtubule filaments are present in many kinds of fluorescence microscopy images. To quantify their conformations and dynamics, we propose a fully automated method to extract these networks and analyze their topology. This method handles well intersecting filaments, and can also detect relatively faint structures from noisy microscopic images in both 2D and 3D. First we automatically initialize a large number of Stretching Open Active Contours (SOACs) from ridge points in a multi-scale fashion. These SOACs then elongate along the bright centerlines of laments by minimizing an energy function. During their evolution, they merge and stop growing at junctions, forming a network that represents the topology of the filament ensemble. We further dissect converged SOACs at junctions and reassemble these SOAC segments by a graph-cut spectral clustering method,

respecting continuity at junctions. The proposed approach is generally applicable to extracting network and intersecting curvilinear structures in noisy 2D and 3D images. We demonstrate its potential using two kinds of data: (1) actin filaments imaged by Total Internal Reflection Fluorescence Microscopy (TIRFM) in vitro in 2D; (2) 3D actin cytoskeleton networks formed by actin filaments in fission yeast imaged by spinning disk confocal microscopy in live cells. Results have shown that the method can not only extract the skeleton of the networks but also reveal quantitative information of their topology.

Time fluctuation of single cell rheology by atomic force microscopy.

P. Cai[1], Y. Mizutani[1], M. Tsuchiya[1], T. Okajima[1]; [1]Hokkaido University, Sapporo, Japan

Living cell is a soft viscoelastic material, which is strongly related to the highly dynamic and continuous remodeling of cytoskeleton. Previous studies have consistently revealed that the ensemble-averaged rheological properties, e.g. the complex shear modulus, G*, of various types of cells forced in an external stress followed a power-law rheology. However, it is little known how G* fluctuates in time and the time distribution is related to the ensemble one. Here we investigated the time distributions of G* of single mouse fibroblast cells, which were arranged on microarray, for t = 2.5 h by atomic force microscopy (AFM) as a function of frequency, f. It was observed that (1) the frequency dependence of time-averaged G* followed a power-law rheology, (2) the time distribution of G* exhibited a log-normal distribution, and (3) the variation of the time distribution, σ, decreased with increasing f. These results were similar to those observed in the ensemble (cell-to-cell) measurements. Moreover, we found that σ varied in each cells and was small compared with the ensemble variation and that σ(t) of time distribution attained a constant value at ~ 2 h. The results indicate that single cells are weekly trapped in a partial region in their possible states of single cell rheology.

Alterations of Cell Edge Dynamics and Actin Cytoskeleton Define Migration Properties of Transformed Fibroblasts.

M. Lomakina[1], M. Shutova[1,2], T. Svitkina[2], A. Alexandrova[1]; [1]Russian Cancer Research Center, Moscow, Russia, [2]University of Pennsylvania, Philadelphia, PA

Leading edge protrusion plays an important role in cell migration. It is well known that neoplastic transformation is accompanied by significant changes in the cytoskeletal organization and leads to enhanced invasion and metastasis of malignant cells. However, specific behavioral and cytoskeletal changes accompanying the invasive phenotype are poorly understood. In this study, we investigated distribution, dynamics, and the cytoskeletal architecture of leading edge protrusions in control fibroblast cell lines and their transformed derivatives, and compared these parameters to the cell migratory phenotypes. The most significant differences between transformed and non-transformed cell types were found their protrusive behavior. Two studied control cell lines, human skin fibroblasts (1036) and human embryo lung fibroblasts (MRC5), had an elongated polarized cell shape and a dominant leading edge. More rarely, a few protrusive areas were observed. In contrast, the corresponding transformed cell lines, human fibrosarcoma HT-1080 and SV-40-transformed MRC5 cells (MRC5-V1 and MRC5-V2), were poorly polarized and had multiple protrusion, frequently in the form of ruffles. However, the percentage of cell perimeter occupied by protrusions was significantly greater in transformed cells (up to 95% in HT-1080 cells) than in control fibroblasts, where protrusion-containing cell edges occupied ~50% of cell perimeter. Kymograph analysis revealed that lamellipodia of transformed cells advanced a shorter distance in each cycle than control cells, but the frequency of protrusions was increased compared to control cells. Importantly, although

transformed cells moved slower and more randomly than control fibroblasts in 2D cultures, they displayed an increased transmigration in Boyden chambers and greater invasion of Matrigel. Additional differences revealed in transformed fibroblasts included smaller and more randomly organized stress fibers and focal adhesions, a decreased cell area, and an increased thickness of lamellae, as compared to control cells. We propose that observed redistribution of the protrusive activity, together with changes in the actin cytoskeleton and the leading edge dynamics, leads to altered motile behavior of transformed fibroblasts suitable for invasive migration.

Microtubule Dynamics and Its Regulation I

240

An imaging based survey of CLASP-interacting protein functions in regulating microtubule dynamics.

J. Baughman[1], M. Bagonis[1], G. Danuser[1], D. Van Vactor[1]; [1]Cell Biology, Harvard Medical School, Boston, MA

The microtubule (MT) cytoskeleton is a key effector downstream of various signaling pathways and is subject to tight regulation in response to intrinsic and extrinsic cues, often through transient interactions with a variety of microtubule-associated proteins (MAPs). Current research in our laboratory focuses on Drosophila CLASP, a microtubule (MT) plus-end tracking protein, and its interactors. CLASP contains binding domains for both MT and actin, suggesting it may be important in coordinating MT behavior with other cellular components. In this study, we have performed a dynamic imaging-based screen to define the microtubule-regulatory functions of recently identified candidate CLASP interactors. Double-stranded RNA (dsRNA) was used to knock down expression of 45 candidates in Drosophila S2 cells. Using EB1-GFP as a marker for the growing MT plus-end, we captured time-lapse movies of cells treated with dsRNA for 72 hours and plated on Concanavalin A to facilitate their adhesion and spreading. Imaging was followed by systematic, multi-parametric quantification of microtubule dynamics using plusTipTracker, a Matlab-based open-source software. PlusTipTracker allows for a fully automatic unbiased detection, classification and analysis of changes in MT behavior. Our results suggest that we are able to detect subtle but significant changes in MT dynamics at time points where loss of protein expression has no obvious impact on gross MT morphology and/or tubulin stability as assessed using immunofluorescence. Overall, approximately 50% of the CLASP-interacting proteins significantly affected EB1 localization at the MT plus-end and/or had significant and reproducible effects on MT dynamics. As predicted from their MT assembly-promoting activities, knockdown of APC, Clip-190 and Shortstop, among other genes, cause a significant alterations in growth dynamics such as increased growth speed or decreased growth lifetimes. However, although genes thought to play similar roles in MT regulation, such as MT plus-end interacting proteins (+TIPs), showed similar phenotypes, subtle but mutually exclusive functional profiles (“fingerprints”) emerged. This suggests that these proteins act in comparable but distinct ways to regulate the cytoskeleton. For example, knockdown of p150glued and Clip190 increased MT dynamics; however, while both exhibit an increased lifetime of MT growth events, p150glued appears to affect primarily MT catastrophe and rescue while Clip190 affects the rate of transition between MT growth and pause. In addition, despite their identification as CLASP interactors, candidate actin-binding proteins showed little influence on MT dynamics in these highly adherent cells. Finally, we have demonstrated a novel role in regulating MT dynamics for proteins involved in signal transduction, protein translation, and GTP hydrolysis.

This study shows that automated quantitative analysis of MT dynamics provides a powerful tool to define and compare the specific actions of proteins that populate broad functional classes.

241

p150^{Glued} is a multifunctional microtubule modulator.

J. E. Lazarus[1], M. K. Tokito[1], E. L. Holzbaur[1]; [1]Department of Physiology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA

Dynactin subunit p150^{Glued} binds to and activates cytoplasmic dynein. However, p150^{Glued} may also have important dynein-independent effects on microtubules. Here, we determine the mechanisms by which p150^{Glued} both catalyzes microtubule nucleation and promotes microtubule polymerization. Full length native p150^{Glued} is a dimer that encodes two tandem N-terminal microtubule-binding sites: a CAP-Gly domain followed by a basic region. We find that an N-terminal monomeric construct which lacks the dimerization domain cannot nucleate microtubules. An equivalent construct dimerized by the canonical GCN4 coiled coil promotes microtubule nucleation in a robust concentration-dependent manner, significantly reducing the lag time associated with microtubule nucleation. Both the CAP-Gly and basic domains are necessary for nucleation; dimeric constructs representing physiological splice forms that lack either domain cannot nucleate microtubules. Further, a single point mutation in the CAP-Gly domain, linked to inherited Parkinsonism, is also sufficient to block nucleating activity. Using TIRF microscopy to directly observe microtubule polymerization, we also see that monomeric p150^{Glued} only weakly promotes polymerization, while dimeric p150^{Glued} containing both domains act as an anticatastrophe factor and markedly enhances polymerization, more than doubling the rate of assembly. Finally, we show by size exclusion chromatography and FRET that, while the monomeric construct binds only a single soluble tubulin subunit, dimeric p150^{Glued} forms a ternary complex with two tubulin subunits, potentially coordinating them in close lateral register. We propose that, when dimerized, the tandem CAP-Gly and basic domains of p150^{Glued} contribute to nucleation by lowering the energy of an unfavorable substep in tubulin oligomerization, and promote polymerization by locally increasing the concentration of tubulin subunits near the microtubule. These functions may be dynamically regulated in the cell by the differential expression of p150^{Glued} splice forms. Importantly, these novel functions of dynactin may be particularly relevant in the extended axonal processes of mammalian neurons, consistent with our observation that a Parkinson's disease-associated mutation abrogates function.

242

Dissecting biological function of EB1 family and Dis1/TOG/XMAP215 family proteins in interphase HeLa cells.

Y. Mimori-Kiyosue[1], T. Shimozawa[1], S. Nakamura[1]; [1]Center for Developmental Biology, RIKEN, Kobe, Japan

Recently, two classes of microtubule-end-binding proteins, EB1 (end-binding 1) family and Dis1/TOG/XMAP215 family proteins, have been proven to autonomously associate with growing microtubule plus end and positively regulate microtubule growth using in vitro reconstitution systems (Bieling et al., Nature, 2007, 45, 1100-5; Brouhard et al., Cell, 2008, 132, 79-88). Although the in vitro systems have revealed their mechanistic properties for plus end recognition and microtubule growth promoting activities, functional redundancy or synergy between them in biological processes is obscure.

In this study, we compared the roles of EB1 family and ch-TOG, a *Xenopus* XMAP215 homologue, in microtubule organization using HeLa cells. In interphase HeLa cells, many

microtubule plus ends are attached and stabilized at the peripheral regions of cells. CLASP proteins are potent microtubule-anchoring factors in HeLa cells: CLASPs bind to EB1 at their middle portion and this interaction is involved in the stable attachment of microtubule ends to the basal cell cortex (Mimori-Kiyosue et al. JCB, 2005, 168, 141-153). Consistent with this previous observation, siRNA-mediated nockdown of EB1 reduced microtubule density at the cell periphery, while ch-TOG was remained at the microtubule ends. On the contrary, knockdown of ch-TOG increased CLASP accumulation and microtubule density at the cell periphery. High-resolution SIM (structured-illumination microscopy) technique revealed that ch-TOG localizes to distinct portion of EB1/CLASP-accumulating microtubule plus end, where is the more distal of the EB1 comet. These observations suggest that ch-TOG and EB1/CLASP complex can act independently at microtubule plus ends and exert opposite effects on microtubule stability at the cell periphery.

243

Quantitative Live Imaging and Function of Microtubule Plus-End-Tracking Proteins in the Neuronal Growth Cone.

L. A. Lowery[1], M. A. Baird[2], M. W. Davidson[2], G. Danuser[1], D. Van Vactor[1]; [1]Department of Cell Biology, Harvard Medical School, Boston, MA, [2]National High Magnetic Field Laboratory, Florida State University

Proper neural connections, essential to nervous system function, depend upon precise navigation by the neuronal growth cone. A fundamental problem in growth cone cell biology is how guidance pathways are integrated to coordinate cytoskeletal dynamics, thus driving accurate steering. To address this question, we focus on the plus-ends of microtubules (MTs), which explore the growth cone periphery and play a role in growth cone steering. MT plus-end dynamics are regulated by a conserved family of proteins called “plus-end-tracking proteins” (+TIPs). Yet, it is unclear how +TIPs interact with each other and with plus-ends to control MT behavior. Additionally, it is largely a mystery how signaling mechanisms downstream of extracellular cues coordinate +TIPs to guide the growth cone in the right direction.

One conserved node of integration for multiple guidance pathways is the Abelson kinase (Abl). Our work identified the +TIP XMAP215 and its co-factor Maskin as genetic antagonists of the +TIP CLASP, which is a direct Abl substrate. We also found that accurate axon guidance requires XMAP215 and Maskin *in vivo*, and that they antagonize Abl function.

In order to determine how +TIPs directly affect MTs inside the growth cone, we analyzed and quantified parameters of +TIP dynamics using PlusTipTracker, a Matlab-based open-source software, following acquisition of high-resolution live-imaging data of tagged +TIPs within cultured *Xenopus* growth cones. Simultaneous dual channel imaging of +TIPs, including EB1, CLASP, and XMAP215, demonstrate that while all of them localize to the plus-ends, they do so with different dynamics of binding. We are particularly interested to investigate how manipulations in Abl signaling lead to changes in +TIP binding patterns and subsequent MT dynamics. Furthermore, we also examine +TIP function by manipulating their expression levels in *Xenopus* growth cones. For example, partial knock-down of XMAP215 leads to a 40% increase in EB1-GFP velocity, which is unexpected given that XMAP215 is known to have MT polymerase activity. We are currently investigating the mechanism underlying this surprising phenotype. These combined results will tell us how +TIPs differentially behave within the growth cone, thus bringing us one step closer to illuminating how the growth cone MT+TIP complex may respond to changes in guidance cue signaling to affect MT dynamics and growth cone behavior.

244

A novel method using dual color-coded display (dCCD) of EB3-GFP to examine spatial and temporal regulation of microtubule dynamics in live cells.

L. Ma[1], M. Shanmugam[1], A. Garrison[1], C. Xia[1], Z. Wang[1]; [1]Zilkha Neurogenetic Institute, University of Southern California, Los Angeles, CA

Investigating the spatial and temporal control of microtubule assembly in live cells is critical to understanding many cellular processes in development and disease. Traditionally, fluorescent tagged tubulin molecules were used to follow microtubule dynamics, but recently, GFP-tagged plus end binding proteins (+TIPs) became the tool of choice, because they allow the visualization of the plus or growing ends in dense microtubule networks. However, the current methodology relies heavily on tracking microtubules over a period of several minutes and requires frequent imaging to obtain the dynamic information for each microtubule. To complement the tracking method and to minimize the damage of live cells that are sensitive to fluorescence excitation, we developed a dual color-coded display (dCCD) method that uses a two-color coding scheme to visualize EB3-GFP labeled microtubule ends and to rapidly detect dynamic changes of microtubule assembly in real time. Using digital image processing algorithms, we developed computational tools to identify and separate the distinctive color-coded microtubules ends that correspond to different events of microtubule assembly, including growth, rescue, and catastrophe/pause. By constructing a space map of these events, we can obtain a global view of microtubule dynamics in the cell, and compare it in different regions at different times. This method requires minimal imaging and has high sensitivity and accuracy to capture the change in microtubule dynamics. It has been tested in several cell types, including fibroblasts and epithelial cells, as well as motile structures such as nerve growth cones, and provided a fresh new look of microtubule regulation in live cells. Thus, the dCCD method offers a novel approach to studying microtubule dynamics in complex cellular processes.

245

Synergistic Modulation of Microtubule Dynamics by EB1 and CLIP170 Involves Displacement of the Stably Bound Tubulin-GDP-P_i at Microtubule Ends.

M. Lopus[1], C. Manatschal[2], R. Buey[2], S. Bjelic[2], M. Steinmetz[2], L. Wislon[1]; [1]Dept. of Molecular, Cellular, and Developmental Biology, and the Neuroscience Research Institute, University of California, Santa Barbara, CA, [2]Biomolecular Research, Paul Scherrer Insititut, Villigen PSI, Switzerland

Microtubule plus end-tracking proteins (+TIPs) target to growing microtubule plus ends and are precisely positioned to modulate microtubule dynamics. The objective of this study was to elucidate the molecular mechanisms by which the +TIP proteins EB1 and CLIP 170 cooperatively regulate microtubule dynamics. Because CLIP170 can auto-inhibit itself through an intramolecular interaction between the CAP-Gly domains and its zinc-knuckle motifs, we used a truncated CLIP170 version devoid of the zinc-knuckle motifs (CL12, 27.175 kDa, S48–M300). Using small angle X-ray scattering, we found that CL12 adopts a largely extended conformation with two non-interacting CAP-Gly domains. Similar analysis of EB1 indicated that, in solution, EB1 is an elongated dimer. Analytical ultracentrifugation of EB1 and CL12 mixtures indicated that they form a 1:1 molar complex. By video microscopy, we found that EB1 and CL12 individually modulated steady-state microtubule dynamics- mainly by increasing the growth rate and decreasing the shortening rate. When EB1 and CL12 were present together, their effects on dynamics were several fold stronger than when present separately. For example, a 1:20 molar ratio of EB1 to tubulin increased the growth rate 30% and decreased the shortening rate 21%. The same molar ratio of CL12 to tubulin increased the growth rate 19% and the shortening rate 18%. However, at a highly dilute 1:80 molar ratio to tubulin, the mixture

of EB1 and CL12 still increased the growth rate ~30% and much more strongly decreased the shortening rate (by ~50%). Using [γ32P]GTP, we further found that the +TIPs partially depleted the microtubule ends of stably-bound tubulin-GDP-P_i, indicating that EB1 and CLIP170 may regulate microtubule dynamics in association with affecting the stabilizing cap at microtubule ends. Consistent with their effects on dynamics, depletion of tubulin-GDP-P_i was considerably higher with reconstituted EB1-CL12-microtubules than with microtubules assembled with EB1 or CL12 alone. The data support the hypothesis that +TIP proteins act synergistically to regulate microtubule dynamics by modulating the cap mechanism.

TON2/FASS promotes microtubule nucleation in interphase plant cells.

A. Kirik[1], D. Ehrhardt[2], V. Kirik[1]; [1]Biological Sciences, Illinois State University, Normal, IL, [2]Plant Biology, Carnegie Institution for Science, Stanford

Arabidopsis *TON2* gene encodes the B'' regulatory subunit of the protein phosphatase PP2A. *ton2* mutants display severe defects in the cortical microtubule arrays: the density of the interphase cortical microtubules is reduced and the preprophase band is completely absent. To address the role *TON2* in the formation of cortical microtubule arrays we created and analyzed transgenic plants co-expressing microtubule nucleation marker GCP2:GFP and the microtubule marker Cherry:TUB5. These lines allowed us to compare the frequency of microtubule nucleation events the epidermal cells of wild-type and the *ton2* mutant. In the *ton2* mutant total nucleation frequency was 6.7 events per 100 um area in 1 hour, compared with 18.6 events in wild type. This corresponds to 2.8 fold reduction in microtubule nucleation activity in the *ton2*. We also found that cortical microtubules required the *TON2* function for the reorientation in response to the light signal. Our data indicate that *TON2* function is required for efficient nucleation of cortical microtubules and their reorganization. We hypothesize that the *TON2*-regulated MT nucleation plays a critical role in the organization of the cortical microtubule cytoskeleton during PPB formation, in cell morphogenesis and in response to environmental cues.

DRB perturbed the interaction between casein kinase-2 and microtubules, depolymerized microtubules and induced apoptosis in MCF-7 cells.

A. Rai[1], D. Panda[1]; [1]Wadhwani Research Centre, Department of Biosciences and Bioengineering, Indian Institute of Technology Bombay, Mumbai, India

Casein Kinase 2 (CK2) has various roles in cell functioning including signaling, transcription and apoptosis. CK2 has been shown to interact with microtubules and to increase microtubule assembly, though its significance remains unknown. In the present study, we have explored the role of CK2 in regulating the assembly and stability of microtubules. Double immunofluorescence and co-immunoprecipitation experiments suggested that CK2 interacts with microtubules in cells. The pharmacological inhibition of CK2 by DRB, (5,6-Dichlorobenzimidazole 1-β-D-ribofuranoside), a small molecule inhibitor of CK2, induced apoptosis in MCF-7 cells. The cells exposed to DRB showed increased nuclear localization of p53 indicating the activation of p53 dependent apoptotic pathway. It inhibited the proliferation of MCF-7 cells with half maximal inhibitory concentration of 5.8 ± 0.2 μM. DRB enhanced the antiproliferative effect of microtubule depolymerizing agents including colchicine, nocodazole and vinblastine, whereas it reduced the effect of taxol, a microtubule stabilizing agent. Further,

CK2/tubulin ratio in MCF-7 cells was found to decrease by 31% and 54% in the presence of 20 and 40 μM DRB, respectively, indicating that DRB perturbed the interaction of CK2 and microtubules in MCF-7 cells. DRB treatment induced disassembly of cellular microtubules in MCF-7 cells. The ratio of soluble to polymeric tubulin increased from 0.42 in control cells to 1.3 in the presence of 36 μM DRB suggesting that DRB-treatment decreased the polymeric mass of tubulin in cells. However, DRB did not affect the assembly of purified tubulin *in vitro* indicating that it did not directly inhibit microtubule polymerization. In addition, DRB inhibited the growth of nocodazole-depolymerized microtubules after nocodazole washout suggesting that it suppresses the reassembly of microtubules in cells. The results together suggested that CK2 may have a role in regulating microtubule assembly dynamics.

248

Spatial Partitioning of a Model Cytoplasm by Microtubule Asters.

P. A. Nguyen[1], C. M. Field[1], A. C. Groen[1], K. Ishihara[1], T. J. Mitchison[1]; [1]Department of Systems Biology, Harvard Medical School, Boston, MA

The cytoplasms of large egg and embryo cells are organized primarily by radial arrays of microtubules called “asters.” Asters center pronuclei after fertilization and paired sister aster position the cleavage furrow in telophase. In polyspermic fertilization and natural syncytial embryos, asters space themselves and nuclei out regularly in cytoplasmic domains. Using interphase *Xenopus* egg extract to recapitulate aster behavior, we asked three questions: how do asters grow, how do neighboring asters interact, and how do asters move? Permeabilized sperm nuclei, with their associated centrosome, and Ca^{++} were added at time zero to mimic polyspermic fertilization. In some experiments, sperm nuclei were replaced by centrosomes, or beads coated with Aurora A antibody which mimic centrosomes (Tsai & Zheng, 2005, *Curr Biol 15*, 2156-63). Aster growth and interaction were scored by live imaging of thin squashes between passivated coverslips. Asters expanded by a combination of classic radial polymerization and an additional mechanism that adds new microtubules near the periphery. When growing asters contacted each other they formed interaction zones of low microtubule density, as seen in whole embryos. Asters tended to move away from these zones, and thus space themselves regularly. Aster movement, but not aster growth or aster-aster interactions, was blocked by dynein inhibitors. Normal aster growth and formation of interaction zones depended on the kinesin Kif4, as assayed by immunodepletion. Interaction zone formation, but not aster growth, depended on Aurora B kinase activity, as assayed by drug inhibition. Both Kif4 and Aurora B localized to microtubule bundles in interaction zones by live imaging, though they may be recruited by different mechanisms. We propose a mechanistic model for microtubule depletion at aster-aster interaction zones that involves Kif4, Aurora B, and a hypothetical microtubule crosslinker. This limits microtubule growth, leading to aster movement away from the zone by dynein-dependent pulling. Our model begins to explain positioning of centrosomes, nuclei, and cleavage furrows in early embryos.

Cytoplasmic self-organization of internal membranes, microtubule- and actin-cytoskeleton inside microfluidics generated droplets.

S. Tang[1,2], M. Renz[1,3], M. Driscoll[1,4], S. Reber[1,5], A. Nguyen[1,6], B. Daniels[1,3], C. Field[1,6], J. Lippincott-Schwartz[1,3]; [1]Physiology Course, Marine Biological Laboratory, Woods Hole, MA, [2]Department of Mechanical Engineering, Stanford University, Stanford, CA, [3]National Institute of Child Health and Human Development, NIH, Bethesda, MD, [4]Department of Chemistry and Biochemistry, University of Maryland, College Park, MD, [5]MPI of Molecular Cell Biology and Genetics, Dresden, Germany, [6]Department of Systems Biology, Harvard Medical School, Boston, MA

Rodionov and Borisy suggested that internal membranes are critical for the self-organization of cytoplasmic melanophore fragments [1]. On the other hand, Nedelec et al. reported that purified tubulin and motors alone result in microtubule aster formation in vitro [2]. Since then, the role of intracellular membranes in cytoplasmic self-organization has been discussed. Using microfluidic systems to generate droplets, we describe the self-organization of cytoplasmic frog egg extract in a spatially confined compartment surrounded by a pegylated, inert scaffolding oil. We characterized the temporal and spatial interplay of internal membranes and cytoskeletal components with directly labeled Tubulin and DiI staining. In the absence of centrosome, microtubules emerge from multiple nucleation sites which eventually coalesce. In parallel, initially dispersed internal membranes accumulate in the center of the droplet. Finally, microtubules form a cage around the internal membranes. This self-centering of microtubules and internal membranes can be prevented by inhibition of dynein motors with vanadate and by disruption of microtubules with nocodazole. In the late stage of cytoplasmic self-organization inside a droplet, the microtubule cage gets laterally constricted. Since the final lateral constriction can be prevented by latrunculin, but not by blebbistatin or nocodazole, it is probably due to curvature-induced cortical actin in a Myosin II independent manner.
To define determinants of three-dimensional arrangement, we addressed aspects of stiffness and gravity. The positioning of the microtubule cage and internal membranes along the z-axis is apparently due to both factors, while the lateral arrangement is clearly associated with differential stiffness of the scaffolding compartment.

Tang S., Renz M., and Driscoll M. contributed equally.

Induced transverse organization of Arabidopsis cortical microtubule arrays.

L. E. Vineyard[1], J. Lucas[1], S. Dhingra[1], A. Elliott[1], S. L. Shaw[1]; [1]Biology, Indiana University Bloomington, Bloomington, IN

Cortical microtubule arrays are critical for cell morphogenesis in plants and provide a unique model for investigating microtubule interaction and regulation. Microtubules form complex and dynamic patterns at the plant cell cortex in the absence of a centrosome or a known microtubule-organizing center. In rapidly elongating Arabidopsis epidermal cells, the cortical array organizes into a highly co-aligned network transverse to the cell axis and patterns extra-cellular matrix deposition. We hypothesize that plant cells create transverse microtubule array patterns by regulating the localization of nucleation sites and subsequent trajectories of new microtubules. To address our hypothesis, we have developed a treatment regimen using

exogenously applied plant hormones to induce a transverse microtubule array organization. We are examining the kinetics of array organization by imaging GFP:Tubulin or GFP:Eb1 expressing cells that are transitioning to the transverse alignment. Using the hormone induction as an assay, we show that organization into a transverse array does not require an intact actin cytoskeleton and is insensitive to Brefeldin A treatment, which blocks polarized secretion of several cell polarity markers. Quantitative tracking of the GFP:Eb1 probe revealed a strong bias for microtubule plus ends moving out of the outer periclinal cell face into the anticlinal cell faces. Hormone treatment changes the microtubule plus end distribution and promotes a gradual influx of new transverse microtubules from the lateral anticlinal faces of the cell that progressively organize the array into a transverse alignment. We propose from these data that transverse microtubule array organization is actively driven by the redistribution of microtubule nucleation sites into positions that favor transverse microtubule trajectories.

251

Rho-kinase controls asymmetric patterning of microtubules essential for anterior-posterior axis formation in epithelial cells.

A. J. Lomakin[1], M. W. Davidson[2], G. Danuser[1]; [1]Harvard University, Boston, MA, [2]National High Magnetic Field Laboratory, Tallahassee, FL

Microtubules (MTs) have been found to play a central role in cell shape determination and polarized cell movements. In migrating cells, through acquiring an asymmetric configuration, the MT cytoskeleton contributes to the polarization of cellular activities that allow the cell to migrate in a directional fashion. Despite the importance of MTs for migratory cell polarity, relatively little is known about the molecular mechanisms by which MTs acquire a specific arrangement that enables asymmetric distribution of cellular activities.

In the present study we focus on the question how the organization of MT networks may be signaled in the cytoplasm by the Rho-kinase/ROCK-mediated pathway. Inhibition of ROCK activity induces symmetric discoid-shaped epithelial cells plated on a planar substrate to polarize along the anterior-posterior axis. Based on this observation, we decided to check whether this cell shape polarity reflects polarity in MT organization. In contrast to non-treated (NT) cells, dynamic MTs in ROCK-inhibited cells show an overall gradient of decreasing density from anterior to posterior. Close inspection of MT tracks collected over time in living cells revealed that cells with compromised ROCK activity switch the patterns of MT organization from a meshwork of randomly oriented MTs to an array of MTs with a strong bias toward the anterior. Therefore, we then set out to measure parameters of MT dynamic instability in these cells, since changes in such parameters are often used to explain distinct patterns in MT organization. By doing so, we showed that in ROCK-inhibited cells the growth of anterior MTs is often interspersed with episodes of pauses and shortenings that decrease the time MTs spent processively growing. The ratio of MT growth lifetimes between anterior and posterior MTs (lifetime A/P ratio) in ROCK-inhibited cells is ~0.5 compared to ~1 in NT cells. Moreover, unlike NT-cells, ROCK-inhibited cells show asymmetric distribution of MT growth, pause, and shortening densities between anterior and posterior. A/P ratio for these parameters in ROCK-inhibited cells is ~3 vs. ~0.8 in NT cells. Comparison of posterior MT dynamics in NT cells vs. ROCK-inhibited cells show absence of significant differences. Thus, we conclude that dramatic changes in MT arrangement seen upon ROCK suppression are explained by the local modulation of dynamics of MTs growing toward the cell anterior pole. This modulation presumably favors the accumulation of growing MTs in the vicinity of anterior cortical regions. Interestingly, treatment of ROCK-inhibited cells with Taxol, an MT-stabilizing drug that disorganizes polarized MT arrays, resulted in the loss of the anterior-posterior axis. In such conditions, the cells undergo dramatic spreading to the point where they formed round cells that looked like fried eggs.

Taken together, these findings suggest that ROCK-mediated signaling in epithelial cells attenuates anterior-posterior axis formation by organizing dynamic MTs into symmetric meshworks. Delineating the molecular mechanism underlying this phenomenon as well as determining its physiological role in morphogenetic cell behaviors is an ongoing part of our research program.

Role of tubilins in structural and functional organization of energy metabolism in the muscle cells.

M. A. Gonzalez-Granillo[1], M. Le Guen[1], A. Grichine[2], Y. Usson[3], M. Karu-Varikmaa[4], F. Boucher[5], A. Kuznetsov[6], V. Saks[1,4], R. Guzun[1]; [1]Laboratory of Fundamental and Applied Bioenergetics (LBFA), Université Joseph Fourier Grenoble I, Grenoble France, [2]Institut Albert Bonniot - CRI U823, Université Joseph Fourier Grenoble I, Grenoble, La Tronche Cedex, France, [3]Laboratoire TIMC-IMAG équipe Dyctim, Grenoble, La Tronche Cedex, France, [4]Laboratory of Bioenergetics, National Institute of Chemical Physics and Biophysics, Tallinn, Estonia, [5]Experimental, Theoretical and Applied Cardio-Respiratory Physiology, Laboratory TIMC-IMAG, Université Joseph Fourier Grenoble I, France, [6]Department of Heart Surgery - Cardiac Surgery Research Laboratory, Innsbruck Medical University, Innsbruck, Austria

It is becoming clear that the structure of the cell is important for the organization and energy metabolism of cells. Nowadays, it is known that tubulins are important for cell's energy metabolism; previous studies in our lab showed how βII-tubulin is the isotype attached to the outer mitochondrial membrane giving to VDAC its selective permeability in cardiac cells. Furthermore, this restricted permeability for ADP and ATP, favours their recycling in the coupled MtCK-ATP synthasome reactions in mitochondria, connecting oxidative phosphorylation to PCr synthesis within a supercomplex.
Based on these previous studies in cardiac cells, the present study shows the intracellular distribution of the different tubulin β isotypes in skeletal muscles (gastrocnemius white, gastrocnemius red, soleus and extensor digitorum longus), which are composed of fast-twitch, slow-twitch and mix-twitch fibres; finding out how this structural organization is playing a main role in the energy metabolism of cells, controlling the energy fluxes of ADP and ATP through the outer mitochondrial membrane and controlling VDAC's affinity.
Immunofluorescent staining and western blot analysis were carried out in adult skeletal muscle cells, revealing a different tubulin isotypes distribution in each skeletal fibre analysed, which may suggest us how the intracellular distribution of structural proteins are playing a role in the compartmentalisation and use of substrates.

In vivo imaging of microtubule dynamics throughout tissue biogenesis and cell differentiation.

B. Lacroix[1], J. Dorn[1], S. Ihara[2], D. R. Sherwood[2], P. S. Maddox[1], A. S. Maddox[1]; [1]IRIC, Université de Montréal, Montréal, Québec, Canada, [2]Duke University

Microtubules (MTs) are dynamic polymers composed of alpha/beta-tubulin heterodimers. The alternating polymerization and depolymerization of MTs, called dynamic instability, is important for interphase microtubule functions and spindle assembly and dynamics during cell division. Since many agents that block mitotic progression directly affect MT dynamics, this phenomenon is of great interest to develop and improve anticancer drugs. Measurements of dynamic instability in vitro and in cultured cells and early embryos have revealed differences in the speeds of growth and shortening and the frequencies of catastrophe and rescue in vitro and in vivo and among cell types. However, it is not known how these data relate to MT behavior in

intact animals. Specific unknowns include how the geometry (2D versus 3D) of the cell environment, and the degree of cellular differentiation contribute to dynamics. These are all important considerations for understanding MT biology in development and pathologies, and to manipulate MTs with pharmaceuticals.
We have developed methods to measure MT dynamics in an intact animal. We created a C. elegans strain in which GFP-tagged tubulin is expressed specifically in the vulval epithelial cells, several uterine muscle cells and their respective precursors. This system allows us to measure and compare MT dynamics in cells of the same lineage at different developmental stages within the same organism. Time-lapse acquisitions at one second intervals are made using real-time confocal imaging, and image processing and analysis are done with ImageJ and custom Matlab programs. MT dynamics can be observed in 2 dimensions with high spatial and temporal resolution. Protein depletion by lineage-specific RNAi and small molecules are used to dissect the role of known and candidate MT-associated proteins at each developmental stage.
Interestingly, MTs from differentiated cells have a higher growth rate than those of precursor cells (8.39 +/- 2.50 vs. 6.13 +/- 1.60 μm/min), and display long biphasic growth excursions, slowing as they near the cell periphery. Precursors cells' MTs have shorter growing phases and higher catastrophe and rescue frequencies. We screened 90 candidate MT regulators and found that MTs in differentiated cells and precursors cells respond distinctly to protein depletions. In the future, we will use this model to study mitotic MT dynamics in vivo. Ultimately our novel method will facilitate identification of drug targets, and eventually drugs, that can specifically disrupt MTs in dividing cells, sparing post-mitotic neurons unlike current anticancer drugs.

Microtubule Dynamics and Nucleation in Live Muscle Fibers.

S. Oddoux[1], V. Tate[1], S. Nandkeolyar[1], W. Liu[1], K. J. Zaal[1], E. Ralston[1]; [1]Light Imaging Section, Office of Science and Technology, NIAMS, NIH, Bethesda, MD

The organization of microtubules in proliferating cells is understood well enough that even static images convey dynamic information about microtubule origin and growth direction. But in cells with a non-conventional microtubule network, as is the case for skeletal muscle fibers, this is impossible. Muscle fibers are large, multinucleated cells. Their microtubules form complicated 3D lattices which include the nuclei and the numerous small Golgi complexes. We know nothing of muscle microtubule dynamics, polarity, or origin and therefore can neither understand the role of microtubules in muscle function, nor predict the consequences of the microtubule disruptions observed in many pathological conditions. In order to bring to light microtubule dynamics in muscle fibers, we first sought a suitable fluorescent microtubule marker. Several were tested, first by transfection of the C2 muscle cell line, and then by injection and electroporation in the mouse Flexor Digitorum Brevis (FDB) muscle. It became clear however that different markers best suit each system. EB3-GFP and GFP-tubulin are well incorporated in the microtubules of FDB fibers and can be followed for extended periods of live cell confocal imaging, allowing us to visualize entire microtubules and their plus-ends. We find that muscle microtubules are highly dynamic and grow at rates comparable to those of proliferating cells (about 16 micrometers/min). They move longitudinally and transversely, and can switch from one to the other. The plus-end of the microtubules are all along the lattice, suggesting that this scaffold is made of microtubule bundles. To resolve the question of microtubule origin we have been following recovery from nocodazole-induced depolymerization. Numerous asters are seen, originating from the Golgi complex elements, which must be associated with or directly involved in the nucleation process. In support for such a role, we find that microtubule recovery is affected by Brefeldin A. We are also using shRNA to knock down specific Golgi proteins such as GM130 in order to assess their function in muscle microtubule nucleation. Nucleation from the

many Golgi elements gives the muscle microtubule network hundreds of origins and minus ends, and the potential for local regulation of trafficking and organelle positioning. The tools developed have allowed us to see for the first time how microtubules form and move in live muscle fibers and provide us with a platform for exploring the role of microtubules in muscle and the consequences of their defects in muscle diseases.

255

Quantitating Microtubule Dynamics in Intact Mammalian Epidermis.

L. N. Seldin[1], T. Lechler[2]; [1]Cell Biology, Duke University, Durham, NC

Microtubules, integral components of a cell's cytoskeletal network, influence cell shape and motility, function in organelle transport and organize into the mitotic spindle that facilitates chromosome organization and segregation during cell division. In stratified mouse epidermis, microtubule organization varies between cell layers: microtubules within the proliferative basal cells focus around centrosomes, whereas microtubules within the differentiated layers lose association with the centrosome and reorganize to the cell cortex. It remains unclear, however, whether proliferative and differentiating epidermal cells exhibit distinct microtubule nucleation and growth rates. In this study, we engineer mice to express a fluorescently tagged microtubule end-binding protein EB1 to facilitate microtubule tracking during nucleation from interphase centrosomes *in vitro* and *in vivo*. In addition, this tool will assist in characterizing *in vivo* microtubule dynamics during asymmetric cell divisions in epidermal basal cells. Previous research has defined a complex of proteins that localize to the apical cortex of basal cells to drive spindle reorientation and asymmetric division. One of these proteins, NuMA, has binding domains in its N- and C-terminus that facilitates its interactions with dynein and microtubules, respectively. We are particularly interested in determining whether these NuMA/microtubule interactions play a role in the regulation of both microtubule dynamics and spindle orientation during epidermal stratification. Taken together, these studies will lend further insight into the function of interphase and mitotic microtubule dynamics during mammalian epidermal morphogenesis.

Cilia and Flagella I

256

3-D architecture of growing flagella.

J. L. Hoog[1], S. Lacomble[1], E. O'Toole[2], C. Bouchet-Marquis[2], R. J. McIntosh[2], A. Hoenger[2], K. Gull[1]; [1]University of Oxford, Oxford, United Kingdom, [2]University of Colorado

Many cells have a cilium or flagellum, organelles that generate cell motility and important sensory and signaling organelles. Two of the most studied flagella with a canonical 9+2 structure are those of the green-algae Clamydomonas reinhardtii and the parasitic protozoa Trypanosoma brucei. C. reinhardtii has two flagella that are reabsorbed and shed prior to mitosis. T. brucei has a single flagellum for about half its cell cycle when a new flagellum starts growing along the pre-existing flagellum in preparation for mitosis. Thus, growing flagella can be found in recently divided C. reinhardtii and in T. brucei cells with two flagella. The large protein complexes containing the flagellar building blocks are delivered to the site of axonemal elongation in an evolutionary conserved process called intra flagellar transport (IFT). IFT transport is well studied, yet we know little about the order by which these structural components of the axoneme assemble into the growing flagellum. To examine the process of axoneme elongation, we studied the tips of growing flagella in C. reinhardtii and T. brucei using

electron tomography. The axoneme is disorganized during growth in long T. brucei flagella since associated proteins are not added at the same rate as MTs grow. We also show that membrane extension is not dependent on axonemal pushing.

257
A novel distal appendage protein required for primary cilium formation.
B. Tanos[1], W-J. Wang[1], R. Soni[1], M. Tsou[1]; [1]Cell Biology, MSKCC, New York, NY

Primary cilia (PC) are microtubule-based organelles that play important mechano- and chemosensory roles in eukaryotic cells, and whose function is compromised in a number of diseases including polycystic kidney disease, obesity, and certain forms of mental retardation. The basal body that functions in PC assembly derives from the older mother centriole, which can be distinguished from the younger mother by the acquisition of subdistal and distal appendages, which are required for cilia formation. Here we have identified CCDC41 as a component of the mother centriole. We found that CCDC41 is recruited to mother centrioles between late S and the beginning of G2 phases of the cell cycle, coincident with the recruitment of two other previously characterized appendage proteins, Cep164 and Odf2, but prior to the recruitment of a third appendage protein, centriolin. Furthermore, CCDC41 colocalizes with Cep164, a distal appendage protein, but not with Odf2 or Centriolin, both subdistal appendage proteins. Knockdown of CCDC41 resulted in a defect in primary cilia formation and length, and a failure to recruit Cep164 and Odf2, but had no effect on centriolin recruitment. We hypothesize that CCDC41 is recruited to mother centrioles during appendage formation in a complex with other appendage proteins that likely includes Cep164.

258
The pf27 mutant is defective in radial spoke transport in the cilium.
L. M. Alford[1], S. Dutcher[2], W. Sale[1]; [1]Emory Univ Sch Med, Atlanta, GA, [2]Washington Univ Sch Med

Ciliary proteins are generated in the cell body and subsequently targeted to precise locations in the cilium. To address the mechanisms of assembly and transport, we focused on assembly of the radial spoke structure. The radial spoke first assembles as 12S precursor complexes in the cytoplasm. This is followed by IFT mediated transport in the ciliary compartment and docking of a fully assembled 20S radial spoke structure (Diener et al., 2011; Yang et al., 2005; Qin et al. 2004). We took advantage of the Chlamydomonas reinhardtii mutant pf27, which is deficient in ciliary radial spokes (Huang et al., 1981). Comparison of cytoplasmic extracts from pf27 and wild-type show no difference in composition of the 12S radial spoke precursor complex. Interestingly, the spokes that assemble in pf27 are localized to the proximal third of the axoneme, but otherwise are fully assembled into the mature 20S radial spoke complexes. Furthermore, 20S spoke complexes derived from wild-type axonemes are competent to bind pf27 axonemes in vitro. Thus, pf27 is apparently not defective in radial spoke assembly in the cytoplasm or docking of radial spokes to the axoneme. Rather, our results suggest that pf27 is defective in the transport of spoke complexes. To further test this idea, complementation in temporary dikaryons of wild-type and pf27 reveal rescue of radial spoke assembly from tip to base as previously described for other radial spoke mutants (Johnson and Rosenbaum, 1992). Additionally, Next-Generation high-throughput sequencing of pf27 reveals a mutation in a candidate flagellar associated protein (FAP) predicted to be a kinase. Consistent with this prediction, radial spoke proteins exhibit reduced phosphorylation in pf27 axonemes (Huang et al., 1981). Based on these results, we hypothesize that PF27 encodes a protein kinase required for facilitating interaction between the radial spoke precursor complex and the ciliary IFT transport machinery.

259

A Novel Cytoplasmic Protein Necessary for Proper Assembly of Eukaryotic Flagella.

B. W. Smith[1], D. R. Mitchell[2]; [1]SUNY Upstate Med Univ, Syracuse, NY

Nearly all organisms in the eukaryotic branch of life are dependent on motile (9+2) cilia. Proper function of motile cilia is essential for normal embryonic development, mucous clearance from the respiratory tract and reproduction. A breakdown of normal ciliary function can lead to Primary Ciliary Dyskinesia (PCD), which is characterized by respiratory disorders, male infertility and female subfertility as well as body plan defects. As cilia have multiple regulatory structures, including the central pair, radial spokes and the dynein regulatory complex, a defect with even a portion of any of these structures may result in PCD. Little is currently understood about how these structures are assembled, this is especially the case with the central pair. Using the model organism *Chlamydomonas reinhardtii*, we have isolated a new central pair mutant called *uncoordinated 1(unc1)*. *Unc1* was originally identified as nearly immotile, resulting from asymmetrically activating flagella that often stall mid-bend. Electron microscopy of unc1 axonemes shows that the C2b projection is missing in 95% of observed cross-sections, and of these about half are missing part or all of the C2 microtubule and its associated projections. Using available antibodies for central pair proteins, western blotting of unc1 axonemes reveals reductions in Klp1 and Hydin, while Cpc1 and PF6 levels are equal to that of wild-type, confirming that unc1 results in C2 specific defects. The *UNC1* locus maps along LG V, and is part of a tandem duplication. Both UNC1 and its tandem duplicate are predicted subtilisin-like serine proteases. Knockdown of the tandem duplicate with an amiRNA construct results in a similar motility phenotype to unc1. Transformation of a epitope-tagged UNC1 construct restores motility with a normal waveform. Isolation of cell bodies, cytoplasmic extracts and flagella from rescued cells shows that UNC1-HA localizes to the cell body, supporting a potential cytoplasmic role for UNC1p in central pair pre-assembly processing events. Supported by NIGMS 44228 to DRM.

260

Regulation of ciliary assembly through intron retention.

T. C. Boothby[1], S. M. Wolniak[1]; [1]Cell Biology and Molecular Genetics, University of Maryland, College Park, MD

The microspore of Marsilea vestita is a meiotic product that produces a male gametophyte. A series of nine divisions in precise planes generates a gametophyte comprising 7 sterile cells and 32 spermatozoids. Each spermatozoid possesses ~140 cilia. Gametophyte development is rapid and temporally precise (reaching completion in 11 h), spatially precise (cells and division planes are fixed within the microspore), and transcriptionally quiescent (the microspore stockpiles proteins and RNA, which are used to carry out spermatogenesis with no new RNA production). We employed deep sequencing (Solexa Illumina) and de novo transcriptome assembly (Trinity) to gain insights into how the gametophyte regulates the storage, processing and translation of stored RNA.

In silico analysis was used to generate a list of annotated ‘early’ transcripts predicted to contain retained introns. Many of these intron-containing transcripts encode proteins whose biological functions are required during late stages of development. A subset of these transcripts (e.g., PF16/SPAG6, PFK, IFT88/OSM-6, FAP234, FAP71, Shaggy/GSK3) has previously been found to be essential for ciliary/flagellar axoneme formation or are associated with axonemal structures. Early in gametophyte development, ~30% of all identified ciliary/flagellar axonemal transcripts contain retained introns. Comparisons of genomic and RNA sequences of ‘early’ intron-retaining ciliary transcripts reveals that these transcripts possess at least 1 intron embedded in the coding sequence both in the desiccated microspore and during early

gametophyte development, while other introns within and beyond the ORFs had been previously removed from the pre-mRNAs. In all cases examined, these retained introns are within the coding sequence of the transcript, code for a premature stop codon, and usually disrupt conserved encoded protein domains. Isoforms of these 'early' intron-containing transcripts were found at later stages of development to lack any introns, and this loss of intron retention results in an mRNA encoding for a full length, functional protein. We performed RNAi knockdowns of intron containing transcripts at the onset of development. Detectable anomalies in phenocopies were not observed until after the developmental time point when these transcripts are spliced, suggesting that the later spliced isoforms of these transcripts are developmentally essential, while the intron-containing transcripts might serve only as translationally/functionally incompetent precursors. While the proportion of ciliary/flagella axonemal transcripts found in our study to retain introns (8) constitutes only a small portion of the ciliome (i.e., 124 components in C. reinhardtii) it is important to note that several of these intron-retaining transcripts encode proteins essential for ciliary/axoneme formation and/or stability (e.g., SPAG6 and OSM-6). Our data suggest that the retention of introns may be a mechanism involved in temporally regulating the onset of translation of essential ciliary axonemal proteins and thus, forestall the assembly of cilia in the rapidly developing gametophyte until late in spermatid maturation. Supported by NSF grant 0842525 to S.M.W.

261

Whole genome transcriptome analysis identifies new cilia genes.

A. J. Albee[1], A. L. Kwan[2], G. D. Stormo[1], S. K. Dutcher[1]; [1]Genetics, Washington University School of Medicine, St. Louis, MO, [2]Molecular and Cellular Technologies, Platform Technology and Science, GlaxoSmithKline, Collegeville, United Kingdom

Cilia are microtubule based organelles that project from a cell. Cilia are found on almost every cell type of the human body and numerous diseases are associated with defects in cilia including respiratory infections, male infertility, situs inversus, polycystic kidney disease, retinal degeneration, and Bardet-Biedl Syndrome. Mass spectrometry analysis has identified over 600 proteins that compose cilia. At the base of cilia lie basal bodies that template cilia and recruit proteins for ciliary assembly. To understand how cilia are formed, we used Illumina-based whole genome transcriptome analysis during flagellar growth in the biflagellate green alga *Chlamydomonas reinhardtii*. *Chlamydomonas* cells were deflagellated by pH shock and then sampled at 3, 10, 30, and 60 min during flagellar growth for whole transcriptome analysis. We identified over 1400 genes that were upregulated during flagellar growth. We also used phylogenetic profiling to identify genes that are conserved in organisms with basal bodies, triplet microtubules and motile cilia; we found 65 proteins that have coevolved in *Chlamydomonas*, humans, zebrafish and moss and are missing from land plants, fungi, and nematodes. We focus on those genes that are conserved among this set of ciliated organisms and a set of genes that are up-regulated during flagellar growth. To validate these genes, we used 4-5 different shRNA lentiviral constructs to knockdown each candidate gene in human retinal pigment epithelial cells (hTERT-RPE) stably expressing centrin-GFP, a basal body/centriole marker. We focused our analysis on five phenotypes: the percent ciliated cells, cilia length, numbers of basal bodies/centrioles, distance between basal bodies/centrioles, and cell cycle defects as determined by EdU staining. We show that knockdown of GLOD4, a glyoxylase implicated in retinal degeneration, is upregulated 7-fold following deflagellation in *Chlamydomonas*. Knockdown in RPE cells leads to decreased ciliation of cells and the severity of the ciliary phenotype is correlated to the GLOD4 mRNA levels. ZMYND10, a zinc finger protein containing an MYND domain, is upregulated 71 fold following deflagellation in *Chlamydomonas*. Knockdown in RPE cells leads to cell cycle defects without affecting cilia or basal body/centriole numbers. In total, we validated 22 of our predicted genes and a large proportion of these show

defects in at least one of the five phenotypic categories. Characterization of these genes helped us to gain insight into the molecular mechanism by which centrosomes and cilia are assembled. Research is funded by grants from the National Institutes of Health.

262

A Forward Enhancer Screen in C. elegans to Identify Novel Ciliopathy Genes.

J. Pieczynski[1], S. Masyukova[2], D. Landis[2], S. Henke[2], C. Williams[1], B. Yoder[1,2]; [1]Department of Cell Biology, University of Alabama at Birmingham, Birmingham, AL, [2]Department of Genetics, University of Alabama at Birmingham

Cilia are signaling organelles and defects in cilia signaling or structure lead to diseases referred to as ciliopathies. Many ciliopathies including, Nephronopthisis (NPHP) and Meckel-Gruber Syndrome (MKS), are autosomal recessive disorders and can involve a series of mutations in multiple, overlapping genetic loci, most of which have yet to be identified. It has been hypothesized that the complex genetic program of ciliopathies leads to a spectrum of related phenotypes determined by the nature of the mutation and/or the combination of different mutations (mutational load) in the patient's background. Genetic screens in *C. elegans* can be utilized to identify candidate genes that contribute to cilia dysfunction. The ciliated sensory neurons (CSNs) of *C. elegans* can be used to assess the mutational load of ciliopathy defects based on quantifiable assays including CSN regulated behaviors and the ability of CSNs to uptake lipophilic dye. Worms unable to take up dye are designated *Dyf,* for dye-filling defective. We previously demonstrated this phenomenon by crossing worms mutant for the homolog of the human ciliopathy gene NPHP4 (*nphp4*$^{-/-}$) with worms mutant for a homolog of a human MKS gene (*mks(x)*$^{-/-}$). Alone, *nphp4*$^{-/-}$ or *mks(x)*$^{-/-}$ have very mild or no *Dyf* phenotypes but when crossed, the resultant *nphp4*$^{-/-}$*;mks(x)*$^{-/-}$ F_2 generation display enhanced *Dyf* phenotypes as well as behavioral phenotypes indicative of CSN defects. Using this *nphp4*$^{-/-}$ *Dyf*-based enhancer phenotype paradigm we performed chemical mutagenesis on *nphp4*$^{-/-}$ mutant worms to identify genes that enhance *Dyf* phenotypes and contribute to mutational load. After outcrossing, we identified nine independent worm strains with synergistic *Dyf* phenotypes on the nphp4$^{-/-}$ mutant background that were more severe than those found in *nphp4*$^{-/-}$ mutants alone. The enhanced *Dyf* phenotype in these strains segregated in ratios indicative of double recessive mutations. Bulk chromosomal analysis and non-complementation tests were used to map mutations and check for allelism. After mapping, we employed Illumina deep sequencing to identify causative genes/alleles. We have begun to analyze the function of new candidates in an effort to understand how mutations in these genes cause synergistic phenotypes with the NPHP4 mutation. Genes from this screen are likely to be strong candidates for novel human ciliopathy genes.

263

Structural and functional transition of choroid plexus epithelial cilia revealed by proteomic analysis.

K. Narita[1], H. Kozuka-Hata[2], Y. Nonami[3], H. Ao-Kondo[2], M. Oyama[2], T. Inoue[3], S. Takeda[1]; [1]Department of Anatomy and Cell Biology, Interdisciplinary Graduate School of Medicine & Engineering, University of Yamanashi, Chuo, Japan, [2]Medical Proteomics Laboratory, Institute of Medical Science, University of Tokyo, Minato-ku, Japan, [3]Department of Life Science and Medical Bio-Science, Waseda University, Shinjuku, Japan

Mammalian cilia and flagella have been classified into three major subtypes depending on the function and axonemal structure, namely, motile 9+2 cilia, non-motile 9+0 primary cilia and motile 9+0 nodal cilia. In addition, whereas 9+2 cilia are expressed as many as hundreds, 9+0 primary and nodal cilia are usually solitary. One of the rare exceptions is the multiple 9+0

primary cilia expressed in choroid plexus epithelial cells (CPECs). We have previously reported that CPEC cilia modulate the production of cerebrospinal fluid (Narita et al., Traffic, 11:287-301, 2010). In the present study, we performed a proteomic analysis of CPEC cilia to elucidate their exceptional features in molecular basis. By LC-MS analysis of proteins from purified swine CPEC cilia, 868 proteins were identified as a CPEC ciliome, of which 419 were not shared with other ciliome datasets. Unexpectedly, we found several molecules implicated in ciliary motility in the CPEC ciliome. Real-time PCR also validated the expression of these molecules in mouse CPECs. Immunostaining for one of them, radial spoke head 9 homolog (Rsph9), demonstrated that the molecule localized to a subpopulation of CPEC cilia. Live imaging of choroid plexus tissue exhibited that some CPEC cilia could beat vigorously at the neonatal stage, whereas adult CPEC cilia were non-motile. When observed with high-speed video microscopy, the beating pattern appeared to be similar to that of typical 9+2 cilia of ependyma, though several parameters were different. The motility of CPEC cilia did not produce any directional planar flow, as assessed by the movement of fluorescent microbeads added to the medium. Transmission electron microscopy of P1 mouse choroid plexus revealed that the coexistence of 9+0 and 9+2 cilia. In conclusion, our proteomic analysis revealed unique structural and functional changes of CPEC cilia, which highlight the diversities of mammalian cilia. Based on the present study, we propose a new concept on ciliary subtype classification to deal with various atypical cilia systematically, with consideration to possible molecular mechanisms underlying the diversity.

264

Epsilon tubulin is essential for the formation and maintenance of basal bodies in Tetrahymena thermophila.

I. Ross[1], C. Clarissa[2], T. Giddings[2], M. Winey[2]; [1]MCD Biology, University of Colorado, Boulder, CO, [2]MCD Biology, University of Colorado

Basal bodies and centrioles are conserved microtubule based organelles whose improper assembly leads to a number of diseases, including ciliopathies and cancer. Tubulin family members play integral roles in the function of these structures. I have identified the ε-tubulin gene in Tetrahymena thermophila and localized it through immunofluorescence to basal bodies. Immunoelectron microscopy has revealed that ε-tubulin localizes to the three main domains of the basal body: the proximal end, the distal end, and the microtubule scaffold. A complete knockout of ε-tubulin reveals that it is an essential gene required for the assembly and maintenance of the core triplet microtubule structure of basal bodies. Most recently we have identified possible novel binding partners of ε-tubulin that may shed insight into the mechanism of ε-tubulin's function. Concurrently, a mutational analysis of ε-tubulin is underway, with the hope of establishing a structure function relationship for this protein. The results of this research have enhanced our current understanding of the function of ε-tubulin and will further shed light on its role at basal bodies.

265

The two human centrin homologues in Tetrahymena have similar but distinct functions at basal bodies.

T. Vonderfecht[1], M. W. Cookson[1], T. H. Giddings[1], C. Clarissa[1], M. Winey[1]; [1]Molecular, Cellular, and Developmental Biology, University of Colorado at Boulder, Boulder, CO

Centrins are a ubiquitous family of small Ca2+ binding proteins at centrioles and basal bodies. Structurally, they consist of two domains tethered by a short linker with each domain containing a pair of EF hands, a Ca2+ binding motif. Centrins are grouped into two groups based on sequence similarity to the human centrins, Centrin 2 and Centrin 3, and analyses of components that make up centrioles or basal bodies in different species suggest that they

contain a centrin isoform from each group. The study of centrins has largely focused on those belonging to the human Centrin 2 group, while neglecting those in the human Centrin 3 group. We used the ciliate protist Tetrahymena thermophila to gain a better understanding of the functions of the two centrin groups and to determine their redundancy. We have previously shown that the Tetrahymena Centrin 1 (Cen1), the human Centrin 2 homologue, is required for basal body stability, assembly, orientation of assembly, and separation. Here, we show that the Tetrahymena Centrin 2 (Cen2), the human Centrin 3 homologue, shares similar functions as Cen1. However, an examination of Cen2's molecular mechanisms shows that it behaves differently than Cen1, suggesting that the two proteins are distinct. In all, our data suggest that centrioles and basal bodies require a centrin from both groups in order to function correctly.

266

Modular organization of known and novel proteins at the ciliary transition zone.

V. L. Jensen[1], C. Li[1], C. L. Williams[2], K. Kida[3], O. E. Blacque[3], B. K. Yoder[2], M. R. Leroux[1];
[1]*Molecular Biology and Biochemistry, Simon Fraser University, Buranby, BC, Canada,*
[2]*University of Alabama,* [3]*University College Dublin, Ireland*

Objective: We recently discovered that multiple proteins concentrated within the proximal region of the cilium, termed transition zone, are required for at least two inter-related events in an early ciliogenic pathway: attachment of the basal body to the plasma membrane and formation of a so-called ciliary gate. Our goal has been to identify additional components of the transition zone and understand how they fit within different modules localising to this ciliary region, whose role is critical for maintaining the functional compartmentalisation of the sensory organelle.

Methods: We employ C. elegans as a model system to study the localisation, function, and interactions of known and novel components of the ciliary transition zone. Novel transition zone and other ciliary proteins are uncovered using a combination of comparative genomics, functional genomics, expression profiles, and in vivo cell biology approaches.

Results: Our analyses indicate that MKS-5 (RPGRIP1L/NPHP8), implicated in several ciliopathies, including Meckel syndrome, Joubert syndrome, and nephronopthisis, serves as a major scaffolding protein within the transition zone. Specifically, MKS-5 is required for the proper localisation of all known transition zone proteins tested (three B9 domain proteins, MKS-2, MKS-3, MKS-6, NPHP-1 and NPHP-4), as well as three novel membrane-associated proteins. All proteins can be ascribed to one of two modules, termed "MKS" or "NPHP", with the latter containing NPHP-1 and NPHP-4. These results are largely based on robust genetic interaction data whereby disruption of two or more proteins within the MKS module, or the NPHP module, does not result in prominent ciliogenesis defects—but disruption of any combination of MKS and NPHP module proteins causes major ciliogenic phenotypes. Our findings also provide insights into the hierarchical assembly of MKS module proteins; in particular, we find that MKS-2 and B9 proteins represent 'core' components of the MKS module.

Conclusion: The transition zone, a previously unappreciated region of the cilium that is entirely conserved in evolution, is now implicated in ciliogenesis and gating of the cilium. Our findings provide insights into the organisation and functions of many known transition proteins. In addition, we have uncovered novel components of this ciliary region, revealing its surprising complexity. Furthermore, the novel proteins represent strong ciliopathy candidates for being implicated in ciliopathies such as Meckel/Joubert syndrome and/or nephronophthisis—which collectively affect development and various physiological functions (kidney, eye, etc.).

267

Cdc14 association with basal bodies in the oomycete Phytophthora infestans indicates potential new role for this protein phosphatase.

A. M. Ah-Fong[1], H. S. Judelson[1]; [1]Plant Pathology & Microbiology, University of California Riverside, Riverside, CA

The dual-specificity phosphatase Cdc14 is best known as a regulator of cell cycle events such as mitosis and cytokinesis in yeast and animal cells. However, the diversity of processes affected by Cdc14 raises the question of whether its cell cycle functions are truly conserved between species. Analyzing Cdc14 in the lower eukaryote Phytophthora infestans, a member of the oomycete group of the Stramenopile kingdom, should provide further insight into the role of Cdc14 since this organism does not exhibit a classical cell cycle. Prior study in this organism already revealed differences in Cdc14. For example, instead of being post-translationally regulated like its fungal and metazoan relatives, PiCdc14 appears to be mainly under transcriptional control. It is absent in vegetative hyphae where mitosis occurs and expressed only during the spore stages of the life cycle which are mitotically quiescent. Since transformants overexpressing PiCdc14 exhibit normal nuclear behavior, the protein likely does not play a critical role in mitotic progression although PiCdc14 is known to complement a yeast Cdc14 mutation that normally arrests mitosis. Further investigation into the role of PiCdc14 uncovered a novel role. Subcellular localization studies based on fusions with fluorescent tags showed that PiCdc14 first appeared in nuclei during early sporulation. During the development of biflagellated zoospores from sporangia, PiCdc14 transits to basal bodies, which are the sites from which flagella develop. PiCdc14 interacted with microtubules in vitro, and abnormal cleavage of sporangial cytoplasm during zoosporogenesis occurred in transformants overexpressing PiCdc14. A connection between Cdc14 and flagella is also supported by their phylogenetic distribution (gain or loss), suggesting an ancestral role of Cdc14 in the regulation of basal bodies or development of flagellated cells.

Kinesin-13 regulates microtubule dynamicity and ciliary motility in *Tetrahymena thermophila.*

K. Vasudevan[1], T. Hennessey[2], J. Gaertig[1]; [1]Cellular Biology, University of Georgia, Athens, GA, [2]Biological sciences, SUNY Buffalo, NY

Previous research localized kinesin-13, a microtubule end depolymerase, to the tip of axonemes, and implicated this protein in negative regulation of ciliary length in diverse ciliated species (Blaineau et al., Curr. Biol., 2007,17:778-82; Dawson et al., Euk. Cell, 2007, 6: 2354-2364; Piao et al., Proc. Natl. Acad. Sci. USA. 2009, 106:4713-8). *Tetrahymena thermophila* has three kinesin-13 encoding genes: *KIN13A*, *KIN13B* and *KIN13C*. When tagged with GFP at the native locus, Kin13Ap-GFP was detected inside the micronucleus and the dividing macronucleus. Kin13Cp-GFP tagged at the native locus localized to the contractile vacuole pore. Kin13Bp tagged with GFP at the native locus did not produce a detectable fluorescence signal, but when overproduced, localized near basal bodies and inside cilia (including tips), and caused rapid disassembly of axonemes. Knocking out either *KIN13B* or *KIN13C* genes alone did not change the gross phenotype. However, cells lacking both *KIN13B* and *KIN13C* grow and move extremely slowly. Cilia of double knockout cells beat more slowly and have decreased curvature when viewed after fixation. Surprisingly, in KIN13B and KIN13C double knockout cells, the number, length and ultrastructure of axonemes and cortical microtubule bundles appear unaffected. However, the double knockout cells are hypersensitive to paclitaxel, indicating a change in microtubule dynamicity. A *GFP-KIN13B* transgene rescued taxol hypersensitivity of double knockout cells and GFP-Kin13Bp localized primarily to the basal

bodies. Based on immunofluorescence, the double knockout cells have increased levels of acetyl-K40 α-tubulin in cilia and cell cortex, consistent with decreased dynamicity of microtubules. We hypothesize that in *Tetrahymena*, kinesin-13 promotes tubulin subunit turnover in cortical and axonemal microtubules possibly by depolymerizing both the plus and minus ends, and that this activity is important for ciliary motility.

269

CrKinesin13, a microtubule depolymerizer, depolymerizes cytoplasmic microtubules to control tubulin pool for flagellar assembly in Chlamydomonas.

P. Tian[1], L. Wang[1], J. Pan[2]; [1]Tsinghua university, Beijing, China, [2]School of Life Sciences, Tsinghua university, Beijing, China

Cilia and flagella are microtubule based cellular organelle. They may be reassembled upon completion of cell division, or upon chemically or mechanically induced loss. How the molecular mechanisms underlying cytoplasmic microtubule dynamics to control assembly of this organelle is not well understood. Previously we have found that CrKinesin13, a microtubule depolymerizer, functions in both flagellar assembly and disassembly in Chlamydomonas reinhardtti. CrKinesin13 is phosphorylated in the cell body during flagellar assembly while it is targeted to the flagella during flagellar shortening. RNAi experiment demonstrates that CrKinesin13 is required for both processes. Here, we show that CrKinesin13 regulates the pool of cytoplasmic tubulins by depolymerizing cytoplasmic microtubule to regulate flagellar assembly. Conditions that interfere with cytoplasmic microtubule dynamics affect flagellar assembly. After flagella are removed chemically and the cells are allowed to reassemble flagella, control cells assemble around half length flagella in the absence of protein synthesis while CrKinesin13 RNAi cells assemble no flagella at the same condition. Similarly, adding Taxol to control cells completely blocks flagellar assembly in the absence of protein synthesis. At onset of flagellar assembly, cell body pool of free tubulin increased and cytoplasmic microtubules were shorter and sparse. In contrast, CrKinesin13 RNAi cells showed little or no changes in the amount of free tubulin or morphology of microtubule networks. The phosphorylated residues of CrKineisn13 were determined to be S100 and S522 by mass spectrometry. However, in vitro assay showed that protein phosphorylation did not affect microtubule disassembly activity of CrKinesin13. We conclude that CrKinesin13 controls cytoplasmic microtubule disassembly to regulate flagellar assembly and protein phosphorylation may facilitate CrKinesin targeting to microtubules by interacting with unknown factors. This work was supported by NSFC (Grant 30830057).

The primary cilium regulates the expression and subcellular localization of kinesin-3 family member Kif13B.

R. I. Thorsteinsson[1], A. Aleliunaite[1], I. R. Veland[1], S. T. Christensen[1], L. B. Pedersen[1]; [1]Department of Biology, University of Copenhagen, Copenhagen, Denmark

Intraflagellar Transport (IFT) motors of the kinesin-2 family are known to participate in building of the ciliary axoneme, but additional kinesins may contribute to certain aspects of cilia assembly or function. In *Caenorhabditis elegans* the kinesin-3 family protein Klp6 is required for localization of polycystin-2 to the membrane of sensory cilia (Peden and Barr, Curr Biol, 2005) and for regulation of IFT (Morsci and Barr, Curr Biol, 2011). A kinesin-3-encoding gene from *Drosophila* was found to contain a consensus binding site for cilia-specific RFX-type transcription factors, suggesting a potential ciliary function for this kinesin (Laurencon et al., Genome Biol, 2007). Furthermore, it was demonstrated that the kinesin-3 Kif13A localizes to

centrosomes in HeLa cells (Sagona et al., Nat Cell Biol, 2010), but if any mammalian kinesin-3 family proteins play a role in ciliary assembly or function is unknown.
We recently showed that kinesin-3 Kif13B is strongly up regulated during growth arrest in mouse NIH3T3 cells, suggesting potential cilia-related functions for this kinesin (Thorsteinsson et al., Methods Cell Biol, 2009). Further, we showed that the primary cilium plays a critical role in regulating directional cell migration in mouse fibroblasts (Schneider et al., Cell Physiol Biochem, 2010). Here we report that both endogenous and GFP-fused Kif13B are localized to the base of the primary cilium, as well as to cell-cell adhesion sites, in growth-arrested mouse fibroblasts and other cultured mammalian cell types. This localization is abolished in *Tg737*^{orpk} mouse embryonic fibroblasts (MEFs), which lack primary cilia, and in *inv*$^{-/-}$ MEFs, which are defective in cilia-mediated Wingless/Int signaling, cell polarity, and directional cell migration. Using RT-qPCR we show that the expression level of Kif13B is dramatically reduced in ciliated *inv*$^{-/-}$ MEFs compared to wild type MEFs, indicating that ciliary signaling controls the cellular level and localization of Kif13B. We hypothesize that KIF13B functions downstream of the cilium to promote cell polarity and directional cell migration.

271

Phosphorylation of the Kinesin II Motor KIF17 Impacts OS Turnover in Cone Photoreceptors.

J. Bader[1], C. Insinna[1], J. Besharse[1]; [1]Cell Biology, Neurobiology, and Anatomy, Medical College of Wisconsin, Milwaukee, WI

Photoreceptor outer segments (OSs) are highly specialized cellular compartments, which are essential for vision. Various proteins are targeted to the OS where they function in the vision pathway, however, the molecular details of protein targeting to the OS are not well understood. Recent studies have focused on intraflagellar transport (IFT) which is a highly conserved bidirectional transport pathway which occurs along the MT-based ciliary axoneme. The canonical IFT pathway requires several components; the multiprotein IFT particle, the heterotrimeric kinesin II or KIF3 complex (anterograde), and cytoplasmic dynein 2 (retrograde). Previous work from our lab has demonstrated that photoreceptor IFT requires an additional kinesin 2 family motor, the homodimeric KIF17. Inhibition of KIF17 leads to a significant disruption of OS formation without impacting photoreceptor inner segments (ISs), a defect which is not phenocopied by KIF3 complex inhibition. These findings suggest an OS specific, non-redundant role for photoreceptor KIF17-based IFT. However, the mechanism used to coordinate KIF17 and the KIF3 complex is not clear. We have identified a role for phosphorylation, at a highly conserved serine residue in KIF17's tail domain, in regulating KIF17-based photoreceptor IFT. Analysis utilizing non-phosphorylatable and phosphomimetic KIF17 mutants revealed that phosphorylation modulates KIF17's translocation to the distal tip of zebrafish cone photoreceptor cilia. Consistent with this, phosphorylation impacts KIF17 distal tip accumulation in cultured kidney epithelial cells suggesting a conserved mechanism of KIF17 regulation. Because the c-terminus of KIF17 links the motor to the IFT complex we tested if this phosphorylation event, through kinase inhibition assays and overexpression of our mutant constructs, regulates the motor-IFT interaction necessary for OS formation. The aforementioned assays, coupled with biochemical analysis revealed that phosphorylation of the KIF17 tail domain regulates the interaction between the motor and the IFT complex. Next we investigated the role of KIF17 phosphorylation in OS development and maintenance. Compared to WT KIF17 and non-phosphorylatable KIF17, expression of the phosphomimetic KIF17 in zebrafish cones induced a significant increase in OS disc shedding. These findings reveal a new mechanism used to coordinate KIF17 activity in photoreceptor OSs, which is essential for regulating OS turnover.

272

Differential Calcium-dependent Regulation of Embryonic Cilia.

R. M. Tombes[1], L. Francescatto[1], S. C. Rothschild[1]; [1]Biology, Virginia Commonwealth University, Richmond, VA

Zebrafish embryos have multiple populations of cilia that emerge from cells in tissues such as the KV, the pronephric kidney, the developing ear and in neuromasts. Each of these ciliated tissues exhibits Ca^{2+} elevations and activated CaMK-II. CaMK-II autophosphorylates (T^{287}) upon Ca^{2+}/CaM stimulation and can be immunodetected in zebrafish embryos, thus identifying subcellular compartments of prolonged and relevant Ca^{2+} signaling. The KV (Kupffer's vesicle) is a transient ciliated organ where cilia-driven fluid flow leads to left-sided elevations of Ca^{2+} and activation of the "nodal" cascade to establish left-right organ asymmetry. CaMK-II is activated in ~4 ciliated cells on the left side of the KV. The pronephric kidney has ductal and cloacal cilia, but only cloacal cilia exhibit activated CaMK-II. Ca^{2+} elevations in the KV and kidney are mediated by polycystin-2 (PKD2), a "TRP" family Ca^{2+} channel. Hair cells in the ear exhibit kinocilia that nucleate otoliths, the bony particles that respond to sound or gravity. P-CaMK-II is enriched at the base of the kinocilium, just above the basal body, in the region corresponding to the transition zone. Activated CaMK-II is also enriched in ciliated neuromast clusters, which are sensory cells that migrate and differentiate along the lateral line. Suppression of CaMK-II causes a loss of left-right asymmetry, and incomplete morphogenesis of the kidney, ear and lateral line. KV cilia are shorter, cloacal cilia disassemble, ear kinocilia beat improperly, while ductal and spinal cord cilia are unaffected. Downstream from CaMK-II, potential targets that could explain these roles include members of the histone deacetylase (HDAC) and kinesin families. These are promising targets of CaMK-II since a) mutants also show defects in left-right asymmetry and kidney development, b) family members have been implicated in Ca^{2+}-dependent ciliary resorption and c) HDAC's and kinesins are known substrates or binding partners of CaMK-II. HDAC inhibitors preferentially elongate cloacal cilia, while ectopic KIF2C interferes with left-right asymmetry. Our results suggest that activated CaMK-II sequesters KIF2C and HDAC family members, such as HDAC6. Upon CaMK-II inactivation, KIF2C and/or HDAC6 become active and cilia are resorbed. These findings are relevant to development and the dynamics of primary cilia.

273

The Effect of Calcium on IC138 Phosphorylation.

T. A. Jackson[1], B. N. Mason[1], T. W. Hendrickson[1]; [1]Biology, Morehouse College, Atlanta, GA

Ciliary/flagellar motility, which is driven by the microtubule motor dynein, has been shown to be regulated by changes in intraflagellar calcium. One of the key regulatory dyneins is IC138, an intermediate chain subunit of the inner arm dynein complex, I1. A network of axonemal kinases and phosphatases controls IC138 phosphorylation; when IC138 is phosphorylated the dynein is inactive. Many of the axonemal kinases and phosphatases are associated with the central pair apparatus and the radial spokes. Chlamydomonas mutants lacking these structures are paralyzed and their flagella contain hyperphosphorylated levels of IC138. Moreover, axonemes isolated from these mutants have low microtubule sliding velocities. These phenotypes can be rescued by treatment with phosphatases and kinase inhibitors. Additionally, treatment of wild-type axonemes with a high calcium buffer results in increased microtubule sliding velocities. However, the role of calcium as it relates to the localized phosphorylation of specific dynein subunits is not known. Based on these data, we hypothesize that calcium regulates IC138 phosphorylation. Preliminary data indicate that IC138 phosphorylation levels are altered in response to a high calcium treatment, as seen through western blotting techniques. These results provide additional evidence for a signaling pathway initiated by calcium and transduced

through the central pair apparatus and radial spokes, resulting in the activity/inactivity of the dynein motors. Future studies will determine the exact mechanism through which calcium influences IC138 phosphorylation, and thus dynein activity

274

Functional balance between ciliary kinase Mak and a microtubule-associated protein RP1 regulates ciliary length and survival of retinal photoreceptor cells.

T. Chaya[1], Y. Omori[1], K. Katoh[1], T. Furukawa[1]; [1]Developmental Biology, Osaka Bioscience Institution, Suita, Japan

Ciliary dysfunction is associated with various diseases that can be broadly classified as “ciliopathies” in humans. While ciliary components and transport machinery have been well studied, regulatory mechanisms of ciliary formation and maintenance are poorly understood. Here we show that male germ cell-associated kinase, Mak, regulates retinal photoreceptor ciliary length and subcompartmentalization. Mak was localized both in the connecting cilia and outer segment axonemes of photoreceptor cells. In the *Mak*-null retina, photoreceptors exhibit elongated cilia and progressive degeneration. We observed accumulation of IFT88 and IFT57, expansion of Kif3a and acetylated α-tubulin signals in the *Mak*-null photoreceptor cilia. We found abnormal rhodopsin accumulation in the *Mak*-null photoreceptor cell bodies at P14. Electron microscopy analysis revealed aberrant outer-segment disk formation in Mak deficient photoreceptors. In addition, overexpression of RP1, a microtubule-associated protein localized in outer segment axonemes, induced ciliary elongation, and Mak coexpression rescued excessive ciliary elongation by RP1. The RP1 N-terminal portion induces both ciliary elongation and microtubule acetylation, and is phosphorylated by Mak. We identified a phosphorylation site of RP1 by Mak. Furthermore, we investigated whether Mak phosphorylates Kif3a or not. We found that Mak directly phosphorylates Kif3a. These results suggest that Mak is essential for ciliary protein transport, regulation of ciliary length, acetylation of ciliary microtubules, and is required for the long-term survival of photoreceptors.

275

A Small Molecule-based Approach for Identifying Molecular Pathways Regulating Ciliary Length.

P. Avasthi[1], W. Marshall[1]; [1]Univ California-San Francisco, San Francisco, CA

Cilia or flagella are organelles that protrude from the surface of most mammalian cells and play diverse roles in sensing light, mechanical, and chemical signals as well as in generating flow of extracellular fluid. These nearly ubiquitous structures are so critical for normal cellular function that even minor alterations in ciliary length, assembly, or function can result in a variety of severe maladies including situs inversus, polycystic kidney disease, retinitis pigmentosa, and many pleiotropic disorders including Bardet-Biedl Syndrome, Joubert, Syndrome, and Meckel Syndrome. The ciliary core is a cylindrical arrangement of microtubule doublets and therefore regulation of ciliary structure and length has rightfully been addressed by studying the intraflagellar transport machinery and motor proteins required for ciliary assembly and disassembly. However, identification of long and short flagella mutants in the unicellular green algae, *Chlamydomonas reinhardtii*, has also highlighted the importance of signaling proteins not restricted to the flagellum. In this study, an unbiased chemical screen was performed to uncover pathways that are critical for ciliary formation and length regulation as well as identify potential targets for therapeutic intervention of ciliary malformation and malfunction. The annotated Sigma LOPAC1280 chemical library was utilized and flagellar phenotype was determined by assays for cell viability as well as flagellar length, motility and severing. Data from all assays were utilized to cluster potential targets for identification of novel pathways regulating flagellar

length and motility. The most frequently targeted protein family found to be involved in flagellar length regulation were the dopamine binding G-protein coupled receptors (GPCRs). *Chlamydomonas* is known to express GPCRs and have catecholamine biosynthesis and metabolism pathways. Further support for the role of this pathway in ciliary regulation comes from other ciliates in which biogenic amines are known to alter ciliary beat frequency and, in some cases, stimulate ciliary regeneration. Additionally, in mammals, dopamine receptors have been localized to neuronal cilia. Clustering analysis also predicted dopaminergic, opioid, and adrenergic receptors as potential regulators of flagellar motility, which was subsequently tested by high speed imaging. Comparison of data from a variety of assays using the same chemical library has successfully identified many novel signaling pathways that are potentially critical for ciliary formation and length maintenance. These include a variety of protein kinase pathways that may be ideal therapeutic targets for rescue of ciliary phenotypes.

276

NDR is required for ciliogenesis through the phosphorylation of Rabin8.

S. Chiba[1], Y. Amagai[1], S. Kanno[2], A. Yasui[2], M. Fukuda[3], K. Mizuno[1]; [1]Dept. of Biomol. Sci.,Grad. Sch. Life Sci., Tohoku Univ, Sendai, Japan, [2]IDAC, Tohoku Univ, [3]Dept. Dev. Biol. & Neurosci., Grad. Sch. Life Sci., Tohoku Univ

The primary cilium is a microtubule-based membrane projection localized on the surface of many vertebrate cells. Defects of cilium formation (ciliogenesis) and/or function cause an array of genetic disorders, such as Bardet-Biedl syndrome and polycystic kidney disease. Accumulating evidence indicated that vesicular transport mechanism involving Rab8 and its specific guanine nucleotide-exchange factor (GEF) Rabin8 (also known Rab3IP) is required for cilium formation. However, little is known about the regulation mechanisms of Rabin8 activity and localization during ciliogenesis. Nuclear Dbf2-related protein kinase (NDR) is an evolutionarily conserved Ser/Thr protein kinase. Although NDR family kinases are known to have a critical role in polarized growth, morphogenesis and cell cycle progression in yeast and invertebrates, the physiological function of mammalian NDR remains poorly understood. Here, we identified Rabin8 as a physiological substrate of NDR. In vitro kinase assay and western blot analysis revealed that Rabin8 is phosphorylated by NDR in vitro and in cultured cells. Furthermore, we show that NDR-mediated Rabin8 phosphorylation is required for primary cilia formation in hTERT-RPE cells. siRNA-mediated depletion of NDR caused the defect in cilium formation. The defects of ciliogenesis in Rabin8 knockdown cells were rescued by the expression of siRNA-resistant (sr)-Rabin8, but not by expression of a non-phosphorylatable or phospho-mimetic mutant of sr-Rabin8. Intriguingly, these Rabin8 mutants exhibited aberrations in proper accumulation of Rabin8 at the centrosome after serum withdrawal. These results indicate that phosphorylation is required for the Rabin8 function during ciliogenesis. We also provided the evidence that the phosphorylation of Rabin8 does not affect its GEF activity toward Rab8 in cell-free assays. A proteomic approach revealed that 14-3-3 proteins were bound to Rabin8, dependent on the phosphorylation of Rabin8. Together our results suggest that NDR-mediated Rabin8 phosphorylation and subsequent association of 14-3-3 are involved in Rabin8 localization and function during ciliogenesis.

277

TSGA14 is mutated in the ciliopathy Joubert syndrome and is required for tubulin glutamylation at the cilium.

J-E. Lee[1], J. Silhavy[1], M. Zaki[2], J. Schroth[1], S. Bielas[1], J. Olvera[1], K. Ikegami[4], M. Setou[3], F. Hildebrandt[4], D. Doherty[5], E. Valente[6], C. Johnson[7], J. Gleeson[1]; [1]Univ California-San Diego, San Diego, CA, [2]Clinical Genetics Department, National Research Centre, [3]Department of Cell Biology and Anatomy, Hamamatsu University School of Medicine, Japan, [4]Department of Pediatrics and Communicable Diseases, University of Michigan, [5]Divisions of Developmental Medicine and Genetic Medicine, University of Washington Seattle Children's Hospital, [6]CSS-Mendel Laboratory, Casa Sollievo della Sofferenza Hospital, [7]Section of Ophthalmology and Neurosciences, St James's University Hospital

Tubulin glutamylation is a post-translational modification (PTM) occurring predominantly on ciliary axonemal tubulin and has been suggested to be important for ciliary function. However, its relationship to disorders of the primary cilium, termed 'ciliopathies', has not been explored. Here, in Joubert syndrome (JBTS), we identify the JBTS13 locus and the responsible gene as TSGA14, encoding a centrosomal protein of 41 KDa (CEP41). We show that CEP41 is localized to the basal body/primary cilium, and regulates ciliary entry of TTLL6, an evolutionarily conserved polyglutamylase enzyme. Depletion of TSGA14 causes ciliopathy-related phenotypes in zebrafish and mouse, and induces cilia axonemal glutamylation defects. Our data identify loss of TSGA14 as a cause of JBTS ciliopathy and highlights the involvement of tubulin PTMs in the pathogenesis of the ciliopathy spectrum.

278

Tubulin polyglutamylation regulates flagellar motility by modulating the function of inner arm dynein "e".

T. Kubo[1], T. Yagi[2], R. Kamiya[1]; [1]Department of Biological Sciences, Graduate School of Sciencee, University of Tokyo, Tokyo, Japan, [2]Department of Cell Biology and Anatomy, Graduate School of Medicine, University of Tokyo

Tubulin polyglutamylation is a post-translational modification that affects various microtubule-dependent cellular functions. The *tpg1* mutant of *Chlamydomonas* lacks a homologue of mouse TTLL9 (a tubulin polyglutamylase) and has a reduced level of polyglutamylated α-tubulin in the outer-doublet B-tubule. It displays lowered flagellar motility because of deficient interaction between inner-arm dynein and doublet microtubules (Kubo et al. Curr. Biol. 20, 441-445, 2010). *Chlamydomonas* has seven major species of inner-arm dyneins, designated dynein a~g. Dynein f (dynein I1) is a two-headed dynein containing two heavy chains, while all others are one-headed. In the present study, we produced double mutants of *tpg1* and various inner-arm-deficient mutants, and found that the *tpg1* mutation did not affect the lowered motility of mutants lacking inner-arm dynein e, while it greatly reduced the motility of mutants lacking dyneins other than dynein e. This observation suggests that tubulin glutamylation most sensitively affects the function of dynein e. The exceptionally basic microtubule binding site (the stalk tip) of dynein e may account for its high sensitivity to the *tpg1* mutation, which should greatly change the microtubule surface charge. Because dynein e is associated with the dynein regulatory complex (DRC; a multi-protein complex involved in dynein regulation and inter-doublet linkage) in the axoneme, and also because most mutants lacking dynein e examined in this study also lacked part of the DRC, it is possible that the *tpg1* mutation lowered the flagellar motility by affecting the function of the DRC as well as dynein e.

279

Identification of a flagellar-specific adenylyl cyclase as a candidate for the enzyme regulated by flagellar adhesion and cilium-generated signaling in *Chlamydomonas* gametes.

F. Li[1], Q. Wang[1], J. Ning[1], G. Vanderlaan[1], O. Billker[2], T. Otto[2], F. Schwach[2], W. J. Snell[1]; [1]Cell Biology, UT Southwestern Medical Center at Dallas, Dallas, TX, [2]The Wellcome Trust Sanger Institute, Hinxton, United Kingdom

The cilium/flagellum increasingly is being recognized as a key organelle in activation of developmental pathways. During fertilization in the biflagellated green alga *Chlamydomonas*, flagellar adhesion between plus and minus gametes activates a signaling pathway in flagella, leading to an ~15-fold increase in cAMP. Gamete activation triggered by the increase in cAMP elevation prepares the gametes for cell-cell fusion. Previously we described a flagellar adenylyl cyclase activity with regulatory properties specific to gamete flagella. Here we report studies on a gamete-specific adenylyl cyclase, ACgf. The protein has several putative transmembrane domains, one putative TPR domain, and one cyclase homology domain. RT-PCR analysis demonstrated that ACgf transcripts are upregulated during flagellar regeneration. RNA-Seq analysis showed that transcripts are barely detectable in asexual, vegetative cells, 20-fold higher in gametes, and are upregulated another 5-fold during gamete activation. Fractionation of cells expressing an epitope-tagged form of ACgf indicates that the protein is highly enriched in flagella. Thus, ACgf is a candidate for the gamete specific, flagellar adenylyl cyclase whose activity is regulated by cilium-generated signaling in *Chlamydomonas*. Supported by NIH grant GM25661 to W. J. S. and a Wellcome Trust grant to O. B.

280

Differential phosphorylation of the Chlamydomonas flagellar length marking protein CALK during flagellar assembly and disassembly.

M. Cao[1], J. Pan[1]; [1]School of Life Sciences, Tsinghua University, Beijing, China

The cellular and molecular mechanisms that underlie the assembly and disassembly of cilia and flagella as well as control of organelle length are poorly understood. Previously we showed that the phosphorylation state of the aurora-like protein kinase CALK in Chlamydomonas is a marker of the presence of flagella. Compared to CALK in cells with flagella of steady state length (CALK78), the CALK in deflagellated cells and in cells mutationally or physiologically rendered aflagellate became phosphoryated (CALK80) based on a phosphatase-sensitive electrophoretic shift in SDS-PAGE. We do not yet know the residues(s) whose phosphorylation is responsible for the electrophoretic shift in apparent molecular mass from 78kDa to 80kDa. CALK phosphorylation state also is a marker of flagellar length. During flagellar assembly only CALK80 was present in cells with flagella equal to or less than � length, and CALK80 was dephosphorylated to CALK78 when the flagella became greater than � length. Here, we show that CALK activity and phosphorylation state are differentially regulated during flagellar assembly and disassembly. In vitro protein kinase assays (with mutated forms of CALK) showed that phosphorylation of threonine residue 193 (T193) in the activation loop was essential for CALK to phosphorylate an exogenous substrate, but was not essential for autophosphorylation of CALK. Using an anti-phospho-CALK antibody (pT193), we made the unexpected observation that in cells with flagella of steady state length, even though the unknown residue responsible for the CALK 78-80 shift was not phosphorylated, T193 on CALK was phosphorylated. Upon flagellar loss, however, the unknown residue became phosphorylated concomitantly with dephosphorylation of T193. It was not obligatory for one residue to be phosphorylated and the other dephosphorylated, because when flagellar shortening was triggered (either by NaPPi treatment or during zygote development) the

unknown residue(s) and T193 both were phosphorylated. GST pull-down assays using truncated forms of CALK indicated that the C-terminal, non-kinase domain interacted with N-terminal protein kinase domain. We conclude that CALK interacts both with itself and with other regulatory proteins, and that this protein kinase is at the nexus of multiple cellular pathways that sense and regulate flagellar assembly, flagellar disassembly, and flagellar length. This work is partly supported by the National Natural Science Foundation of China (30830057) and Tsinghua university (2010THZ0).

Novel Interaction and Reciprocal Regulation between Annexin A2 and Keratin 17.

B. Chung[1], C. Murray[2], J. Van Eyk[2], P. Coulombe[1,2]; [1]Johns Hopkins School of Public Health, Baltimore, MD, [2]Johns Hopkins University

Keratins are cytoplasmic intermediate filament proteins providing crucial structural support in epithelial cells. Keratin expression has diagnostic and even prognostic value in disease settings, and recent studies have uncovered novel non-mechanical functions of keratins in cell signaling. Elevated keratin expression in select cancers is correlated with higher expression of epidermal growth factor receptor (EGFR), whose overexpression and/or mutation give rise to cancer. In order to explore the role of keratins in oncogenic signaling pathways, we examined the regulation of epithelial growth-associated keratin 17 (K17) in response to EGFR activation. K17 is specifically upregulated in detergent-soluble fraction upon EGFR activation, and immunofluorescence analysis revealed alterations in K17-containing filaments. Interestingly, we identified AnxA2 as a novel interacting partner of K17, and this interaction is antagonized by EGFR activation. K17 and AnxA2 proteins show reciprocal regulation. AnxA2 overexpression delays EGFR-mediated change in K17 detergent solubility, and downregulation of K17 expression results in decreased AnxA2 phosphorylation at Y23. These findings uncover a novel interaction involving K17 and AnxA2, and identify AnxA2 as a potential regulator of keratin filaments.

282

The Role of Tubulin Polyglutamylation on The Regulation of Neuronal Cytoskeleton.

K. Ohata[1], Y. Konishi[2], R. Tsuchiya[3], K. Ikegami[4], M. Setou[1]; [1]Hamamatsu University School of Medicine, Shizuoka, Japan, [2]University of Fukui, Fukui, Japan, [3]Mitsubishi-Kagaku Institute of Life Sciences, Tokyo, Japan

Microtubules, a major cytoskeletal component, form the structural basis of neuronal morphology and partake in directing intracellular transport. Tubulins are known to be highly polyglutamylated in neurons, and we, along with another group, have recently shown that a part of tubulin tyrosine ligase-like (Ttll) proteins catalyzes polyglutamylation of tubulins though the subsequent function of this polyglutamylation remains unclear. Present study demonstrates that Ttll1 and Ttll7 play major roles in adding glutamate chain to alpha and beta tubulin respectively in the brain. Ttll1 or Ttll7 single-knockout mice exhibited only a slight decrease in total polyglutamylation. To reveal the polyglutamylation function in the brain, we generated Ttll1-Ttll7 double-knockout mice which showed significant decrease in neuronal polyglutamylation. Immunohistochemical and electron microscopic analyses showed fewer neurofilaments in dendrites of cortical neurons in the double-knockout mice compared to the wild type, while the neurofilament distribution in Ttll1 or Ttll7 single-knockout mice was similar to that of the wild

type. This aberrant arrangement was specific to dendritic neurofitaments of double-knockout mice. The distributions of neurofilaments in axons and of microtubules in both dendrites and axons were comparable to that of the wild type. These results suggest that polyglutamilation regulates dendritic neurofilament distribution in the brain.

Monitoring the desmin-nebulin assembly kinetics by single molecule approaches.

D. C. Gillis[1], S. Winheim[2], N. Mucke[2], H. Herrmann[3], J. Langowski[2], G. M. Conover[1];
[1]Department of Veterinary Pathobiology, Texas A&M University, College Station, TX, [2]Division of Biophysics and Macromolecules, German Cancer Research Center, Heidelberg, Germany, [3]Division of Molecular Genetics, German Cancer Research Center, Heidelberg, Germany

Recent mathematical models support the idea that desmin intermediate filaments act as mechanical tethers to stabilize Z-discs between adjacent myofibrils and the extracellular matrix. Desmin association to nebulin is a key element in the maintenance of sarcomere connectivity, which is thought to be responsible for the lateral alignment of myofibrils. While the localization of the major integral proteins of striated muscle sarcomeres has been well characterized, the mechanisms that regulate the spatial organization with associated intermediate filaments are not yet well understood, particularly in regards to their role in muscle disease. To gain insight into the molecular mechanisms responsible for desminopathy, our study aims to understand structurally how desmin physically binds to nebulin fragments in vitro. We evaluated the early assembly kinetics using stopped flow experiments of two desminopathy-associated desmin mutants mapping to desmin binding peptides localized in the head (S46Y) and coil 1b (E245D) regions of desmin. Our data showed comparable light scattering at the tetramer level for desmin E245D and wild-type, while increased signals were obtained for desmin S46Y. However, during filament elongation no major differences were observed. Our sedimentation velocity analysis shows that the binding profiles of the nebulin fragment M160-164 shifted to higher s-values when mixed with either of these mutant desmin as compared to when mixed with wild-type desmin, suggesting that the interaction of these proteins responds to changes in desmin filament architecture. Using solid-phase binding assays, we detected that mutant desmin E245D bound with an increased binding capacity to nebulin M160-164 as compared to wild-type desmin, while no changes were detected for the interaction with mutant desmin S46Y. Using a combination of atomic force and total internal reflection microscopies ongoing single molecule experiments are evaluating in real-time the effect of nebulin fragment binding to fluorescently labeled desmin during late stages of filament elongation. All together our approach offers a powerful strategy to determine how complex cellular networks in muscle cells -intermediate filaments and sarcomeres- function in space and time.

284

Desmin exhibits versatile strategies to connect with sarcomere thin filaments.

C. M. Wilcox[1], D. C. Gillis[1], G. M. Conover[1]; [1]Department of Veterinary Pathobiology, Texas A&M University, College Station, TX

Desmin intermediate filaments (IF) form an intricate three-dimensional meshwork that organize and integrate myofibers inside muscle cells. Highly regular arrays of interdigitating actin and myosin filaments compose the sarcomeres, muscle's minimal contractile units demarcated by Z-discs structures within myocytes. Limited data is available regarding the mechanisms that regulate the spatial organization of intermediate filaments and sarcomeres. It is not completely understood why the relative abundance of nebulin and actin filament lengths distribution differs in skeletal and cardiac muscles. In this study, we hypothesize that desmin IFs attach to the actin thin filaments in skeletal muscle via nebulin, while in cardiac muscle this connection is mediated

by nebulette. Moreover, a deeper understanding on the linkage between intermediate filament and sarcomeres may be relevant to deciphering molecular causes for muscle diseases such a desminopathy caused by inherited mutations in desmin. To unravel the nature of the association of desmin IFs and sarcomeres, we compared the binding affinity of desmin to nebulette M1-5 to that of nebulin M160-164 by solid-phase binding assays. Our results show that both fragments bound strongly to desmin with comparable disassociation constants (Kd ~17nM). Furthermore, we show that desminopathy-associated mutant desmin E245D (coil 1B) and T453I (tail), localized within nebulin-binding desmin peptides, reveal a tight specific association with either nebulette or nebulin fragments (Kd ~5nM). Using negatively stained electron microscopy we detected nebulette binding to desmin filaments in a similar fashion as that observed for nebulin. We also observed areas of co-localization for desmin and nebulette in cardiomyocytes near the Z-band region of the sarcomere. Our finding that a marked decrease of nebulette and actin protein levels in heart tissues from desmin null mice supports a strong functional relationship between nebulette and desmin. Ongoing studies are using siRNA to silence nebulette in cardiomyocytes to determine the effects its downregulation has on sarcomeric markers (F-actin and tropomodulin) and Z-disc associated IFs (plectin and synemin) distribution. We predict that most likely desmin and actin transcript and protein levels will be significantly decreased in myocytes depleted of nebulette. We present a working model in which desmin association with nebulette tailors specific functions to satisfy physiological demands of involuntary cardiac muscle, which in voluntary skeletal muscles are met instead by desmin association with nebulin.

285

Regulation of Vimentin Expression Modulates p53 Levels and Apoptosis in Cancer Cells.

A-M. Fortier[1], É. Asselin[1], M. Cadrin[1]; [1]Chem/Biol, Molecular Oncology and Endocrynology Group, Univ Quebec at Trois-Rivières, Quebec, Canada, Quebec, PQ, Canada

Vimentin, a mesenchymal-specific intermediate filament (IF) protein, is often express in epithelial cancers exhibiting a de-differentiated phenotype. Vimentin is associated with increased chemoresistance and metastatic potential. Chemoresistance is a multifactorial phenomenon which is a major cause of treatment failure in human cancer. Some IF proteins are known to promote resistance to stress-induced apoptosis, but the role of vimentin in this process is still unknown. In the present study, we investigate the role of vimentin in response to apoptosis-induced chemotherapeutic drugs in different epithelial carcinoma cell lines. Surprisingly, using siRNA, our results show that vimentin downregulation decreases caspase-3 and PARP cleavage induced by cisplatin, doxorubicin and TNFalpha. This unexpected result could be explained by the decrease of p53 protein levels in vimentin-downregulated cells. Indeed, we observed that vimentin knockdown decreases p53 protein levels in a proteasome-independent manner. PI3K/Akt pathway is well known to promote chemoresistant phenotype in different cancers and Akt can also regulate p53 function. Our results show that vimentin-induced p53 decrease is associated with an increase of Akt activation/phosphorylation and XIAP protein levels. We propose that vimentin knockdown results in an increase of Akt activity which in turn regulates p53 levels. Previous studies already shown that vimentin can sequester p53 in cytoplasm. However, to our knowledge, these results represent the first indication that vimentin could regulate p53 levels and Akt activity in response to apoptosis-induced chemotherapeutic drugs. We have recently showed that Akt isoforms regulates vimentin expression in epithelial cancer cells, suggesting that it is directly involved in PI3K/Akt signaling pathway. These results support the hypothesis that modulation of vimentin expression plays an active role in cancer progression. Supported by NSERC to MC and IRSC to EA.

Vimentin's Effect on Stiffness Depends on Cell Type.

M. Mendez[1], Q. Wen[1], P. Janmey[1]; [1]Institute for Medicine and Engineering, University of Pennsylvania, Philadelphia, PA

The mechanical characteristics of intermediate filaments (IF), including vimentin, support previous experimental results that showed roles for IF in the maintenance of cell mechanical properties and force resistance. Vimentin's involvement in cell motility was also recently demonstrated, and the formation of lamellipodia in regions devoid of vimentin provided further evidence that vimentin may locally stabilize the plasma membrane. We are investigating the effects of vimentin expression and distribution on cell stiffness, as well as how substrate stiffness affects vimentin dynamics. In order to compare the local stiffnesses of regions containing or not containing vimentin filaments, we generated micron-resolution stiffness maps of live cells expressing a fluorescently-tagged vimentin and correlated the stiffness and fluorescence intensity at each pixel. Our results demonstrate that in mouse embryo fibroblasts (mEF) on glass coverslips, regions containing vimentin filaments are less stiff than regions in which no vimentin is evident. Similar results are obtained when cells are immunostained for their endogenous vimentin. Vimentin-containing regions of mEF or epithelial MCF-10A cells, both of which endogenously express vimentin, are less stiff than regions where vimentin filaments are not present. These studies suggests that when cells express all three cytoskeletal filament types, cytoskeletal regions formed by relatively rigid F-actin and microtubules alone are stiffer than regions in which the more flexible vimentin filaments are present. Intriguingly, transient transfection with vimentin in MCF-7 epithelial cells, which do not express vimentin endogenously, increases their stiffness relative to non-transfected cells, possibly because in this case the added vimentin compounds the stiffness of the existing keratin IF network. We compared the average stiffnesses of clusters of single point measurements made over the nuclear region, the perinuclear region or near the cell periphery. In all three regions, MCF-7 cells expressing vimentin are stiffer than non-transfected cells of similar morphology on the same coverslip. We are also investigating how substrate stiffness affects the distribution and dynamics of the vimentin network. FRAP experiments in cells plated on substrates of varying stiffnesses demonstrate that the rate of vimentin subunit turnover is greater in cells grown on soft (5-10 kPa) than on very stiff (glass) substrates. These results suggest that one effect of vimentin expression is to 'tune' a cell for existence on a substrate of certain stiffness. Supported by NIH-GM083272 and GM096971.

Electron Microscopy Structure Studies of Keratin Filaments.

L. Sandblad[1,2], A. Hoenger[1], L. Norlen[3]; [1]The Boulder Lab for 3D EM, University of Colorado at Boulder, Boulder, CO, [2]Umeå Center for Microbial Research, Umeå University, Umeå, Sweden, [3]Department of Cell and Molecular Biology, Karolinska Institutet, Stockholm, Sweden

A disorganization of the keratin cytoskeleton in the outer skin layers physically creates a skin barrier dysfunction causing increased water permeability. This is a central feature in many skin diseases such as atopic dermatitis as well as for genetic disorders that are based on specific keratin mutations. We aim at understanding how cellular keratin filaments achieve this assignment and how keratin filaments are spatially organized and regulated.

We use negative staining, cryo-electron microscopy and cryo-electron tomography to characterize the structure, assembly and organization of keratin filaments in vitro. Purified recombinant keratin polymerizes into structurally variable filaments depending on dialysis conditions. Filaments in physiological buffer were vitrified on electron microscopy grids by

plunge-freezing. By this method macromolecular assemblies can be imaged in their native states without fixative or staining artifacts. These in vitro studies can be compared to electron micrographs of vitreous sections of native human skin. The advantages with cryo-electron microscopy are that intramolecular as well as intermolecular organization and the 3D properties are maintained during preparation and data collection. This allows us to study at molecular detail the 3D structure of keratin filaments and reconstruct a model for assembly and skin keratinocyte maturation.

288

Mechanical Modeling of Keratinocyte Cell Spreading.

J. Kim[1], C-H. Lee[1], P. A. Coulombe[1,2]; [1]Biochemistry and Molecular Biology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, [2]Biological Chemistry, Johns Hopkins University, Baltimore, MD

Keratin intermediate filaments (IFs) are known to form crosslinked arrays so as to fulfill their structural support function in epithelial cells and tissues subjected to external stress. How the crosslinking of keratin IFs impacts the morphology and differentiation of keratinocytes in the epidermis and related surface epithelia remains an open question. Experimental measurements established that keratinocyte spreading area is inversely correlated to the extent of keratin IF bundling in two-dimensional culture. In an effort to quantitatively explain this relationship, we developed a simple continuum mechanical model in which isotropic cell spreading is considered as a first approximation. Relevant physical properties such as actin protrusion and adhesion events have been included in this model. The corresponding response of lamella formation at the cell periphery was included as a mathematical formula related to Bell's equation, along with experimental data relating time-dependent changes in keratinocyte surface area during spreading. Simulation results confirm the notion that the mechanical properties of crosslinked keratin filaments impact cell spreading, and detail the kinetics of this effect. The proposed model also provides insight into the distribution of stress within the cell and the impact of adhesion events during spreading. These *in silico* findings provide further support to the notion that differentiation-related changes in the density and intracellular organization of keratin IFs impact the morphological characteristics in epidermis and related stratified epithelia.

A wound-induced keratin regulates Src activity during keratinocyte migration and tissue repair.

J. Rotty[1,2], P. Coulombe[1,]2; Johns Hopkins School of Medicine, Baltimore, MD, [2]Johns Hopkins Bloomberg School of Public Health, Baltimore, MD

The overall objective of this study is to mechanistically characterize the migratory enhancement of keratin 6 null mouse keratinocytes. Injury to the epidermis triggers an elaborate homeostatic response resulting in tissue repair and recovery of the vital barrier function. The type II keratins 6a and 6b (K6a, K6b) are among the genes induced early on in wound-proximal keratinocytes and maintained during re-epithelialization. Paradoxically, genetic ablation of K6a and K6b in mouse results in enhanced keratinocyte migration. Here we show, primarily by analyzing keratinocytes in primary culture settings, that this trait results from activation of Src kinase and key Src substrates that promote cell migration. Endogenous Src physically associates with keratin proteins in keratinocytes in a K6-dependent fashion, as seen in co-immunoprecipitation and co-localization studies done in primary culture. Purified Src binds K6-containing filaments in vitro in co-sedimentation and far western overlay experiments via its SH2 domain in a novel, phosphorylation-independent manner, resulting in kinase inhibition. Detergent-resistant membrane preparations show that K6 occurs in lipid rafts, a key site of Src regulation, and rafts

from K6 null keratinocytes are depleted in both keratin and Src. We conclude that K6 negatively regulates Src kinase activity and the migratory potential of skin keratinocytes during wound repair, and possibly in related contexts such as cancer.

290

Vimentin's Role in Lipid Droplet Biology.

B. Grin[1], R. D. Goldman[1]; [1]Cell and Molecular Biology, Feinberg School of Medicine at Northwestern University, Chicago, IL

Adipoctyes are specialized cells containing numerous lipid droplets (LDs) that are surrounded by vimentin intermediate filament (VIF) cages. Using the 3T3-L1 system as a model for adipocyte differentiation we have investigated the interaction between LDs and VIF. In pre-adipocytes the VIF network extends throughout the cytoplasm; as differentiation progresses VIF wrap around medium and large LDs as reported by others. Electron micrographs of platinum replicas of adipocytes clearly show that VIF wrap around and terminate on the LD surface. To determine if there is a physical link between VIF and LDs, cells were treated with nocodazole to depolymerize microtubules; in pre-adipocytes this causes the VIF to re-organize into a perinuclear cap. In adipocytes, however, VIF remain wrapped around the lipid droplets after nocodazole treatment, suggesting a physical link between VIF and LDs. To extend our microscopic findings we isolated LDs from adipocytes using sucrose density gradient centrifugation and found that VIF co-purified with the LDs, in agreement with previously published proteomic studies. Since the major function of LDs is to store fatty acids in the form of triacylglycerides we have initiated studies to determine if VIF modulate lipolysis, the process of release of fatty acids from adipocytes. We have found that stimulation of adipocytes with isoproterenol (an adrenergic receptor agonist) results in phosphorylation of VIF by PKA. PKA is the major activator of lipolytic processes in the adipocytes. In order to determine whether there is a specific role for VIF in lipolysis, vimentin expression was reduced using shRNA. The loss of vimentin resulted in a 42% reduction in the rate of lypolysis as measured by glycerol release, suggesting that VIF play an important role in lipolysis.

291

Assembly properties and cellular distribution of human lamin A progeria mutants.

H. Herrmann[1], D. Möller[1], M. Mauermann[1], K. Nöske[1], M. Hergt[1], U. Aebi[2]; [1]B065, German Cancer Research Center (DKFZ), Heidelberg, Germany, [2]M.E. Müller Institute for Structural Biology, Biozentrum, University of Basel, Basel, Switzerland

We have analysed the assembly properties of eight point-mutated variants of lamin A causing premature ageing: T10I, Y45L, A57P, R133L, L140R, S143F, E145K, Y376L, as well as the “classical” lamin A mutant progerin. We followed a robust assembly protocol for paracrystal formation, employing high concentrations of CaCl2, and screened the assembly products by transmission electron microscopy. With wt-lamin, regular paracrystals of different size are abundant from 30 min on. By one hour, extensive paracrystalline arrays are observed at low magnification (3,000x) that upon closer inspection exhibit the well known regular transverse banding pattern with a 24.5-nm axial repeat. Surprisingly, the majority of the mutant variants assembled into structures seemingly identical to those exhibited by wt-lamin A, except for the E145K and the A57P mutant. Whereas the former produced long fibers with some kind of ordered substructure – but no regular transverse banding pattern – the latter formed exclusively non-structured aggregates. Similarly, under standard filament forming conditions, the A57P-lamin A did not assemble into extended filaments but only into aggregates like under paracrystal conditions.

When the mCherry-tagged A57P-lamin A was transfected into human U2OS cells, the protein did not integrate into the nuclear envelope but was distributed, different from mCherry-wt lamin A, in extensive fibrillar arrays throughout the cytoplasm. Hence, the mutation of alanine to proline at position 57 of lamin A compromises its assembly properties strongly, both in vitro and in vivo. Despite the fact that this alanine is in a b- rather than an a-position of the heptad repeat pattern, the proline at this position appears to have a dramatic effect on the structure of the coiled-coil dimer and thereby impedes all types of regular higher-order assembly. Furthermore, alanine 57 is not conserved in the various intermediate filament proteins and therefore most probably mediates a lamin A-specific molecular interaction.

Myosins

292

Regulating motor force in skeletal muscle contraction.

B. chen[1], H. Gao[2]; [1]IHPC, Singapore, Singapore, [2]School of Englineering, Brown Univ.

In active biological contractile processes, multiple motors can perform coordinated and synchronous actions while individual myosin motors appear to randomly attach to and detach from actin filaments. Recent experiment has demonstrated that, during skeletal muscle shortening at a wide range of velocities, individual myosin motors maintain a force about a fixed value during a working stroke. To understand how such force “homeostasis” can be so precisely regulated in an apparently chaotic system, here we develop a molecular model within a coupled stochastic-elastic theoretical framework. The model reveals that the unique force-stretch relation of myosin motor and the stochastic behavior of actin-myosin binding cause the average number of working motors to increase in linear proportion to the filament load, so that the force on each working motor is rather precisely regulated, in excellent agreement with experiment.

293

Nonmuscle Myosin II Drives Contractile Ring Constriction by Exerting Tension on but not Translocating Actin-Filaments.

X. Ma[1], M. Kovács[2], R. S. Adelstein[1]; [1]Laboratory of Molecular Cardiology, NHLBI/NIH, Bethesda, MD, [2]Department of Biochemistry, ELTE-MTA “Momentum” Motor Enzymology Research Group, Eötvös University, Hungary

During vertebrate cytokinesis it is thought that contractile ring constriction is driven by nonmuscle myosin II (NM II) translocation of antiparallel actin-filaments, similar to muscle contraction. Here we report in vivo, in situ and in vitro observations that challenge this hypothesis. NM II-B is essential for normal cardiac myocyte development. Ablation of NM II-B in mice resulted in defects in cardiac myocyte cytokinesis. Surprisingly, expression of mutant NM II-B R709C that cannot translocate actin filaments and has a substantially diminished MgATPase activity, in place of wild-type NM II-B, successfully rescues multinucleation in NM II-B ablated cardiomyocytes in mouse hearts. Graded siRNA knockdown of NM II-B in cultured COS-7 cells reveals that the amount of NM II limits contractile ring constriction. Time-lapse analyses show that both the rate and extent of ring constriction depends on the level of NM II expression. In addition expression of motor-impaired mutant NM IIs (NM II-B R709C, NM II-A N93K and NM II-A R234A) restores contractile ring constriction in COS-7 cells depleted of NM II-B, even though these mutant NM IIs are incapable of translocating actin-filaments. However contractile ring constriction is blocked by blebbistatin inhibition of myosin II strongly bound to actin in cells expressing either wild-type or mutant NM IIs. These results support a role for NM II

in generating tension but not translocating actin-filaments during contractile ring constriction. This role is substantiated by in vitro transient kinetic experiments with baculovirus-expressed NM II proteins using stopped-flow analyses. The mechanochemical properties of mutant NM II-B R709C show extremely high affinity for actin, despite loss of actin translocation. Under loaded conditions, mutant NM II exhibits prolonged strong actin attachment during which a single mechanoenzymatic cycle spans most of the time of cytokinesis. This prolonged attachment promotes simultaneous binding of essentially all NM II heads to actin, thereby increasing tension generation and resisting expansion of the ring and cell cortex, but further preventing translocation of actin-filaments.

294

Defining the Properties of Nonmuscle Myosin IIs Using Full Length Proteins.

N. Billington[1], A. Wang[2], A. Nagy[1], J. R. Sellers[1], R. S. Adelstein[2]; [1]LMP, NHLBI, Bethesda, MD, [2]LMC, NHLBI, Bethesda, MD

Nonmuscle myosin IIs (NMIIs) are filament-forming myosins which are involved in a wide variety of cellular processes including cell adhesion, migration and cytokinesis. There are three paralogs of NMII in humans and mice, based on heavy chain expression by three different genes, located on different chromosomes. Owing to the difficulty in expressing the full length proteins (composed of dimers of a 230 kDa heavy chain and two pairs of light chains), previous studies on NMII have used tissue purified protein or expressed fragments of the molecule; both cases present potential drawbacks for in vitro protein characterization. To approach their native properties, we have successfully expressed full length wild type and mutated NMII proteins using the Sf9-baculovirus system. We also expressed two chimeric NMII proteins [Wang A et al. PNAS 2010, 107(33):14645-50] and GFP-NM II fusion proteins. We find that: I) although full length NMIIA, IIB and IIC exhibit biochemical differences, the morphology of the filaments determined by negative-staining electron microscopy (EM) is essentially indistinguishable among the three paralogs. In the presence of ATP all three paralogs display a similar ability to adopt the 10S compact conformation. II) EM images of chimeric molecules show that the tail domains of the paralogs are interchangeable in terms of filament formation and formation of the 10S compact conformation; III) In contrast to a previous report, the presence of point mutations in full length NM IIA proteins (N93K, D1424N, E1841K) causing human diseases has little or no obvious effects on filament formation; IV) GFP fused to NM II allows us to directly analyze in vitro motility (IVM) by TIRF microscopy.

295

Mutations in the Motor and Rod Domains of Murine Nonmuscle Myosin II-A Cause Similar Defects and Mimic Human *MYH9*-Related Disease.

Y. Zhang[1], M. Conti[1], D. Malide[1], F. Dong[2], A. Wang[1], Y. Shmist[1], C. Liu[1], P. Zerfas[3], M. Daniels[1], C-C. Chan[4], E. Kozin[5], B. Kachar[5], M. Kelley[2,6], J. Kopp[7], R. S. Adelstein[1]; [1]National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health, Bethesda, MD, [2]Department of Medicine, Duke University Medical Center, Durham, NC, [3]Office of Research Services, Division of Veterinary Resources, National Institutes of Health, Bethesda, MD, [4]National Eye Institute (NEI), National Institutes of Health, Bethesda, MD, [5]National Institute of Deafness and other Communication Disorders (NIDCD), National Institutes of Health, [6]Medical Services, Durham Veterans Affairs Medical Center, Durham, NC, [7]National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), National Institutes of Health, Bethesda, MD

Point mutations in *MYH9*, the gene encoding nonmuscle myosin heavy chain IIA (NMHC II-A), underlie autosomal dominant syndromes in humans (incidence 1 in 500,000). The abnormalities can manifest as macrothrombocytopenia, granulocyte inclusions, progressive proteinuric renal

disease, cataracts, and sensorineural deafness. To gain insight into the pathological mechanism of *MYH9*-related disease in humans, we generated three mouse lines, each with a different mutation in *Myh9* (R702C, D1424N and E1841K). Each line develops *MYH9*-related disease similar to that found in human patients. R702C mutant *human* cDNA fused with GFP was introduced into the first coding exon of *Myh9*, and D1424N and E1841K mutations were introduced directly into the corresponding exons. Homozygous R702C mice die at embryonic day 10.5-11.5 while homozygous D1424N and E1841K mice are viable. All heterozygous and homozygous mutant mice show macrothrombocytopenia with prolonged bleeding times, a defect in clot retraction and increased extramedullary megakaryocytes. Studies of cultured megakaryocytes and live cell imaging of megakaryocytes in the bone marrow show that heterozygous R702C megakaryocytes form fewer and shorter proplatelets with less branching and larger buds. The results indicate that disrupted proplatelet formation contributes to the macrothrombocytopenia in mice and most likely in humans. We also observed premature cataract formation, kidney abnormalities including albuminuria, focal segmental glomerulosclerosis with progressive kidney disease and mild hearing loss. Our results show that heterozygous mice with mutations in the myosin motor or filament-forming domain manifest similar phenotypes to humans with *MYH9*-related disease.

296

HCM and DCM causing mutations affect the velocity and force producing capacity of human beta-cardiac myosin.

K. Ruppel[1], E. Choe[1], M. W. Elting[1], J. Sung[1], P. Shaklee[1], S. Sutton[1], L. A. Leinwand[2], J. A. Spudich[2]; [1]Stanford University School of Medicine, Stanford, CA, [2]Colorado University, Boulder

Over 250 mutations in the β-cardiac myosin heavy chain can cause either hypertrophic or dilated cardiomyopathy (HCM or DCM), but the underlying molecular effects on the myosin molecule remain elusive. The primary reason the effect of HCM and DCM mutations on purified human β-cardiac myosin has not been elucidated is due to difficulties in expressing this protein in a functional and highly purified form. However, recent advances have resulted in the ability to express functional human α– and β-cardiac myosin in a mouse myoblast cell line. Using this expression system, we have purified wildtype human α– and β-cardiac S1 to which human cardiac essential light chain (MYL3) is bound. Analysis of these proteins in an in vitro motility assay reveals a velocity of ~ 0.5u/s for the β-cardiac S1 and ~1 u/s for the α–isoform at room temperature. Single molecule analysis using a dual beam optical trap assay to measure the stroke size under low load and the maximum force that single molecules of myosin can produce also show significant differences between the isoforms. Expression and purification of mutated forms of human β-cardiac S1 corresponding to mutations observed in patients with HCM (R403Q, R453C) and DCM (S532P) has been carried out, and ongoing analysis suggests these mutations alter both velocity and force production of the myosin motor.

297

Structure of Human β-Cardiac Myosin Motor Domain at 3.2 Å.

D. A. Winkelmann[1], M. T. Miller[2], A. M. Stock[2,3], L. Liu[1]; [1]Pathology and Laboratory Medicine, Robert Wood Johnson Medical School, Piscataway, NJ, [2]CABM, Rutgers University, Piscataway, NJ, [3]Biochemistry, Robert Wood Johnson Medical School

Point mutations in the human ß-cardiac myosin heavy chain are linked to devastating human cardiac diseases such as familial hypertrophic and dilated cardiomyopathies. Over 192 individual disease-causing mutations have been identified in the ß-cardiac myosin heavy chain alone. A systematic analysis of the mutations in the human myosin has been hindered by the

instability and heterogeneity of the protein when obtained from human specimens and by the lack of an adequate expression system to produce human ß-cardiac myosin. We showed that the principle obstacle for the expression of vertebrate striated muscle myosin is motor domain folding which requires a regulated folding pathway unique to striated muscle. As a proof of principle we constructed a human ß-cardiac myosin Motor Domain (MD)::GFP chimeric protein with a GFP domain substituting for the light chain binding region and expressed it in muscle cells using adenovirus vectors. The human ß-cardiac myosin MD::GFP chimera expressed in this manner is a functionally active motor that has been purified, crystallized, and its structure determined at 3.2 Å resolution. The human cardiac myosin MD is structurally homologous with the other two striated myosin motor domains in the PDB: the chicken skeletal myosin S1 and the scallop striated myosin S1. The protein was crystallized without nucleotide and has a sulfate ion in the ß-phosphate binding loop similar to the earlier structures. There are two non-identical cardiac MD's in the crystallographic asymmetric unit and both MD's are in a near-rigor conformation with an open 50 KDa cleft and extended switch 2 loop. The two distinct cardiac MD::GFP molecules are tightly packed against one another and are essentially identical up to the converter domain-lever arm-GFP extension, that projects at different angles from the two molecules. The structure determination of the human ß-cardiac myosin MD provides a new opportunity to investigate the mechanics of this motor, analyze the structural changes that lead to disease, study cardiac myosin specific drug interactions, and explore new drug designs. (Supported by a grant from the AHA, NIH and HHMI.)

298

Influence of the Activity of Myosin II on the Stiffness of Suspended Cells.

F. Lautenschlaeger[1], K. Chalut[2], J. Guck[2]; [1]Institut Curie, Paris, France, [2]University of Cambridge, United Kingdom

Mechanical properties of cells, e.g. stiffness, are closely related to cell function. For example, we could show that cancerous cells are less stiff than normal cells (Guck et al. 2005) or that the deformability of a haematopoietic precursor cell line (NB4) changed significantly when cells were ATRA differentiated. Cellular stiffness is mainly defined by the cytoskeleton, specifically the amount and cross-linking of the different filaments. Here, we investigated the influence of the activity of the molecular motor myosin II on the stiffness of different cell types. Adherent cells often form actin stress fibers which have the potential to change the stiffness of the cells by simple physical reinforcement of the cytoskeleton but also play a role for myosin II binding to actin. Therefore, we chose to measure cells in suspension without any physical contact to avoid stress fibers. This was possible using a dual beam laser trap (optical stretcher), which enabled us to hold and stretch single cells at a high throughput rate. We compared the deformability of three different cell types (NB4 cells, 3T3 fibroblasts and TNGA cells) before and after the treatment with 50 ÂµM blebbistatin and found a significant stiffening of blebbistatin treated cells, a result which has been reported with the opposite trend measured on adherent cells by AFM before. Further experiments with Y-27632 and 12,13-dibutyrate have been performed. These experiments sheet new light on the influence of molecular motor activity on cellular stiffness, but also raise awareness of the adherence status of cells when investigating their mechanical properties.

299

Differential Evolutionary Constraints On The Coiled-Coil Proteins Tropomyosin, Paramyosin, and Myosin II In Invertebrate Striated Muscle.

G. White[1], E. Fox-Penner[1], G. Fiore[1]; [1]Science Department, Maret School, Washington, DC

The myofilaments of invertebrate striated muscle contain three coiled-coil proteins: tropomyosin (Tm) in the thin filament, and paramyosin (Pm) and myosin II (Myo) in the thick filament. The coiled-coil domains are important for both the assembly of the filaments and the packing of the proteins in the filaments. Using protein sequences from GenBank, the PCOILS coiled-coil prediction program and BLAST, we analyzed percent amino acid sequence (AA seq) divergence for identical AAs only in the coiled-coil domains of these three proteins for 62 invertebrates representing four major Phyla: Nematoda, Arthropoda, Plathyhelminthes, and Mollusca. Taken as a whole, our results demonstrate that the AA seq of these coiled-coil proteins are very highly constrained, with Tm being the most constrained in the majority of organisms examined (varying 0% – 1% within most Orders). Given actin's high conservation throughout Eukaryota, it is consistent that Tm's coiled-coil domain is so highly constrained. Phyla members were also subdivided to make comparisons between more closely related organisms. Our results also demonstrate differential constraints for the coiled-coil domains of Tm, Pm, and Myo, both between Phyla and within a Phylum. In Nematoda, in the genus *Caenorhabditis*, the order of constraint is: Tm > Myo B > Pm > Myo A (including the 322 AA region essential for stability). In *Caenorhabditis*, where there are two isoforms of myosin in the thick filament, it was unexpected that Myo B has the highest constraint and Myo A has the lowest constraint given that Myo A, the filagenins and Pm constitute the thick filament core, with Myo B added to complete the assembly. However, for plant and animal parasitic nematodes, the general order of constraint is: Pm > Tm > Myo B > Myo A with the Tm sequences diverging 2% - 6% within an Order. Parasitic nematodes are the only animals studied where Pm is the most highly constrained coiled coil. In Arthropoda, in the genus *Drosophila*, the order of constraint is: Myo > Tm > Pm. In the three most closely related *Drosophila* species (time to the last common ancestor (TLCA) < 10 MYA), the Tm's are identical, but for six more distantly related species (TLCA ≈ 10 - 35 MYA), the Tm coiled coils diverge ≈ 6%. For the other Orders of arthropods, however, the order of constraint is: Tm > Myo > Pm. Of special interest in insects is the Tm of indirect flight muscle. In those insects where the coiled-coil domain starts near the N-terminus and is then split by a long polyproline rich region, their coiled coils are slightly less constrained than Tm-2, while for those where the coiled-coil domain is centrally located, those are significantly less constrained than Tm-2. In Plathyhelminthes, the order of constraint is: Tm > Myo > Pm. In Mollusca, with a limited data set, Pm and Tm are equally constrained. With paramyosin located in the core of the thick filament, it seems counterintuitive (with the exception of the parasitic nematodes), that its coiled-coil domain is less constrained than myosin's, as one might assume that the assembly of the thick filament core would necessitate a closely packed, and hence, more highly constrained protein structure. However, it appears that the packing of the myosin onto the outside of the thick filament requires the greater constraint. The differential selection pressures on the maintenance of the coiled coils of tropomyosin, paramyosin, and myosin suggests that the exact role of each coiled-coil domain in the assembly of the thick and thin filaments may vary considerably within invertebrate striated muscle.

Structural characterization of thick filaments from *Drosophila* flight muscles.

J. O. Vigoreaux[1], L. R. Nyland[1], J. Budzik[1], T. Ruiz[2]; [1]Biology, University of Vermont, Burlington, VT, [2]Molecular Physiology & Biophysics, University of Vermont, Burlington, VT

Flightin is a novel myosin rod binding protein that is essential for flight muscle function in *Drosophila*. The absence of flightin compromises the structural integrity and functional rigidity of thick filaments. We have initiated an electron microscopy analysis of negatively stained thick filaments with the goal of identifying the structural basis for the effect of flightin mutations on thick filament and muscle properties. Previous attempts at defining the structure of *Drosophila* IFM thick filaments were hampered by the lack of helical order. Here we investigated experimental conditions required to order myosin heads along the thick filament backbone. We show that thick filaments isolated in near physiological relaxing solution with the addition of blebbistatin, a small-molecule noncompetitive inhibitor of myosin II shown to stabilize the helical order of tarantula thick filaments, allow the collection of two dimensional images of *Drosophila* thick filaments with well ordered myosin heads. The diffraction pattern of filaments in relaxing solution produced clear layer lines 1 (43.5nm), 3 (14.5nm) and 6 (7.2nm). The addition of blebbistatin produced more layer lines and the subsidiary maxima of the Bessel functions are more persistently clear. Tomographic reconstruction provided strong evidence of a hollow core. A detailed three dimensional model of the thick filament from the fruit fly flight muscle will be generated by 3D electron microscopy and image processing. A combination of molecular labeling techniques and comparison of filament structures with and without flightin will result in the identification and localization of flightin in the thick filament. These studies will provide the first higher resolution three dimensional structure of thick filaments from a model genetic organism and will provide the foundation for the structural analysis of *Drosophila* flight muscle mutants with known genetic, biochemical, and mechanical defects. In addition, these studies will serve as a model for understanding how myosin binding proteins contribute to the structural and biomechanical properties of thick filaments.

The E706K IBM3 myosin mutation depresses the chemomechanical properties and the stability of the molecular motor.

A. Cammarato[1,2], Y. Wang[3], J. A. Suggs[3], A. Melkani[3], G. C. Melkani[3], W. A. Kronert[3], S. I. Bernstein[3]; [1]Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD, [2]San Diego State University, San Diego, CA, [3]Biology and the Molecular Biology Institute, San Diego State University

Hereditary myosin myopathies are muscle diseases with variable clinical features and age of onset. Inclusion body myopathy 3 (IBM3) is an autosomal dominant myopathy associated with a missense mutation (E706K) in the myosin heavy chain IIa gene (MYH2). The disease is mild in childhood but appears progressive in adulthood, with proximal muscle weakness affecting movement. Biopsies from adult patients reveal dystrophic alterations and rimmed vacuoles consistent with an increased expression of the mutant motor with advanced age. Here we developed the first Drosophila melanogaster model system to study IBM-3. We constructed a transgene encoding E706K myosin and expressed it in Drosophila indirect flight and jump muscles. Flight and jump abilities were nearly absent in homozygotes. Homozygosity permits acquisition of highly pure samples of mutant myosin to investigate the unambiguous molecular consequences of the E706K mutation. The mutant myosin displayed 80% lower actin sliding velocity and 90 and 88% reductions in basal and actin stimulated ATPase activities compared to wild-type myosin. Heat-induced aggregation kinetics of myosin proteolytic fragments suggest that E706K S1 is more susceptible to aggregation relative to control S1. This observation was

directly verified via electron microscopy (EM), which revealed E706K myosin heads bear a dramatic propensity to unfold and to aggregate relative to wildtype heads. At 23ºC, 77.5% of control molecules exhibited two well-resolved independent heads compared to only 22.5% of mutant myosin molecules. A five minute, 37ºC incubation induced 80.9% of the control molecules' heads to form intra- or intermolecular aggregates versus 95.3% of the mutant myosin heads. This test suggests E706K myosin is far more labile than wildtype myosin. Furthermore, EM reveals E706K myofibrils exhibit Z-disk streaming, a loss of thick filaments and M-lines, sarcolemmal membrane invaginations and protrusions and they lack round shape and hexagonal packing of myofilaments. Cylindrical spiral membranes that resemble sarcolemmal inclusions of human skeletal myopathy are also found. Therefore, the ultrastructural hallmarks seen in adult patients also appear in our fly model. The depressed motor properties and the propensity for the mutant myosin to collapse and aggregate likely contribute to the muscle weakness observed in our fly model and possibly in senescent patients.

Myosin 1s Move Rapidly on Dorsal Surfaces of Lamellipodia.

P. Gupta[1], Y. Zuaning[1], C-H. Yu[1], N. Gauthier[1], M. Sheetz[1,2]; [1]Mechanobiology Institute, NUS, Singapore, Singapore, [2]Columbia University, New York, NY

Because the actin network in active lamellipodia is continuously assembling at the edge, moving inward at speeds up to 200 nm/s and disassembling, there is a question about how actin binding proteins and edge receptors are transported to the leading edge. There has been some indirect evidence of an active transport system but the basis of that transport is unknown. We show here that several myosin 1 isoforms (1G/1B/1C/1F) rapidly move to the leading edges of lamellipodia at different rates up to 5 μm/s. Photoactivation of PAmCherry-myosin 1G shows rapid outward movement on the upper surfaces of lamellipodia. Movement depends upon PH domains for lipid binding and upon ATPase activity. Surprisingly, at membranes bound to fibronectin-coated surfaces (ventral surface of lamellipodia), activated myosin 1G particles move in all directions; although at rapid rates (average velocity 3.4 ± 1.23 μm/s). Thus, it appears that myosin 1s actively move on dorsal actin to the leading edge and are not carried by fluid flow or some other biophysical mechanism. We suggest that myosin 1s transport actin, actin-binding proteins and some membrane receptors to the leading edges of lamellipodia to enable treadmilling. Further, myosin 1s can concentrate proteins at sites of actin polymerization.

303

Effect of Myosin1e Knockdown on Cell Adhesion, Spreading, and Random Cell Migration.

K. S. Cannon[1], L. Hamilton[1], M. Hughes[1], G. Cannarsa[1], D. S. Zuzga[1], C. King-Smith[1];
[1]Department of Biology, Saint Joseph's University, Philadelphia, PA

Class I myosins are actin-dependent molecular motors consisting of a head, neck, and tail; the tail domain contains TH1 (lipid binding), TH2 (proline-rich) and SH3 domains. Myosin1e is one of two "long-tailed" class I myosins, and has been implicated in both endocytic and exocytic membrane trafficking. In previous studies, knock out of another long-tailed myosin I, myosin1f, resulted in an increase in cell adhesion and spreading, and decreased cell motility, due to increased exocytosis of integrin-containing secretory vesicles (Kim *et al.*, 2006, Science **314**:136). The objective of the present research is to investigate whether myosin1e, like myosin1f, affects cell adhesion, spreading, and random cell migration in B16F1 mouse melanoma cells. The effect of myosin1e knockdown on both cell adhesion and cell spreading was examined on an integrin-dependent substrate, laminin, and an integrin-independent substrate, poly-L-lysine. Myosin1e knockdown resulted in significantly less adhesion and cell spreading on laminin compared to controls after 30 minutes. However, no significant difference

in adhesion and spreading was observed in myo1e knockdown cells plated on poly-L-lysine. Time-lapse videomicroscopy was used to track single cell migration in myo1e knockdown and non-targeting control cells. Preliminary random cell migration results demonstrate that myo1e knockdown cells exhibit less migratory behavior after two hours compared to controls. These findings are in contrast to results with myosin 1f-deficient cells, which exhibited increased adhesion and decreased cell motility. Nevertheless, these results suggest that myosin 1e has a role in cell adhesion, spreading, and random cell migration in B16F1 cells, possibly via regulation of integrin presentation at the cell surface.

304

Myosin-1a tail homology 1 (TH1) domain targets to phosphatidylserine enriched microvilli using multiple membrane binding motifs.

J. N. Mazerik[1], M. J. Tyska[1]; [1]Cell & Developmental Biology, Vanderbilt Univ, Nashville, TN

One of the most abundant components of the enterocyte brush border is the actin-based monomeric motor, myosin-1a (Myo1a). Within brush border microvilli, Myo1a forms lateral cross-bridges between the central actin bundle and the apical membrane. Proper physiological function of Myo1a depends on its ability to bind microvillar membrane, an interaction mediated by a C-terminal tail homology 1 (TH1) domain. As little is known about mechanistic details of the Myo1a-TH1/membrane interaction, our goal in this study was to characterize this binding event. In contrast to previously characterized class 1 myosins, Myo1a did not preferentially interact with phosphoinositol (4,5) bisphosphate (PIP2) in lipid binding assays. Additionally, mutating the conserved Myo1-pleckstrin homology (Myo1-PH) domain did not significantly impact microvillar enrichment of Myo1a-TH1 in cellular targeting assays. Using PIP strips to assay for other putative lipid binding partners in vitro revealed that Myo1a-TH1 might preferentially bind phosphatidylserine (PS). Myo1a-TH1 displayed striking colocalization with PS in microvilli of polarized epithelial cells. When co-expressed with the well characterized, bona fide PS binding domain from lactadherin-C2 (Yeung et al., Science; 2008), quantification of microvillar enrichment showed Myo1a-TH1 targeting was reduced, suggesting lactadherin-C2 can compete with Myo1a-TH1 for microvillar membrane binding sites. We sought to use our microvillar targeting assay to identify the minimal regions of Myo1a-TH1 required for microvillar enrichment. Structure/function analysis revealed that an N-terminal basic region, which is conserved across class 1 myosins, and a cluster of basic residues in the distal C-terminus of Myo1a-TH1, are both required for proper Myo1a-TH1 targeting to microvilli. Single molecule TIRF microscopy revealed that, of these two identified motifs, the C-terminal basic motif makes a greater contribution to the membrane bound lifetime of Myo1a-TH1. Taken together, our results suggest Myo1a membrane binding potential is distributed throughout TH1 rather than localized to a single motif and that the detailed mechanism of membrane targeting varies across vertebrate class 1 myosins. This variation may underlie differences in subcellular localization and function observed for distinct myosin-1 isoforms.

Myosin IIIA kinase activity is regulated by phosphorylation of the kinase domain activation loop.

O. A. Quintero[1], W. C. Unrath[1], S. Stevens[2], C. M. Yengo[3]; [1]Cellular and Molecular Physiology, Pennsylvania State University, Hershey, PA, [2]University of South Florida, [3]Pennsylvania State Univ Coll Med, Hershey, PA

Myosin IIIA (MYO3A) is the only member of the myosin superfamily that contains both a motor and kinase domain. We have found that the motor activity is decreased by autophosphorylation while little is known about the regulation of the kinase domain. We confirmed from sequence

analysis that MYO3A is a member of the STE kinase family and that threonine 184 (T184) is a highly conserved phosphorylation site among STE family members. We demonstrate by mass spectrometry that T184 is phosphorylated and identify several other potential phosphorylation sites in the kinase and motor domains. We present the probability of phopshorytion at each site and an examination of the regulatory role of T184. The kinase activity of MYO3A 2IQ with the phosphomimic (T184E) or phosphoblock (T184A) mutations demonstrates that kinase activity is reduced 30-fold as a result of the T184A mutation. Interestingly, the actin-activated ATPase activity of MYO3A 2IQ is impacted by the T184A/E mutations suggesting coupling between the motor and kinase domains. Furthermore, abolishing motor activity with a mutation in the motor active site reduces kinase activity 5-fold. To determine how altered kinase activity modulates the cellular functions of MYO3A, we plan to transfect GFP tagged MYO3A with the point mutations T184A/E into COS-7 cells. In addition, these experiments will be performed in the presence and absence of Espin 1, a known cargo for MYO3A in the stereocilia of inner ear hair cells. Our results suggest that phosphorylation of the kinase domain enhances MYO3A kinase activity, while phosphorylation of the motor domain deceases motor activity. We present a model for how the unique regulation of MYO3A allows it to function as an actin-bundle based transporter and in the formation of actin-bundle based protrusions.

306

Overlap of Cargo Adaptor Binding Sites on Myosin V Coordinates the Movement of Cargoes.

P. Eves[1], Y. Jin[2], M. Brunner[2], L. Weisman[3]; [1]Cell and Molecular Biology, University of Michigan Medical School, Ann Arbor, MI, [2]Life Sciences Institute, [3]Cell and Developmental Biology, Life Sciences Institute

Myosin V motors move multiple cargoes within each cell type. These cargoes move to distinct locations at different times, which raises the question of how myosin V motors select individual cargoes. Specificity is achieved in part through organelle specific adaptor proteins that link the motor to individual cargoes. Here we show that the cargo-binding domain of myosin V also plays a critical role in the selection of cargoes. We show that the cargo binding domain of yeast Myo2 contains at least two distinct binding regions comprised of overlapping binding sites for nine known cargo-specific adaptor proteins. The simpler region interacts with two of these adaptors, Mmr1 and Vac17. Time-lapse analysis of organelle inheritance reveals a direct role for Myo2 interaction with Mmr1 and Vac17 in the transport of mitochondria and vacuoles, respectively. Moreover, we demonstrate that Vac17 and Mmr1 compete for access to Myo2 in vitro and in vivo. Importantly, point mutations that disrupt the interaction of Vac17 with Myo2 cause an increase in the amount of mitochondria inherited. Conversely, mutations that disrupt Mmr1 interaction with Myo2 result in an increase in the amount of vacuoles inherited. Our data suggest that the overlap in cargo adaptor binding sites modulates the total amount of mitochondria and vacuoles that are transmitted from the mother cell to the bud, and thereby plays a role in the distribution of organelles.

307

Tropomyosin is Essential for Processive Movement of a Class V Myosin from Budding Yeast.

A. R. Hodges[1], E. B. Krementsova[1], C. S. Bookwalter[1], P. M. Fagnant[1], K. M. Trybus[1]; [1]Molecular Physiology and Biophysics, University of Vermont, Burlington, VT

In the budding yeast *S. cerevisiae*, the class V myosin Myo2p transports cargo along actin cables from the mother cell to the growing bud. Most class V myosins are processive, able to walk for a micron or more along actin filaments without dissociating, reflecting their role as cargo

transporters. Thus it was surprising when *in vitro* experiments characterized Myo2p as non-processive. However, these experiments were performed under non-physiologic conditions in that they used a track of bare skeletal muscle actin filaments. Here we show that Myo2p is processive on a more native actin track. Myo2p walks for several microns as a single motor along actin filaments containing tropomyosin, but shows no movement on bare actin. Different tropomyosin isoforms have varying effects on Myo2p behavior, but the native yeast tropomyosins Tpm1p and Tpm2p result in the strongest processivity. Smooth muscle tropomyosin also supports processive movement, but to a lesser extent. In contrast, nearly identical results were obtained with yeast and skeletal muscle actin. While moving processively, single quantum-dot labeled Myo2p motors moved at a speed of 5.5 µm/s with a step size of 34 nm. We are currently determine the mechanism by which tropomyosin affects Myo2p function. Initial results indicate that tropomyosin increases the fraction of each ATP hydrolysis cycle that Myo2p is strongly bound to actin (the duty ratio), and recruits more motors to actin filaments. Our results show that tropomyosin is crucial for the proper function of yeast myosin V. We speculate that several class V myosins in higher organisms that are non-processive *in vitro*, including human myosin Vc, may be processive on actin-tropomyosin tracks. In addition, there is growing evidence that myosin isoforms are differentially regulated by tropomyosin, and that tropomyosin may target the correct myosin to the proper actin structure in the cell.

308

A novel isoform of spire1 encodes a mitochondrial actin nucleator.

S. R. Bartholomew[1], R. Taranath[1], M. Stern[1], J. A. Spudich[1]; [1]Stanford Univ, Stanford, CA

Highly dynamic structures, mitochondria play an essential role in cellular energy production, calcium signaling and buffering, and apoptosis regulation. To efficiently carry out these processes, mitochondrial transport and positioning must be tightly regulated. Mitochondria move bi-directionally along microtubule tracks, frequently pausing and reversing direction. It is often necessary, however, for mitochondria to reach microtubule-deficient areas of the cell, such as synapses, growth cones, and microvilli. Myosins have been implicated in the transport of mitochondria to such microtubule-deficient regions, as well as in the frequent pausing events, yet the mechanisms of such events remain elusive. Myosin Va is a molecular motor that transports a diverse array of organelles, secretory vesicles, membranous cargo, mRNA, and vesicles along actin tracks. Identification of the proteins and complexes involved in myosin-dependent transport is paramount for obtaining a clear understanding of these transport processes. To this effect, we performed a biochemical screen using affinity chromatography to identify proteins that bind the globular tail domain of myosin Va. We identified spire1 as a protein that binds myosin Va with high affinity and specificity, and performed subsequent assays to verify direct binding of spire1 to the myosin Va tail *in vitro*. Amplification of the spire1 gene from mouse brain cDNA yielded a novel splice variant that localizes to the mitochondria in numerous cell types. Further analyses revealed that an alternate exon of 58 residues is both necessary and sufficient for mitochondrial localization. Spire1 is a multi-domain protein that nucleates actin through its WH2 domains. It also interacts with formin2 through its KIND domain, yet its role in mitochondrial dynamics remains unexplored. Further analyses using purified proteins, affinity chromatography, mouse models, and live-cell imaging, are being utilized to elucidate the mechanism by which Spire1 may mediate mitochondrial dynamics and localization.

309

Myosin VIIa and sans localization at inner ear hair cell stereocilia upper tip-link density (UTLD) implicates these Usher syndrome proteins in mechanotransduction.

M. Grati[1], B. Kachar[1]; [1]The National Institute on Deafness and other Communication Disorders, The National Institutes of Health, Bethesda, MD

Inner ear hair cell stereocilia convert mechanical vibrations into electrical signals via the coordinated interactions of multiple proteins precisely positioned within the mechanotransduction (MET) complex. The MET complex is present at both ends of a “tip-link”, a bridge comprising cadherin-23 and protocadherin-15, which connects two adjacent stereocilia. Electron microscopy has revealed a protein-dense plaque underlying the stereocilia membrane at each end of the tip-link. The upper tip-link insertion density (UTLD) is presumed to contain the scaffolding protein harmonin, and a cluster of motor proteins that continually pulls on cadherin-23, creating a resting tension on the tip-link that is essential for optimal mechanosensitivity. While early immunolocalization and functional studies suggested that myosin 1c was the tensing or adaptation motor, later localization attempts failed to detect myosin 1c concentrated at the predicted UTLD site. More recent electrophysiological studies with myosin VIIa showed that this Usher syndrome protein was essential for maintaining a resting tension on the tip-link. However, there have been no reports of localization of myosin VIIa at the UTLD. Therefore, the identity of the tip-link tensing motor and the localization of myosin VIIa have both remained unresolved. Using immunofluorescence we show that myosin VIIa and sans, another Usher syndrome protein known to interact with myosin VIIa, cluster together with harmonin-b at the UTLD. We confirm myosin VIIa and sans localization at the UTLD by transfecting hair cells with GFP-tagged constructs for these proteins. Based on the median value of the distribution of immunofluorescence reactivity for each protein, the estimated copy number for myosin VIIa, sans, and harmonin-b is shown to be 8:9:23 respectively. The high number of myosin VIIa molecules that cluster at the UTLD is consistent with a direct role for myosin VIIa in maintaining tip-link tension. Co-transfection studies in COS7 cells show that myosin VIIa, sans, and harmonin-b form a tripartite complex, and that each protein is capable of interacting with one another independently. We propose that myosin VIIa, sans, and harmonin-b form the core components of the UTLD complex, and that myosin VIIa is likely the motor element that exerts tension on the tip-link.

310

Relative functions of myosin VIIa isoforms 1 and 2.

A. Rump[1], D. S. Williams[1]; [1]Jules Stein Eye Institute, University of California at Los Angeles, Los Angeles, CA

Myosin VIIa plays a key role in transport of melanosomes and phagosomes in the retinal pigment epithlelium (RPE), in opsin transport in photoreceptor cells, and in stereocilia formation in the hair cells of the cochlea. Loss of myosin VIIa functions causes progressive retinal degeneration, leading to blindness, and cochlear dysfunction in Usher syndrome type 1B (USH1B). Two transcript variants of myosin VIIa have been reported, isoform (IF) 1 and IF 2. IF 1 has an additional 38 amino acids in the second FERM domain of the tail region.

To assess the relative functions of these two IFs, we first analyzed their association with cellular targets of myosin VIIa. Using confocal microscopy with ARPE 19 cells, we found that the cellular localization of the two isoforms differs. IF 1 is not targeted to phagosomes, which result from uptake of photoreceptor outer segment membranes. In contrast, IF 2 is targeted to these compartments, where it colocalizes with lysosomal-associated membrane protein 2. Real time PCR analysis of the transcription rates of IF 1 and IF 2 in the eyecup, RPE, neural retina and

cochlea of mice showed that IF 2 is transcribed at significantly higher levels than IF 1 in all of these tissues. The same results were obtained with samples of human RPE and neural retina.

Our results suggest that IF 2 accomplishes the major functions of myosin VIIa in the RPE, neural retina, and cochlea. Gene therapy with viral vectors is a promising approach for the treatment of the retinal defects of USH1B. However, the limited capacity of these vectors requires the use of cDNA inserts. Our analysis identifies IF 2 as the most appropriate myosin VIIa transcript variant to use for USH1B gene therapy approaches in the RPE and neural retina.

311

Myosin-10 interacts with wee1: implications for mitotic spindle structure and function.

J. Sandquist[1], S. Woolner[2], W. Bement[1,3]; [1]Zoology Department, University of Wisconsin-Madison, Madison, WI, [2]Faculty of Life Sciences, University of Manchester, United Kingdom, [3]Laboratory of Molecular Biology, University of Wisconsin-Madison

The unconventional myosin, myosin-10 (myo10), contributes to the structural integrity and/or function of various cellular structures including filopodia, meiotic and mitotic spindles. Previous studies from our lab of intact epithelium of the Xenopus laevis (hereafter Xenopus) embryo revealed that myo10 localizes to the mitotic spindle and that depletion of myo10 protein results in several mitotic spindle-related phenotypes including spindle elongation, failed anchoring, mitotic delay and spindle pole fragmentation [1]. However, the mechanisms by which myo10 contributes to proper spindle structure and function are currently unknown. Here we have characterized the distribution of GFP-tagged, full-length myo10 and several myo10 fragments in the embryo epithelium via 4D microscopy (x, y, z and time). Our data demonstrate that the subcellular distribution of GFP-myo10 is cell cycle dependent and that various interaction domains within the myo10 protein regulate different aspects of myo10 function. In particular, a pool of myo10 is nuclear and this localization, as well as spindle pole localization, both appear to be directed by a domain of the myo10 tail. Further results reveal that expression of a portion of the myo10 tail, the MyTH4 domain, induces some but not all of the spindle phenotypes resulting from myo10 depletion. In particular, GFP-MyTH4 expression induces multipolar spindles and abnormal spindle positioning at mitosis, but unlike myo10-depletion spindle length is normal. Preliminary results suggest that the ability of GFP-MyTH4 to produce phenotypes requires microtubule binding, but loss of microtubule binding enhances the localization of this fragment to the spindle pole, suggesting that the MyTH4 domain coordinates multiple myo10 functions. Interestingly, a yeast 2-hybrid screen identified wee1, a mitotic regulatory kinase, as a myo10 interacting protein. In vitro binding assays confirm a direct interaction between myo10 and wee1, and expression of wee1 and wee1 mutants in Xenopus embryos produce spindle phenotypes similar to GFP-MyTH4 expression. Moreover, the expression pattern of expressed, kinase-dead wee1 is perturbed in myo10-depleted cells compared to controls. These results reveal a novel interaction between myo10 and a cell cycle regulatory kinase with implications for regulation of the mitotic spindle structure and function.

312

"Headless" Myo10 is a negative regulator of full-length Myo10 and inhibits cortical axon outgrowth.

A. N. Raines[1,2], J. Courchet[3,4], F. Polleux[3,4], R. Cheney[5]; [1]Curriculum in Neurobiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Cell and Molecular Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, [3]Neuroscience Center, University of North Carolina at Chapel Hill, [4]Scripps Research Institute, [5]Cell and Molecular Physiology, University of North Carolina at Chapel Hill

Filopodia have critical functions in many stages of neuronal development, including axon outgrowth and targeting. Myo10 is an unconventional myosin that induces filopodia formation and moves within filopodia by walking along filopodial actin to reach the tip, where it is enriched. The motor (head) domain is required this intrafilopodial motility, while the tail region can bind to putative cargoes. Myo10 binds PIP3 with 1 of its 3 PH domains, permitting interaction with the cell membrane and positioning Myo10 within the crucial PI3 kinase pathway. The MyTH4 domain binds microtubules, allowing Myo10 to mediate actin-microtubule interactions. The tail region ends with a FERM domain that can bind integrins and the netrin receptors DCC and neogenin. The nervous system expresses both the full-length motor and a "headless" isoform that lacks most of the motor domain and thus cannot move on actin. We have hypothesized that this headless isoform may act as an endogenous dominant negative of the full-length motor, but this hypothesis has not been tested and the function of headless Myo10 remains unknown. We used shRNA specific to each isoform to determine their functions in mouse cortical neurons. Knockdown of full-length Myo10 decreased axon outgrowth by 35% and axon branching by 27%, while knockdown of headless Myo10 increased outgrowth by 90% and increased branching by 57%. To test whether these opposing effects reflect antagonism of full-length Myo10 by the headless isoform, we transfected COS-7 cells with each isoform. Expression of full-length Myo10 was sufficient to increase filopodia more than 5-fold, but co-expression of headless Myo10 prevented this filopodia induction. Together, these data indicate that full-length Myo10 is required for normal axon development and that headless Myo10 acts as a negative regulator of the full-length isoform.

313

Investigating Bundle Selection of Myosin X *In Vivo*.

A. Janik[1], R. S. Rock[1]; [1]The Department of Biochemistry and Molecular Biology, The University of Chicago, Chicago, IL

Cells organize their contents and regulate cell shape and mechanics through molecular motors functioning on cytoskeletal filaments. Myosin X, an actin-based motor that concentrates at the distal tips of filopodia of mammalian cells, selects the fascin-actin bundle at the filopodial core for motility. While poorly processive on single actin filaments, it takes processive runs on actin bundled by fascin. Recently we showed that the post-IQ region is the main contributor to myosin X's selectivity. This region contains a charged single alpha-helix (SAH), which may impart unique mechanical or affinity properties to the motor. The structural character of this region was perturbed by insertion of a free swivel (GSGGSG flexible linker) after the SAH domain. The post-SAH swivel mutant showed no preference for bundled actin for motility *in vitro*, thus providing support to a selectivity model where the search space of the forward head for the next binding site is constrained to neighboring filaments in a bundle. Here we investigate if interrupting the "selectivity module" has the described effect in live cells. To research its *in vivo* behavior we overexpressed the post-SAH swivel mutant in the U2OS cell line and compared it to wild type myosin X as well as our GCN4 forced dimer used in *in vitro* assays. We observe that overexpressed GCN4 forced dimer performs in the cell in the same manner as full-length

myosin X. Introducing a free swivel in the SAH domain region affects the selective nature of myosin X in the natural cytoskeleton environment of the cell interior, as co-localization of GFP labeled protein with filopodial tips does not occur for the Swivel mutant.

314

Myosin XI chaotic oscillations precede F-actin's during polarized growth of *Physcomitrella patens* cells.

Y-C. Liu[1], F. Furt[1], E. Tuzel[2], L. Vidali[1]; [1]Biology and Biotechnology, Worcester Polytechnic Inst, Worcester. MA, [2]Physics, Worcester Polytechnic Inst, Worcester, MA

Tip growth is essential for land colonization by bryophytes, plant sexual reproduction, and water and nutrient uptake. Because this specialized form of polarized cell growth requires both a dynamic actin cytoskeleton and active secretion, it has been proposed that the F-actin-associated motor, myosin XI is essential for this process. Nevertheless, the relationship between myosin XI and F-actin during tip growth is not known. Here, we use the highly polarized cells of the moss Physcomitrella patens to show that myosin XI and F-actin localize, in vivo, at the same apical domain and their signals exhibit an oscillatory pattern. These oscillations may represent an ancestral oscillator to the one observed in pollen tubes and root hairs. We also found that both signals follow chaotic dynamics, and surprisingly, phase analysis shows that myosin XI increase precedes F-actin's. We propose a model where myosin XI coincides with a signal that activates actin polymerization.

315

A novel cyclin-related protein interacts with a class XIV myosin and affects elongation of the macronucleus at amitosis in Tetrahymena thermophila.

M. Gotesman[1], R. E. Hosein[1], J. Flores[1], S. A. Williams[2], R. H. Gavin[1]; [1]Biology, Brooklyn College, CUNY, Brooklyn, NY, [2]Biological Sciences, New York City College of Technology, CUNY, Brooklyn, NY

In Tetrahymena thermophila, the macronucleus divides amitotically. At the onset of amitosis, intramacronuclear microtubules form an array oriented parallel to the axis of macronuclear elongation (Williams and Williams, JCS 20:61). The parallel array is not known to function as a spindle. Nuclei that fail to form the parallel array also fail to undergo macronuclear elongation resulting in grossly unequal division of the macronucleus, a phenotype observed in a MYO1 (Myosin class XIV) knockout and in the overexpression of GFP-tagged Myo1 MyTH4 domain (Gotesman et al., CSK 235:220; Williams et al., JEM 47:561). In the present study, mass spectrometry of immunoprecipitates containing GFP-Myo1 FERM identified a novel 7.4 kDa (p7) Tetrahymena protein with 34 % homology to cyclin-like proteins in Giardia and Trypanosoma. A peptide antibody against p7 detected a 7.4 kDa polypeptide on immunblots of wild type lysate. In a strain expressing a fusion of GFP and p7, antiGFP affinity pulled down the 35.5 kDa fusion protein and therefore confirmed its stable expression. Mass spectrometry identified Rab1B as a potential binding partner of the fusion protein. The p7 antibody detected the fusion protein and endogenous p7 on an immunoblot of lysate from the fusion-expressing strain. GFP-p7 colocalized with antitubulin to intramacronuclear microtubules. However, colocalization of the two signals was not uniform throughout the macronucleus, and separate GFP-p7 and antitubulin signals were also apparent. In contrast, there was significant colocalization of GFP-p7 and antiMyo1 throughout the macronucleus and the micronucleus. Eight hours after initiation of GFP-p7 over expression, 90% of the cells contained randomly-oriented intramacronuclear microtubules, which did not organize into a parallel array over an additional eight-hour period of observation, and the macronuclei did not achieve full elongation. Subsequent macronuclear division in overexpressing cells was either inhibited or grossly unequal. In wild type and in cells

expressing GFP alone, formation of the parallel array and subsequent amitosis appeared normal. This study indicates a novel cyclin-related protein affects elongation of the macronucleus, possibly through interaction with Myo1 and a subset of intramacronuclear microtubules. Biochemical analysis of the myosin-XIX (MYO19) motor domain.

R. C. Adikes[1], W. C. Unrath[2], C. M. Yengo[2], O. A. Quintero[2]; [1]Biochemistry Program, Mount Holyoke College, [2]Department of Cellular & Molecular Physiology, Penn State College of Medicine, Hershey, PA

Myosin-XIX (MYO19) is a novel unconventional myosin involved in mitochondrial dynamics. Analysis of the MYO19 amino acid sequence reveals that the motor domain contains the sequences required for ATPase and motor activity. Interestingly, sequence alignments of the motor domains of thirty MYO19 orthologs indicate conserved, class-specific differences in the motor domain when compared to well-characterized myosins, suggesting possible class-specific enzymatic properties. A tryptophan residue at the end of the P-loop is well conserved in 29 of 30 the MYO19 sequences analyzed, but not present in any other myosin classes. A class-19-specific cysteine substitution within switch I is conserved in 24 of the 30 sequences analyzed. The interaction between myosin and actin is known to be charge-dependent. The predicted actin-binding regions of MYO19 contain differences in charge when compared to the actin binding regions of other myosins, but were conserved at many of the residues implicated in interactions between actin and myosin. To determine the steady-state kinetics, we expressed and purified an S1-like fragment (MYO19-1IQ) as well as a fragment containing the motor and complete neck (MYO19-3IQ) using an insect cell-baculovirus expression system. The ATPase activity of both constructs was actin-activated. MYO19-1IQ also displayed a relatively strong actin affinity in actin co-sedimentation assays. MYO19-3IQ was also capable of moving actin filaments in the *in vitro* motility assay. As exogenous expression of full length GFP-MYO19 resulted in increased mitochondrial dynamics, we generated a construct with a point mutation predicted to interfere with nucleotide binding and examined the effect of expression of this construct on mitochondrial dynamics. Expression of the GFP-tagged construct containing a putative motor-inactivating mutation did not result in increased mitochondrial dynamics as assayed by displacement index (DI). Further characterization of this motor will allow us to elucidate the cellular function of this novel myosin and may suggest cellular instances in which MYO19 mediates mitochondria-actin interactions, such as in transport or anchorage. Supported by NCI-K01CA160667 to OAQ.

Chemotaxis and Directed Migration

317

Open Microfluidics for Passive Chemoattractant Gradient Generation.

G. Wright[1], D. Jowhar[1], A. Terekhov[2], L. Costa[2], W. Hofmeister[2], C. J. Janetopoulos[1]; [1]Biological Sciences, Vanderbilt University, Nashville, TN, [2]Center for Laser Applications, University of Tennessee Space Institute

The ability to elicit chemoattractant gradients in 3 dimensional channels has provided investigators with a whole new set of experimental platforms for cell migration studies. However, a major drawback with these devices is that it is difficult to load cells. In addition, chemoattractant gradients are generally provided by laminar flow and expose the cells to shear

forces that influences cell migration. We have developed several platforms in both polydimethylsiloxane (PDMS) and glass to overcome both of these problems. First, we have combined PDMS technology with a micropipette system and can provide a passive gradient to cells traversing 3D microfluidic channels. Using this system allows us to perform highly quantitative experiments on a cell's response to chemical gradients with varying slopes and mean concentrations. We have also developed a device that allows us to break down and re-establish the polarity of cells while migrating through a channel. Lastly, we have developed devices that are made entirely of etched glass. These glass devices are durable, optically superior, easy to unclog and fill, and are reusable. We have developed several devices in both bulk glass and in cover slips that have incorporated 3D microfluidic channels and have used them to image migrating Dictyostelium discoideum cells. Channels were fabricated using a laser ablation system which consists of a diode-pumped frequency doubled Neodymium-doped Yttrium Orthovanadate (Nd:YVO4) laser pump (Verdi), a Ti:Sapphire laser oscillator (Tsunami) and a regenerative amplifier (RegA9000). These on-chip devices produce passive gradients for migration assays and are useful for confocal and epifluorescent microscopes that are outfitted with environmental chambers or bulky equipment that do not permit the use of a micromanipulator and micropipette system as is typically used to create a passive gradient. We have etched 3D channels in a variety of configurations that range in diameter from several hundred nanometers to tens of microns and have elicited passive gradients of cAMP from single and multiple channels that lead to the successful recruitment of D. discoideum cells. Like the PDMS devices, these platforms are created so that the system is "open". An open system provides easy cell loading and allows the careful control of passive chemoattractant gradients for many hours and potentially days.

318

Unraveling G-protein signaling mechanisms during chemotaxis.

G. A. Wright[1], K. Qu[1], C. Janetopoulos[1,2];

[1]*Biological Sciences, Vanderbilt University, Nashville, TN,* [2]*Cell and Developmental Biology, Vanderbilt University*

Many of the signaling pathways controlling chemotaxis are identical in mammalian cells and in the social amoeba, *Dictyostelium discoideum. D. discoideum* exhibits chemotaxis toward folic acid during vegetative growth and to cAMP during aggregation and multicellular development. Since the majority of signaling components are conserved between folic acid and cAMP chemotaxis, mutants defective for folic acid chemotaxis should also exhibit a defect cAMP chemotaxis. While some mutants can have severe effects on gene regulation during cAMP development we find that we can typically rescue these developmental defects by co-developing mutants with wild-type cells. In this study, polarity and adhesion mutants (rckA and rap1) were assayed for their ability to chemotax under a variety of conditions. RckA is a Regulator of G-protein Signaling (RGS) domain-containing kinase implicated in managing cell polarity. Rap1 is a Ras-like small G protein that is involved in adhesion, chemotaxis, and polarity. The Rap1-CA and Rap1-DN mutations varied in their effects on cAMP chemotaxis depending on whether the mutants were co-developed with wild-type cells or were chemotaxing to folic acid during vegetative growth. RckA null mutants displayed a dramatic gain-of-function phenotype in their ability to chemotax to cAMP when assayed under these conditions. However, rckA mutants did not show a chemotaxis defect towards the chemoattractant folic acid. When the Rap1-CA or Rap1-DN mutations were expressed in a rckA null strain, cAMP chemotaxis was normal when these cells were co-developed with wild-type cells. However, these same cells displayed dramatic defects when tested for their ability to chemotax toward folic acid. These results suggest that RckA is functioning upstream of Rap1 during cAMP chemotaxis. However, during folic acid chemotaxis RckA and Rap1 seem to be regulated in different pathways and only effect

folic acid chemotaxis in the rckA null:Rap1 double mutants. The results also demonstrate that folic acid chemotaxis is not regulated similar to cAMP chemotaxis upstream of the small G-proteins. To our knowledge this is the first evidence of a heterotrimeric G-protein associated protein regulating downstream small-G proteins in *D. discoideum*.

319

Inhibition of Glutaminyl Cyclase Attenuates Cell Migration Modulated by Monocyte Chemoattractant Proteins.

Y-M. Lee[1], Y-L. Chen[1], W-L. Hwu[2], K-F. Huang[1], A. H. Wang[1]; [1]Academia Sinica, Nankang, Taiwan, [2]Pediatrics, National Taiwan University Hospital, Taiwan

Glutaminyl cyclase (QC) catalyzes the formation of N-terminal pyroglutamate (pGlu) in peptides and proteins. pGlu formation in chemoattractants may participate in the regulation of macrophage activation and migration. However, a clear molecular mechanism for the regulation is lacking. In this study, we explored the role of QC-mediated pGlu formation on monocyte chemoattractant proteins (MCPs) in inflammation. We first demonstrated in vitro the pGlu formation on MCPs by QC using mass spectrometry. With purified N-terminal uncyclized MCPs precursor (preMCPs) and pyroglutamate-containing MCPs (pMCPs), we showed that MCPs-stimulated macrophage migration is dependent on the pGlu formation. A potent QC inhibitor, PBD150, significantly decreased the effect of preMCPs on macrophage migration. QC siRNA revealed a similar inhibitory effect. Lastly, we tested whether inhibiting QC can modulate LPS-stimulated macrophage activation. We demonstrated that, in both U937 cells and human peripheral blood-derived monocytes, QC activity is increased by LPS stimulation. Furthermore, PBD150 significantly decreases the effect of LPS. These results strongly suggest that QC-catalyzed N-terminal pGlu formation of MCPs is required for macrophage migration and provide new insights into the role of QC in the inflammation process. Our results also suggest that QC could be a target for anti-inflammatory drug.

320

Polar localization of chemotactic proteins in Vibrio parahaemolyticus.

M. Zepeda Rivera[1], S. Ringgaard[2,3], M. K. Waldor[2,3]; [1]University of Washington, Seattle, WA, [2]Channing Laboratory, Brigham and Women's Hospital, [3]Microbiology and Molecular Genetics, Harvard Medical School

Chemotaxis is the process by which bacteria bias their flagella-assisted swimming in response to their environment. Recent work in the rod-shaped bacterium *Vibrio cholerae*, revealed that ParC plays a key role in promoting the polar localization and segregation of chemotaxis proteins. The purpose of our work is to study ParC and chemotaxis protein localization in *Vibrio parahaemolyticus,* another enteric pathogen, which unlike V*. cholerae,* has lateral as well as polar flagellae. To detect the subcellular localization of ParC and chemotaxis proteins within *V. parahaemolyticus*, we fused genes encoding fluorescent proteins to the genes encoding ParC and to genes encoding other chemotaxis proteins, including VP2226 and CheW. In wild-type *V. parahaemolyticus* time-lapse fluorescence microscopy revealed that ParC and VP2226 localize to the old flagellated pole in newborn cells forming a unipolar focus. Later in the cell cycle, each is recruited to the new pole resulting in bipolar foci. Consequently, after cell division, each daughter cell inherits a ParC/VP2226 focus at the old pole. However a new CheW focus does not form at the pre-divisional proximal pole until post-cell division. This shows a hierarchy in the protein recruitment to the new pole suggesting that ParC, as in *V. cholerae,* is important for recruitment of chemotaxis proteins to the developing pole, but that unlike *V. cholerae,* not all proteins are recruited in the same time frame. We have constructed a *V. parahaemolyticus parC* deletion mutant and analyses of this strain will reveal if ParC is required for proper localization

and segregation of chemotaxis proteins. Our *parC* deletion mutant exhibited a swimming defect, suggesting that ParC is essential for optimal chemotaxis. Preliminary swarmer assays using our *parC* deletion mutant suggest that ParC deficiency does not impair the lateral flagellar system. Finally, a bacteria-two-hybrid assay, revealed that there are multiple inter and intra protein-protein interactions among *V. parahaemolyticus* chemotaxis proteins. Future work includes analyses of requirement for ParC in both flagellar systems, understanding the nature of chemotaxis protein-protein interactions, and utilizing an infant rabbit model to test the effect of ParC deficiency on the intestinal colonization ability of *V. parahaemolyticus*.

Nociceptin is a Chemorepellent in Tetrahymena thermophila.

N. Braun[1], T. Lampert[2], B. Gibson[1], C. Nugent[1], H. G. Kuruvilla[1]; [1]Science and Mathematics, Cedarville University, Cedarville, OH, [2]Biological Sciences, SUNY at Buffalo, Buffalo, NY

Tetrahymena thermophila are free-living, ciliated, eukaryotic organisms that respond to stimuli by moving toward chemoattractants and avoiding chemorepellents. Chemoattractant responses involve faster ciliary beating, which propels the organisms forward more rapidly. Chemorepellent signaling involves ciliary reversal, which disrupts forward swimming, and causes the organism to jerk back and forth, swim in small circles, or spin in an attempt to get away from the repellent. Many food sources, such as proteins, are chemoattractants for *Tetrahymena*, while a variety of compounds are repellents. Repellents in nature are thought to come from the secretions of predators, or from ruptured organisms, which may serve as “danger” signals. Several hormones involved in human pain signaling have been shown to be chemorepellents in *Tetrahymena,* including substance P, ACTH, PACAP, VIP, and nociceptin.
We have been studying the response of *Tetrahymena* to nociceptin, using pharmacological inhibitors in order to elucidate components of the nociceptin signaling pathway. We have found that G-protein inhibitors and a number of mammalian tyrosine kinase inhibitors have no effect on nociceptin avoidance. However, the tyrosine kinase inhibitor, genistein, inhibits avoidance to nociceptin, likely by an unrelated mechanism. Nociceptin avoidance is also inhibited by the calcium chelator, EGTA, and partially inhibited by the ER calcium ATPase inhibitor, thapsigargin. Whole cell electrophysiology experiments in a calcium-containing buffer show that addition of 50 µM nociceptin to the buffer causes a sustained depolarization of approximately 30 mV. This depolarization is nearly eliminated in the presence of EGTA, further supporting the hypothesis that calcium is involved in nociceptin signaling.
J-113397, an inhibitor of the human nociceptin receptor, also inhibits nociceptin avoidance in *Tetrahymena*, though other nociceptin antagonists we tested had no effect on avoidance. Further experimentation on this organism will give a more complete picture of the signaling pathway, as well as allowing greater comparison between nociceptin avoidance in *Tetrahymena* and nociceptin signaling in vertebrates.

322

NANIVID: A new technology to analyze shallow gradient chemotaxis *in vitro* and *in vivo.*

J. K. Williams[1], M. Padgen[1], Y. Wang[2], F. Gertler[3], J. Condeelis[2], J. Castracane[4]; [1]College of Nanoscale Science and Engineering, University at Albany, [2]Albert Einstein College of Medicine, Yeshiva University, [3]Massachusetts Institute of Technology, [4]College of Nanoscale Science and Engineering, University at Albany, Albany, NY

Cancer cells create a unique microenvironment *in vivo* that enables tumor cell migration and dissemination to distant organs. To better understand the role of the tumor microenvironment in dissemination, special tools and devices are required to monitor the interactions between different cell types and the role of chemotaxis in migration and dissemination *in vivo*. Here we

describe the design and optimization of a new, versatile chemotaxis device called the NANIVID (NANo IntraVItal Device). The device is fabricated using BioMEMS techniques and consists of etched and bonded glass substrates, a soluble factor reservoir, fluorescent tracking beads and a microelectrode array for cell quantification. The reservoir contains a customized hydrogel blend that is loaded with epidermal growth factor (EGF). Upon hydration, EGF will diffuse out of the hydrogel to create a well-defined chemotactic gradient that can be sustained for many hours in order to attract tumor cells to the device. Here we show that mammary tumor cells *in vitro* and *in vivo* are chemotactic to the NANIVID. A new insight derived from this study is that tumor cells are capable of following much shallower gradients than previously thought possible. In particular, tumor cells can chemotax up a gradient that is as shallow as 0.7% (Fit R^2 =0.55), indicating that migratory tumor cells found in shallow gradients around co-migratory stromal cells are sufficient for initiating chemotaxis and migration in tumors.

323

The Role of CXCR4 and CXCR7-Mediated Chemokine Signaling in Zebrafish Keratocyte Motility.

A. D. Burke[1], A. G. Van[1], E. E. Hull[1], K. J. Leyva[2]; [1]Biomedical Sciences, Midwestern University, Glendale, AZ, [2]Microbiology & Immunology, AZCOM, Midwestern University, Glendale, AZ

The role of CXCR4 in regulating immunity, cell growth, cancer, angiongenesis, and development has been examined in many systems. Although it is known that the cognate, and only known, ligand for CXCR4 is CXCL12 (SDF-1) and that this cytokine is a known promoter of cellular migration, the role of this receptor in regulating non-immune cell migration is a recent development and has not been previously examined in fish epidermal keratocytes. Our data show that both CXCR4 and CXCL12a are differentially expressed during primary keratocyte explant culture. In our cell sheet migration assays, addition of CXCL12a to explant culture media increases keratocyte motility while addition of AMD3100 (a CXCR4b antagonist) appears to inhibit cell migration. The recently discovered chemokine receptor, CXCR7, binds CXCL11 as well as CXCL12a, although no reports to date have linked an effect of CXCR7 to cell motility. Both CXCR7 and CXCL11 appear to be differentially expressed during explant culture and in our migration assays, the addition of CXCL11 increases keratocyte motility. In order to determine the relative contribution of these two receptors on keratocyte motility, we performed the same migration assays on zebrafish homozygous for nonsense mutations in either CXCR4b or CXCR7b. Our data show that CXC receptors may have a more prominent role in regulating non-immune cell motility than previously thought, providing a first look at how cytokine signaling and the acute inflammatory response affect keratocyte cell migration.

324

N-3-oxo-dodecanoyl-L-homoserine lactone inhibits epithelial cells migration via Rac1/Cdc42, IQGAP1 and actin remodeling.

L. Yakymenko[1], M. Turkina[1], T. Karlsson[1], K-E. Magnusson[1], E. Vikstrom[1]; [1]Department of Clinical and Experimental Medicine, Linkoping University, Sweden

In gram-negative bacteria, cell-to-cell communication based on N-acyl-homoserine lactone (HSL) quorum sensing molecules is known to coordinate the production of virulence factors and biofilms. These bacterial signals can also modulate human immune cell behavior, including cell motility. The aim of this study was to investigate the effect of 3-oxo-C12-HSL from Pseudomonas aeruginosa on the migration of human intestinal epithelial Caco-2 cells. Using wound-healing and migration assays we found that 3-oxo-C12-HSL inhibits Caco-2 cells migration in a dose- and time-dependent manner. The changes in cell migration were paralleled by F-actin cytoskeleton reorganization as evidenced by phalloidin staining and confocal

microscopy. Moreover, for the first time we demonstrated by proteome analysis, Western blot, immunostaining and confocal imaging that the 3-oxo-C12-HSL down-regulates expression levels of the Rho GTPases (Rac1 and Cdc42) as well as their effector, IQGAP1, which binds and stabilizes the active forms of Rho GTPases. Taken together, our findings provide a novel insight on modulation mechanisms between bacterial quorum sensing molecule 3-oxo-C12-HSL and epithelial cells at the sites of bacterial infection.

325

Ca^{++} chemotaxis in Dictyostelium discoideum.

D. J. Wessels[1], A. Scherer[2], D. Lusche[2], S. Kuhl[2], K. Wood[2], K. Daniels[2], P. Steimle[3], T. Egelhoff[4], D. R. Soll[2]; [1]Univ Iowa, Iowa City, IA, [2]Biology, University of Iowa, Iowa City, IA, [3]Biology, University of North Carolina, Greensboro, Greensboro, NC, [4]Cell Biology, Cleveland Clinic Foundation, Cleveland, OH

Using a newly developed microfluidic chamber, we have demonstrated *in vitro* that Ca^{++} also functions as a chemoattractant of aggregation-competent *D. discoideum* amoebae. Effective Ca^{++} gradients are extremely steep compared to effective cAMP gradients. Given that Ca^{++} chemotaxis is co-acquired with cAMP chemotaxis during development of this organism, we speculated on the role Ca^{++} chemotaxis might play, notably the possibility that steep, transient Ca^{++} gradients may be generated during natural aggregation in the interstitial region between neighboring cells. In searching for a potential Ca^{++} chemotaxis receptor, we discovered that deletion of IplA (inositol triphosphate receptor-like protein), a putative Ca^{++} channel, resulted in loss of Ca^{++}, but not loss of cAMP chemotaxis. We also found that *iplA*$^{-}$ cells could not accurately orient towards the aggregation center at the onset of each normal cAMP wave generated and relayed by a majority population of wild-type cells. In support of the independence of two chemotactic systems, we found that of the four myosin II heavy chain kinases, deletion of either myosin heavy chain kinase A (MHCKA) or myosin heavy chain kinase C (MHCKC), blocked Ca^{++}, but not cAMP, chemotaxis. These mutant phenotypes were similar to that of the *iplA*$^{-}$ mutant. Furthermore, we show that neither Ca^{++} nor Ca^{++}/calmodulin directly regulates these kinases intracellularly, a further indication that Ca^{++} chemotaxis is mediated through a surface receptor, potentially IplA. These discoveries increase the complexity of the contextual framework, a paradigm in place for forty years, for interpreting how chemotaxis functions in the natural aggregation of the model organism *D. discoideum*. Finally, we are investigating the role Ca^{++} chemotaxis may play in mammalian cell migration, especially during cancer cell metastasis.

326

HS1-dependent Rac activation is necessary for neutrophil chemotaxis.

P. Cavnar[1], K. Mogen[1], A. Huttenlocher[1]; [1]Medical Microbiology and Immunology, University of Wisconsin-Madison, Madison, WI

HS1 is a 75-kDa protein that is primarily expressed in hematopoietic cells and is heavily phosphorylated in response to B- and T-cell receptor signaling. HS1 is important in antigen-induced proliferation of lymphocytes and like its homologue cortactin, is thought to stabilize F-actin branching through an N-terminal domain that binds Arp2/3 and tandem repeat domains that bind F-actin. HS1 contains a C-terminal proline-rich region and an SH3 domain that are important for a variety of protein-protein interactions including Src family kinases and Vav1. Despite progress in understanding HS1 function in lymphocytes, the function of HS1 during neutrophil chemotaxis remains unknown. Neutrophil chemotaxis is dependent on dynamic actin turnover at the leading edge. Here we investigate the function of HS1 during neutrophil chemotaxis using the neutrophil-like cell line, PLB-985 cells. We show that HS1 co-localizes

with F-actin at the leading edge of PLB-985 cells and primary neutrophils during chemotaxis. HS1 is tyrosine phosphorylated in response to fMLP stimulation and this is dependent on both adhesion and the activation of Src family kinases. Moreover, HS1-deficient cells show impaired activation of Rac GTPases in response to fMLP, suggesting that HS1-mediated Rac activity is necessary for neutrophil chemotaxis. Finally, we also show that phosphorylation of the RhoGEF Vav1 is impaired in HS1-deficient cells providing a link between HS1 and Rac activation. Taken together, our findings suggest that HS1 is necessary for Rac activation through the modulation of Vav1 GEF activity to allow for efficient neutrophil chemotaxis to fMLP.

327

Actin Crosslinking Proteins, Cortexillin I and II, are Required for cAMP-signaling During Dictyostelium Chemotaxis.

S. Shu[1], X. Liu[1], P. Kriebel[2], M. Daniels[3], E. Korn[4]; [1]Laboratory of Cell Biology, NHLBI, NIH, Bethesda, MD, [2]NCI, NIH, [3]NHLBI, NIH, Bethesda, MD, [4]NIH/NHLBI, Bethesda, MD

Dictyostelium has long been an excellent model for understanding the molecular basis of chemotaxis and intracellular and extracellular cAMP signaling. Binding of cAMP to G-protein-coupled cAMP receptors (cAR1) on the cell surface of Dictyostelium amoebae initiates a series of molecular responses. Expression of cAR1 and adenylyl cyclase (ACA) is markedly increased. Gß? released from the heterotrimeric G-protein coupled to cAR1 activates myosin II (via guanylyl cyclase and cGMP), and also activates RasC and RasG which initiates synergistic and partially redundant pathways. One pathway activates target of rapomycin 2 (TORC2) and protein kinase B stimulating actin polymerization at the cell front which, together with actomyosin II contraction at the rear of the cell, drives chemotaxis. The second Ras pathway activates phosphatidylinositol 3-kinase (PI3K), CRAC, ACA and cAMP synthesis. Binding of cAMP to cAR1 also leads to phosphorylation and activation of extracellular signal regulated kinase 2 (ERK2), which also contributes to ACA activation, as does TORC2. Synthesis and secretion of cAMP relays the cAMP signal to neighboring cells. Thus, chemotaxing amoebae form head-to-tail cell streams migrating to aggregation centers where multicellular mounds form and differentiate and develop into mature fruiting bodies. Both cortexillin I and II (ctxI and ctxII), 444 and 441 residues respectively, form parallel dimers with two globular heads and a coiled-coil helical tail. Both cortexillins accumulate in the cell cortex where they bundle and cross-link actin filaments in an anti-parallel fashion, and both localize to the cleavage furrow of dividing cells. We now report that the double deletion of ctxI and ctxII alters the actin cytoskeleton, with bundled actin filaments accumulating in the cell cortex, and substantially inhibits all the molecular responses to extracellular cAMP. Importantly, synthesis of cAR1 and ACA is not stimulated, ACA is not activated, and activation of RasC and RasG, phosphorylation of ERK2, activation of TORC2 and stimulation of actin polymerization are greatly reduced. As a consequence of the inhibition of cAMP signaling, both cell streaming and development of cells into mature fruiting bodies are completely blocked in ctxI/ctxII-null cells, although chemotaxis of individual cells is only slightly impaired. Expression of ACA-YFP in the ctxI/ctxII double null cells significantly rescues the wild type phenotype indicating that the primary chemotaxis defect in the ctxI/ctxII-null cells is ACA synthesis. These results emphasize the importance of a properly organized actin cytoskeleton for the cAMP signaling pathways and chemotaxis.

328

Non-Gaussian motility in 2D and 3D.

P-H. Wu[1], A. Giri[2], O. Yogurtcu[3], S. Sun[3], D. Wirtz[1,2]; [1]Physical Sciences-Oncology Center, Johns Hopkins University, Baltimore, MD, [2]Chemical And Biomolecular Engineering, Johns Hopkins University, [3]Mechanical Engineering, Johns Hopkins University

Trajectories of mesenchymal cells on substrates are typically assumed to be well described by persistent random walks, a mode of migration that would be well suited for efficient space exploration for food and associated with Gaussian distributions of displacements and flat distributions of angular turns. Here monitoring the migration normal and cancer mesenchymal cells, of different species, on 2D substrates and in 3D matrices, in the presence/absence of actomyosin inhibitors, or following shRNA-depletion of proteins regulating motility, over 2.5 temporal decades reveals that distributions of cell displacements do not follow Gaussian, power-law, or Levy-flights statistics. Rather they follow exponential distributions over >4 decades of occurrence. This is because these cells undergo “bursty” migration, with rare, large, and fast displacements whose occurrence is vastly underestimated by Gaussian fits, yet which greatly contribute to overall cell motility. A simple stochastic model of motility parameterizes these distributions and shows how motility parameters are exquisitely regulated by actomyosin contractility and the Arp2/3/N-WASp/Cdc42/Cortactin protein module.

329

Cell Shape Dynamics: From Waves to Migration.

W. Losert[1], M. Driscoll[1]; [1]University of Maryland, College Park, MD

The shape and motion of cells can yield significant insights into the internal operation of a cell. We present a simple, yet versatile framework that provides multiple metrics of cell shape and cell shape dynamics. Analysis of migrating Dictyostelium discoideum cells, a model system for the study of chemotaxis, shows that global and local metrics highlight distinct cellular processes. For example, a global measure of shape shows rhythmic oscillations suggestive of contractions, whereas a local measure of shape, the local curvature, shows wave-like dynamics indicative of actin polymerization waves. At the leading edge of adherent cells, curvature waves are associated with protrusive activity. Like regions of high curvature, protrusive activity travels along the boundary in a wave-like manner. The wave-like character of protrusions provides an alternative rationale for the zig-zagging of pseudopods, and explains how cells can move through viscous fluids and navigate complex three dimensional topography.

The Role of Centrosomal Scaffolding Protein Cep192 in Migration.

B. O'Rourke[1], D. Sharp[1]; [1]Physiology and Biophysics, Albert Einstein College of Medicine, Bronx, NY

The centrosome has been studied for over a century yet has not been found to be exclusively essential for any one particular function, indicating it may play a role in several cellular processes. Indeed, the centrosome has already been shown to be functionally tied to bipolar spindle formation and cell-cycle signaling. Intriguingly, the centrosome is composed of over 500 temporally regulated proteins, all recruited to form an electron dense cloud known as the pericentriolar material (PCM). Our previous work has shown one component of the PCM, centrosomal protein of 192kDa (Cep192), to be a basal scaffolding component, functioning either with, or basal to, the hallmark PCM protein Pericentrin. Cep192 levels are up-regulated in

mitosis and knockdown disrupts maturation and functional spindle assembly by altering centrosomal protein localization and MT nucleation ability.
While Cep192 is most thoroughly studied in mitosis, it persists at the centrosome during interphase. The interphase centrosome provides an asymmetric radial array of MTs, believed to be important for cell polarization and migration. Consistent with this, we have found that U2OS cells depleted of Cep192 display a nearly 2-fold increase in migration rates, as assayed by a wound healing assay, and develop elongate protrusions, which in extreme cases resemble immature neuronal processes. We are currently testing the hypothesis that these phenotypes result because: 1) Cep192 normally ensures that the majority of microtubule nucleation occurs at the centrosome and thus its absence causes an substantial increase in non-centrosomal microtubules and 2) in a similar vein, the loss of Cep192 releases important regulators of microtubule dynamics, particularly Aurora A kinase, into the cytoplasm thereby altering microtubule (and actin dynamics at the cell periphery). Mislocalization of Aurora-A from the centrosome has been shown to increase migration rate in breast cancer cells.

The Effect of a Peptide Mimetic of Heat Shock Protein β6 on Migration is Cell-Type Dependent.

D. H. Eng[1], C. Smoke[2], K. B. Perkins[2], M. R. Sheller[2]; [1]Capstone Therapeutics, Tempe, AZ, [2]Capstone Therapeutics

Previous research has shown that AZX100, a 24-amino acid phosphopeptide analogue of Heat Shock Protein β6 (HSPβ6 or HSP20) containing a protein transduction domain, reduces the amount of filamentous actin in myofibroblasts. In addition, AZX100-induced actin depolymerization has been shown to affect contractile gene expression in myofibroblasts and migration in smooth muscle cells. Both types of cells are integral to wound healing and scar resolution. Thus, investigating how modulation of filamentous actin can affect the migration of invasive fibroblasts as well as vascular cells may elucidate the role of AZX100 in dermal fibrosis.

The present study used two techniques to measure the effect of AZX100 on migration: an Electric Cell-substrate Impedance Sensing (ECIS) system and a Boyden chamber assay. In the ECIS system, cell migration is measured in real time via changes in resistance over electrodes in the bottom of the culture plate. Migration was analyzed in four different cell types: 3T3 fibroblasts, keloid fibroblasts (KF), smooth muscle cells (A7R5 line) and human umbilical vein endothelial cells (HUVEC). In fibroblasts, AZX100 treatment resulted in a dose-dependent decrease in migration compared to the TGFβ1 control. This effect was even greater in KFs, where AZX100 treatment reduced migration by 24%. In contrast, AZX100 treatment in HUVECs and A7R5s caused increased migration. In HUVECs, there was a 51% increase in migration at the highest dose of AZX100 compared to the VEGF control.

In conclusion, AZX100 has an unexpected differential effect in migration behavior of various cell types. The effect of AZX100 in migratory cells such as fibroblasts may be due to disassembly of actin filaments. However, in vascular cells, AZX100 restructuring of actin may trigger a cell response for migration by disrupting the adhesive state of the cell.

Tissue geometry regulates collective cell motility.

S. Manivannan[1], J. Gleghorn[1], J. Nestor[2], C. M. Nelson[1,2]; [1]Department of Chemical and Biological Engineering, Princeton University, Princeton, NJ, [2]Department of Molecular Biology, Princeton University

Collective cell migration plays an important role in embryonic development, wound repair and cancer invasion. Certain cell types have an intrinsic ability to organize themselves and move collectively when they are confined within monolayers. Here, we explored the role of tissue geometry on the collective motility of epithelial cells. In particular, we used microlithography and timelapse imaging to ask whether tissue geometry affects multicellular polarity and supracellular organization that are necessary for collective cell motion. We found that epithelial cells within monolayers tended to rotate as a group, and that increasing the size of the tissue increased the collectiveness of group rotation. The shape and boundary conditions of the tissue organized the motion of the cells by altering group rotation and coherence. The motility parameters of individual cells, including speed and persistence, were also affected by tissue geometry. Our results suggest that the overall architecture of the tissue in which cells reside instructs their movements with respect to each other within a collective. Accurate recapitulation of *in vivo* tissue structure will benefit future studies of processes which involve collective cell migration.

333

Myosin II Isoform Switching Mediates Invasiveness following TGFβ-induced Epithelial-Mesenchymal Transition.

J. R. Beach[1], G. Hussey[2], T. E. Miller[3], A. Chaudhury[4], P. Patel[5], J. Monslow[3], Q. Zheng[3], R. Keri[6], O. Reizes[3], A. Bresnick[7], P. Howe[8], T. T. Egelhoff[3]; [1]Cell Biology, NC10, Cleveland Clinic, Cleveland, OH, [2]Cancer Biology, Hollins Cancer Center, Charleston, SC, [3]Cell Biology, Cleveland Clinic, Cleveland, OH, [4]Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX, [5]Department of Biochemistry, Albert Einstein College of Medicine, Bronx, NY, [6]Pharmacology, Case Western Reserve, Cleveland, OH, [7]Department of Biochemistry, Albert Einstein School of Medicine, Bronx, NY, [8]Hollins Cancer Center, Medical University of South Carolina, Charleston, SC

An epithelial-mesenchymal transition (EMT) occurs when epithelial cells acquire the morphological and phenotypic properties of a mesenchymal cell, including increased migratory and invasive characteristics. TGFβ is a known inducer of EMT in many settings. EMT and EMT-like events are suggested to precede cancer cell metastasis. Despite functional significance of non-muscle myosin II in cell migration and invasion, its role in EMT or TGFβ signaling is unknown. The goal of these studies was to determine the roles and regulation of nonmuscle myosin II during TGFβ-induced EMT in mammary epithelial cells. Analysis of normal mammary gland expression revealed that myosin IIC is expressed in luminal cells while myosin IIB expression is up-regulated in myoepithelial cells that have more mesenchymal characteristics. Furthermore, TGFβ induction of EMT in non-transformed murine mammary gland (NMuMG) epithelial cells results in an isoform switch from myosin IIC to myosin IIB and increased phosphorylation of myosin heavy chain (MHC) IIA on target sites known to regulate filament dynamics (Ser1916, Ser1943). These expression and phosphorylation changes are downstream of heterogeneous nuclear ribonucleoprotein-E1 (E1), an effector of TGFβ signaling. E1 knockdown drives cells into a migratory, invasive mesenchymal state, and concomitantly upregulates MHC IIB expression and MHC IIA phosphorylation. Abrogation of myosin IIB expression in the E1 knockdown cells has no effect on 2D migration but significantly reduced transmigration and macrophage-stimulated collagen invasion. These studies indicate that

transition between myosin IIC/myosin IIB expression is a critical feature of EMT that contributes to increases in invasive behavior.

334

Galectin 3 modulates the mast cells migration.

V. D. Toso[1], M. de Cássia Campos[1], D. A. de Souza Junior[1], M. Dias Bariffi[2], M. Roque Antunes Barreira[1], C. Oliver[1], M. Jamur[1]; [1]Departamento de biologia celular e molecular e biagentes patogenicos, Faculdade de Medicina de Ribeirão Preto - USP, Ribeirão preto, Brazil, [2]Departamento de Biociências Aplicadas à Farmácia, Faculdade de Ciências Farmaucêuticas de Ribeirão Preto - USP

Mast cells are imunorregulatory cells that participate in the defense of the organism and are known for exerting a fundamental role in asthma, allergy and inflammatory reactions, as well as expulsion of parasites. Galectins have a modulatory role in various cell types by regulating growth, adhesion, migration and cell proliferation. The aim of this study was to investigate the role of galectins 1 and 3 in mast cell function, using knockout mice for these galectins. The distribution of mast cells in the spleen, lungs and skin was characterized. The role of galectins in cell adhesion and migration was studied in vitro with bone marrow derived mast cells. The results showed that there were no differences in the number of mast cells in the spleen, skin and lungs between or between the knockout mice and the wild-type mice. Using Transwell assays, bone marrow derived mast cells from galectin-3 knockout mice migrate less in comparison with mast cells from galectin-1 knockout mice or wild-type mice, even in presence of the chemotactic factors IL-3 and SCF. On the other hand, no differences were observed in the adhesion of bone marrow derived mast cells from galectin-1 and 3 knockout mice as well as wild-type mice to components of the extracellular matrix such as fibronectin, laminin, collagen type I and IV. These results indicate that galectin-3 is important for the migration of mast cells, but the absence of galectin-3 does not alter the adhesion of these cells to extracellular matrix components.

335

EB1-dependent microtubule +TIP complexes coordinate protrusion dynamics during 3D epithelial remodeling.

S. Gierke[1], T. Wittmann[1]; [1]Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA

Epithelial remodeling, in which apical-basal polarized cells switch to a migratory phenotype, plays essential roles in development and cancer progression. How microtubules are controlled or contribute to epithelial remodeling in a physiological three-dimensional (3D) environment is not understood. We analyzed microtubule function and dynamics using an epithelial cyst cell culture system in which polarized MDCK epithelial cells undergo a partial epithelial-to-mesenchymal transition (EMT) in response to hepatocyte growth factor (HGF), and cells extend, and migrate into the surrounding extracellular matrix (ECM). Using high-resolution confocal microscopy, we found that extensions at the basal surface of HGF-treated cysts were filled with dense microtubule bundles. Computational tracking of EB1-EGFP showed large numbers of microtubules growing persistently from the apical domain into these extensions, often deforming the extension tip, and an increase in microtubule growth rate in response to HGF before morphological changes were evident. Next, we tested the role of microtubule plus-end tracking protein (+TIP) complexes in HGF-induced migration in 3D by depleting cells of EB1, the central adaptor that mediates association of other +TIP proteins with growing microtubule plus-ends. In EB1-depleted cells, microtubules displayed rapid lateral and retrograde movements demonstrating that EB1 is required to anchor and stabilize microtubules in HGF-induced

extensions. EB1-depleted cysts formed shorter, more branched extensions further suggesting that EB1 is required for productive HGF-induced extension outgrowth. Analysis of cell-matrix interactions and F-actin dynamics revealed that control extensions progressively pulled on and deformed the ECM typically with one F-actin-rich protrusion near the tip. However, EB1-depleted cells produced multiple highly dynamic F-actin-rich protrusions that did not productively engage the matrix. This resulted in extensions that rapidly protruded, retracted, and changed direction. The inability to engage the matrix and stabilize a dominant protrusion was also associated with defects in cell-matrix adhesions. Although EB1-depleted extensions formed nascent adhesions, they never matured, were mislocalized, and were uncoordinated, in contrast to the highly coordinated adhesions of control cells. Together our findings indicate that EB1-dependent microtubule +TIP complexes are required to coordinate protrusion dynamics in migrating cells during 3D epithelial remodeling.

336

Phosphoinositide Signaling Regulates the Exocyst Complex and Polarized Integrin Trafficking in Directionally Migrating Cells.

N. Thapa[1], Y. Sun[1], S. Choi[1], R. A. Anderson[1]; [1]University of Wisconsin-Madison, Madison, WI

Cell migration is essential for many biological processes. Cell migration hinges on the ability of cells to traffic signaling molecules and proteins toward the direction of migration, a process that requires the tight regulation of cytoskeletal and vesicle trafficking machineries. The trafficking of both newly synthesized and recycled integrin molecules to and from the leading edge plasma membrane is critical for directional cell migration. Here, we describe a novel role for the phosphatidylinositol-4,5-biphosphate (PIP2) synthesizing enzyme, PIPKI(i2, in modulating polarized integrin trafficking during cell migration. PIPKI(i2 knockdown impaired directional migration in multiple assays. Loss of PIPKI(i2 impaired Golgi and microtubule orientation towards the direction of cell migration and trafficking of (1 integrin to the leading edge.

PIP2 signaling specificity is defined by the interaction of PIP kinases with PIP2 effectors or compartments containing PIP2 effectors. We show that PIPKI(i2 interacts with the exocyst an evolutionarily conserved vesicle-trafficking protein complex required for polarized trafficking. In vitro binding study showed Sec6 and Exo70 as PIPKI(i2-interacting subunits of the exocyst complex. Upon initiation of directional migration, PIPKI(i2 associated with both the exocyst complex and ?1 integrin and this was dependent both on kinase activity of PIPKI(i2 and its ability to associate with talin.

The integrity of exocyst complex was pivotal for PIPKI(i2-regulated cell migration as knockdown of any exocyst complex components impaired cell migration including polarized trafficking of ?1 integrin to leading edge. Furthermore, the expression of Exo70 mutant defective in PIP2-binding abrogated the PIPKI(i2-regulated cell migration emphasizing the role of PIP2. PIPKI(i2 was specific isoforms to promote integrin-dependent cell migration as its expression specifically promoted the integration of exocyst complex into ?1 integrin-containing vesicle like intracellular compartment. We have discovered a fundamental role for PIP2 in polarized integrin trafficking required for directionally migrating cells.

Myosin-II-mediated contractility coordinates cell movements during collective migration through cell-cell mechanotransduction.

M. Ng[1], A. Besser[1], G. Danuser[1], J. Brugge[1]; [1]Cell Biology, Harvard Medical School, Boston, MA

Collective migration of epithelial sheets is an important process in morphogenesis, tissue repair and tumor invasion. To achieve collective migration, individual cells must communicate with one

another and coordinate their migratory processes. The mechanisms underlying such coordination are not well understood. Using an automated, high-throughput time-lapse microscopy and cell tracking platform, we monitored the migration trajectories of ~0.5 million MCF10A cells undergoing collective migration in wound-healing assays. We used several parameters to assess coordination in cell movements, and found that migration persistence, as well as the correlation in migration velocities and polarization directions between individual cells, is dependent on myosin-II-mediated cell contractility. Decreasing cell contractility by decreasing substrate stiffness or by RNAi-mediated knockdown of myosin-IIA and myosin-IIB reduces coordination in cell motion during collective migration. Importantly, we discovered that contractility can affect coordinated motion by modulating mechanical forces communicated between cells through cadherin-mediated cell-cell adhesions. Using a novel traction force microscopy-based method to measure tension exerted on adherens junctions, we found that the forces transmitted across individual cell-cell junctions positively correlate with cellular myosin-II activity. Interestingly, a high level of actomyosin activity can also disrupt mechanical communication across multiple adjacent cells. These results reveal a complex relationship between actomyosin contractility, cell-cell mechanotransduction and coordination in cell movements during collective migration. Further characterization of this relationship will be an important step towards understanding collective migration, and may shed light on pathological developments such as cancer invasion, which is often associated with altered microenvironmental stiffness, cellular contractility and cell-cell adhesions.

338

F-actin dynamics and actomyosin contraction during neutrophil motility in live zebrafish.

P-Y. Lam[1], R. S. Fischer[2], C. M. Waterman[2], A. Huttenlocher[1]; [1]Cellular and Molecular Biology, University of Wisconsin-Madison, Madison, WI, [2]Cell Biology and Physiology Center, National Heart, Lung, and Blood Institute, National Institutes of Health

Neutrophils are the most abundant white blood cell and are the first cells to respond to sites of tissue injury. The in vivo migration of neutrophils is highly dynamic and involves the generation of multiple leading edge pseudopodia. For directed motility, neutrophils maintain a dominant pseudopodium in the direction of movement while retracting other pseudopodia. Although uropod retraction is known to require myosin II contractility, the cytoskeletal mechanisms that govern pseudopodia selection at the front of the cell are not well understood. To investigate pseudopodia selection in vivo, we used time-lapse spinning-disk confocal microscopy of neutrophils with dual channel imaging of bioprobes specific for all (Lifeact-Ruby) and more stable (GFP-UtrCH) populations of F-actin. We show that dynamic F-actin is localized in the dominant pseudopodium while the more stable F-actin accumulates in the retracting pseudopodia and uropod during neutrophil migration. To determine the role of myosin II in pseudopodia selection, we performed ratiometric imaging of myosin regulatory light chain (MRLC) to a volume marker to allow visualization specifically of cytoskeleton-associated myosin II. This revealed localization of MRCL with the cytoskeleton in the uropod, as expected. However, MRLC also accumulated and localized to the leading edge of pseudopodia precisely at the time of retraction, and this accumulation increased as the retraction progressed. Taken together, we demonstrated that in an in vivo context, F-actin stabilization and myosin II accumulation occur in retracting pseudopodia, suggesting that actin stabilization and myosin II activity are regionally regulated during pseudopodia selection to guide directed neutrophil motility. Further studies will be needed to test if actomyosin contraction is required for biased pseudopodia retraction in directed motility during the immune response in vivo.

Dynamic Cytoskeleton Organization Couple Cell Shape Variations with Migration Phenotypes in HL-60 Cells.

T. Tsai[1], M. Davidson[2], J. Ferrell[1], J. Theriot[3]; [1]Chemical and Systems Biology, Stanford, Stanford, CA, [2]Florida State University, [3]Biochemistry, Stanford University

The neutrophil-like HL60 cell is a common model system for the study of human neutrophil migration. A population of HL60 cells under constant conditions exhibits highly heterogeneous migration phenotypes, as characterized by their speed, shape, and frequency of polarity switching. These natural variations allow us to investigate the mechanism underlying shape determination and its correlation with migration phenotypes.

Well-differentiated HL-60 cells, stably expressing fluorescent protein-tagged actin or myosin, are migrating within uniform field of chemoattractant, and imaged with high spatiotemporal resolution. To mimic the neutrophil's native confined environment, the cells are plated in between the fibronectin-coated coverslip and an agarose pad. To identify important shape parameters, we apply principal component analysis on hundreds of cell contours. Interestingly, the first few principal modes are biologically meaningful. Variations in cell length, leading edge width, and left-right asymmetry can explain close to 70% of total shape variation. These three shape modes are also preserved in migrating human primary neutrophils. Cells with relatively wider leading edge migrate faster and switch polarity less frequently. Left-right asymmetry of cell shape correlates well with asymmetric distribution of myosin, as well as turns in cell trajectory, although interestingly asymmetric myosin accumulation lags behind cell turning.

Inhibition of actin polymerization by latrunculin reduces cell length and leading edge width, while inhibition of myosin by blebbistatin increases cell length and reduces leading edge width. This observation is consistent with our model using membrane tension as a limiting factor for extension of leading edge width and cell length.

Finally, we use the movement and position of cell nucleus relative to the leading edge and cell rear to probe for the cell's internal mechanical properties. Nocodazole treatment increases persistence of protrusion, and reduces the distance between leading edge and the nucleus, while taxol treatment decreases the persistence of protrusion. Variations in microtubule dynamics might affect the cell-nuclear coupling and contribute to variations in migration persistence.

340

An in vivo tracking system to investigate the migration of bone marrow stem cells in an osteochondral defect model.

G-I. Im[1], C-N. Im[1], J-M. Lee[1]; [1]Orthopaedics, Dongguk University Ilsan Hospital, Goyang, Korea

An in vivo system was developed to monitor the migration of human bone marrow-derived MSCs (BMSCs) transplanted within the marrow cavity of athymic nude rats. The in vitro studies confirmed that PDGF (platelet-derived growth factor)-AA had the most potent chemotactic effect of the factors tested, and possessed the greatest number of receptors in BMSCs. In the in vivo study, the BMSCs were labeled with fluorescent nanoparticles and injected into the marrow cavity through an osteochondral defect created in the distal femur of rats. The defect was sealed with HCF (heparin-conjugated fibrin) or PDGF-AA-loaded HCF. In the HCF-only control group without PDGF-AA, the nanoparticle-labeled BMSCs were dispersed outside the marrow cavity within 3 days after the injection. In the PDGF-AA-loaded HCF group, the labeled cells moved time-dependently for 14 days toward the osteochondral defect. The in vivo tracking

patterns differed depending on the PDGF-AA concentration 21 days after injection: HCF-PDGF in low dose (8.5 ng/μl) was more effective than HCF-PDGF in high dose (17 ng/μl) in recruiting the BMSCs to the osteochondral defect. When the osteochondral defect was evaluated macroscopically and histologically, the defects treated with PDGF and TGF-β1-loaded HCF showed excellent cartilage repair compared with other groups. Further in vivo studies confirmed that this in vivo osteochondral BMSCs tracking system (IOBTS) worked for other chemo-attractants (CCL-2 and PDGF-BB). In conclusion, IOBTS can be a very useful tool for examining the effect of growth factors or chemokines on BMSC migration and cartilage repair.

341

Manganese Superoxide Dismutase Inhibited Gastric Cancer Cellular Invasion.

H. Matsui[1], T. Tomita[2], M. Tamura[1], Y. Nagano[1], T. Kaneko[1], I. Hyodo[1]; [1]Graduate school of comprehensive human sciences, Univ Tsukuba, Tsukuba, Japan, [2]Graduate School of Pure and Applied Sciences, Univ Tsukuba, Tsukuba, Japan

Reactive oxygen species (ROS) have been reported to play an important role for cancer cellular invasion. Recently, we have established a new cancerous cell-line RGK-1 from a rat gastric normal epithelial cell-line RGM-1. We also established a stable clone RGK-MnSOD, which overexpressed a manganese superoxide disumutase. In this study, we elucidated a role of ROS for cancer cellular invasion. [Methods] The ROS concentration and the cell membrane lipid peroxidation were determined using fluorescence probes. The kind of ROS was clarified with EPR. The invasion abilities were determined by a matrigel assay. [Results and Discussion] The ROS from cancer cell was O_2^-. Cancer cellular O_2^- concentration was significantly higher than in normal, and MnSOD significantly decreased the O_2^- concentration. The depth of cancer cellular invasion into matrigel was significantly longer than that of normal, and MnSOD also significantly inhibited the invasion. We concluded that cancer specific ROS derived from mitochondria involved the cell invasion ability because MnSOD is a mitochondrion-particular enzyme.

Dynamics of Focal Adhesions and Invadosomes

342

A Molecular Model for How Increased pH Activates Focal Adhesion Kinase.

C-H. Choi[1], D. L. Barber[1]; [1]Department of Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA

Activity of focal adhesion kinase (FAK), a key regulator of focal adhesion turnover and cell migration, is dependent on autophosphorylation of Tyr397. The recently identified FAK crystal structure revealed that FAK activity is inhibited *in cis* by an interaction between its N-terminal FERM and C-terminal kinase domains. Release of this auto-inhibited conformation allows autophosphorylation of Tyr397 in a linker region between FERM and kinase domains, which docks Src kinases that phosphorylate Tyr576/577 in the kinase domain for full activation of FAK. However, how the initial step of releasing an auto-inhibited conformation is regulated remains unknown. We previously showed that increased intracellular pH from activation of the Na-H exchanger NHE1 is necessary for increased FAK-pY397, focal adhesion turnover, and directed cell migration. Our current data suggest that pH > 7.2 disrupts an auto-inhibited conformation of FAK to increase FAK-pY397. The FERM domain of FAK contains an unusually high number of seven conserved histidines compared with FERM domains in other proteins, and two histidines, His41 and His58 are at the interface of the FERM and kinase domains. We reasoned that pH-dependent charges on histidines in the FERM domain might regulate an electrostatic interaction

with the kinase domain. In support of this prediction, we used in vitro kinase assays with recombinant full-length FAK to show increased pY397 from pH 6.5 to 7.5. Increased pY397 at higher pH is dependent on the FERM domain because a truncated FAK lacking the FERM domain has constitutively high pY397 that is pH-independent. We also used separate FERM and kinase domain constructs to show binding *in trans* is markedly greater at pH 6.5 compared with pH 7.5, further suggesting that increased pH releases an auto-inhibited conformation. To test the role of His58 in pH-dependent pTyr397, we used a mutant full-length FAK-H58A to show constitutively high and pH-independent pY397 similar to a truncated FAK lacking the FERM domain. Our data suggest a molecular mechanism for pH-dependent activation of FAK that predicts increased pH > 7.2 and deprotonation of His58 releases an auto-inhibited charge interaction between FERM and kinase domains.

343

A mechanochemistry model of focal adhesion dynamics in cell migration.

Z. Wu[1], S. Plotnikov[1], C. M. Waterman[1], J. Liu[1]; [1]National Heart, Lung and Blood Institute, National Institute of Health, Bethesda, MD

Focal adhesions are essential to mediate cell extracellular matrix (ECM) adhesion and force transmission during cell motilities, which involve the crosstalk between physical signals such as contractile forces or membrane dynamics, and chemical signaling events such as focal adhesion kinase related regulation pathways. However, the underline mechanism of the biophysical regulations of force transmission among actin cytoskeleton, cell membrane, focal complex and ECM remains poorly understood. We constructed a mathematical model to understand the behavior of focal adhesion complex under different experimental conditions. By integrating the cell membrane dynamics, actin network fluid dynamics, and the mechanochemistry of focal complex, the model reveals itself the capability to capture the essential characteristics of focal adhesions in cell motility. In particular, the model explains the focal adhesion growth pattern at different ECM stiffness. The model thus provides a comprehensive vision of the focal adhesion dynamics.

344

Matrix-properties dependent cell migration speed: characterization of the driving force of cell migration.

B. Ji[1]; [1]Beijing Institute of Technology, Beijing, China

It was shown that cell migration exhibits strong mechanosensitivity behaviors, e.g., the migration speed biphasically depends on the matrix rigidity. However, these behaviors have not been quantitatively understood. In this study, a mechano-chemical coupling model was developed for studying the cell migration behaviors by modeling the dynamics of focal adhesion and effect of cell shape on cell traction force distribution, in which not only the rigidity of matrix but also the concentration of ligands on matrix and the activity of myosin were considered. We showed that the cell migration behaviors depended on not only rigidity of matrix, but also the concentration of ligands in a biphasic manner. The underlying mechanism behind these biphasic behaviors is that these parameters can influence the stability of focal adhesions which are crucial for the creation of pulling force by stable focal adhesions at cell front and the cell detachment and retraction triggered by the destabilization of focal adhesion at cell rear. These results agree with the experimental observations. Furthermore, a motility factor was suggested for characterizing the driving force of cell migration which was mainly determined by the cell shape, matrix stiffness and concentration of ligands on matrix. This study provided a quantitative understanding of how cells control their migration behaviors.

345

Direct observation of catch bonds in focal adhesions of living cells.

N. Bonakdar[1], A. Schilling[1], C. Metzner[1], B. Fabry[1]; [1]Biophysics Group, Center for Medical Physics and Technology, Erlangen, Germany

Force spectroscopy measurements on isolated integrins revealed the counterintuitive effect that integrin binding with fibronectin strengthened with force. This so-called catch bond behavior has never been observed in living cells, however. The anchorage of cells to the extracellular matrix is established through a force-transmitting molecular chain of integrin-type adhesion receptors, proteins of the focal adhesion complex, and the cytoskeleton. The resulting adhesion strength is determined by a collective binding energy landscape which arises from the superposition of the energy landscapes of the individual molecular bonds along the force transmission chain. To measure this collective energy landscape, we used high-force magnetic tweezers to apply forces of up to 80 nN to 5 µm RGD coated beads bound to the cell. The forces were applied as a linear ramp (loading rates of 1...40 nN/s) or as staircase-like force steps. The average force at which the beads detached from the cell was recorded and was taken as a measure of bond stability. Bond stability increased with higher loading rates, as expected for thermally activated molecular bonds. Surprisingly, a staircase-like loading protocol further increased bond stability and bond lifetimes. Such behavior cannot be explained by active mechanotransduction processes or by thermally activated molecular bonds, but is consistent with the existence of force-strengthening catch-bonds. A possible molecular mechanism for catch-bond behavior are hidden binding domains in focal adhesion proteins that become available during force-induced unfolding.

346

Lasp-2 Binds Vinculin and Paxillin in Focal Adhesions and Affects Cell Adhesion and Spreading.

K. T. Bliss[1], C. M. Jones-Weinert[1], C. C. Gregorio[1]; [1]Cellular and Molecular Medicine, University of Arizona, Tuscon, AZ

Focal adhesions are intricate protein complexes that facilitate cell attachment, migration and cellular communication. Lasp-2 (LIM-nebulette) is a recently identified member of the nebulin family of actin-binding proteins and appears to be an integral component of focal adhesions. The function of lasp-2 is currently viewed as a molecular scaffold capable of organizing and bundling actin filaments. To gain further insights into the functional role of lasp-2 at focal adhesions, we set out to identify additional binding partners of lasp-2 using yeast two-hybrid screens. Two new focal adhesion interacting partners, vinculin and paxillin, were identified. These novel interactions were confirmed using solid phase binding assays. Immunofluorescence microscopy demonstrated that Lasp-2 co-localizes with vinculin and paxillin in focal adhesions. Interestingly, overexpression of GFP-lasp-2 decreases cell adhesion and the number of vinculin-containing focal adhesions. Reduction of lasp-2 protein levels via siRNA knockdown reduces the ability for cells to spread. Taken together, these data suggest that lasp-2 has an important role in coordinating and regulating the composition and dynamics of focal adhesions.

347

β-actin mRNA compartmentalization by ZBP1 controls focal adhesion stability and directed cell motility.

Z. B. Katz[1], A. L. Wells[1], B. Wu[1], H. Y. Park[1], S. M. Shenoy[1], R. H. Singer[1]; [1]Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Localization of β-actin mRNA is facilitated by the zipcode binding protein, ZBP1. Binding to the cognate zipcode within the 3'UTR of β-actin mRNA enables ZBP1 to asymmetrically distribute mRNA and control translation of its target, a process known to be necessary for directed cell motility. This study utilized a ZBP1 KO fibroblast cell line to compare β-actin mRNA dynamics to wild-type cells. TIRF microscopy and mRNA particle tracking in live cells enabled us to discover a specific compartment near focal adhesions where β-actin mRNA dwells for periods greater than one minute. In ZBP1 KO fibroblasts, the probability of tracking β-actin mRNA within the adhesion environment is significantly reduced. Consequently, adhesion lifetimes are reduced in ZBP1 KO cells. This supports the hypothesis that ZBP1 facilitates mRNA localization to strengthen focal adhesions and therefore direct cell migration. To test directly whether mRNA localization to adhesions can alter adhesion dynamics and cell motility we utilized a novel mRNA tethering technique. We tethered β-actin mRNA to focal adhesion complexes through MS2 stem loops in the 3'UTR of β-actin mRNA and the MS2 coat protein fused to vinculin. This produced a significant increase in adhesion lifetime and adhesion size in cells expressing MS2-β-actin mRNA. Additionally, cell velocity was significantly reduced in cells with tethered β-actin mRNA. These experimental results lead us to conclude that β-actin mRNA compartmentalization to adhesions, mediated by ZBP1, strengthen adhesions and therefore produce an asymmetric force distribution within the cell to control its directionality.

β1- and β3-integrins move and function as distinct adhesion units inside cell adhesions.

G. Giannone[1], O. Rossier[1], V. Octeau[2], J-B. Sibarita[1], C. Leduc[2], D. Nair[1], L. Duchesne[3], O. Destaing[4], V. Gatterdam[5], C. Albiges-Rizo[4], R. Tampé[5], D. Fernig[3], L. Cognet[2], D. Choquet[1], B. Lounis[2]; [1]Interdisciplinary Institute for NeuroScience, UMR5297, Université de Bordeaux and CNRS, 33077 Bordeaux, France, Bordeaux, France, [2]Laboratoire Photonique, Numérique et Nanosciences (LP2N) Institut d'Optique Graduate School, CNRS and Université Bordeaux, France, [3]Institute of Integrative Biology, Crown Street, University of Liverpool, Liverpool L69 7ZB, UK, [4]Institut Albert Bonniot, Université Joseph Fourier; INSERM U823; CNRS ERL 3148 Grenoble, France, [5]Institute of Biochemistry, Biocenter, Goethe University Frankfurt, Frankfurt a.M., Germany

Focal adhesions (FAs) are adhesive structures linking the cell to the extracellular matrix (ECM) and constitute molecular platforms for biochemical and mechanical signals that control cell adhesion, migration, growth, differentiation and apoptosis. Integrin receptors are core components of FAs, where they trigger signaling and connect the ECM to the actin cytoskeleton (F-actin) via recruitment of intracellular scaffolds such as talin. Different classes of αβ-integrin heterodimers perform distinct functions and are simultaneously present in a FA. The static nanoscale organization of FAs has been recently described, with integrins being at the base of a vertical multilamelar protein organization ending with F-actin connection. However, the nanoscale dynamics of integrins within FAs is still unknown. Here we show, using super-resolution microscopy and single particle tracking, that integrins could move and function as nanoclusters within FAs. β3- and β1-integrins form distinct homotypic nanoclusters displaying specific dynamics within the same FA. β3-integrins undergo repeated activation cycles within a FA, seen as rapid switches between levels of free-diffusion, confinement, and immobilization

lasting less than a hundred seconds. Talin binding triggers immobilization more than interaction with the ECM, while both control immobilization duration, suggesting that talin and ECM cooperate to fully activate integrins inside FAs. Comparing β1- and β3-integrins, we showed an increased density of β3-integrin immobilization in FAs, supporting specific functions for each type of β-integrin in the same FA. Thus, this dynamic nanoscale partitioning of homotypic β-integrin nanoclusters within FAs could control local forces and signaling necessary for integrin-mediated cellular processes such as adhesion and migration.

The Endosomal Signaling Adaptor APPL1 Impairs Cell Migration by Inhibiting the Turnover of Adhesions at the Leading Edge.

J. A. Broussard[1], W-H. Lin[1], D. Majumdar[1], B. Anderson[1], D. J. Webb[1,2]; [1]Biological Sciences, Vanderbilt University, Nashville, TN, [2]Cancer Biology, Vanderbilt University

Cell migration is a complex process that requires the coordination of signaling events that take place in distinct locations within the cell. Adaptor proteins are emerging as key modulators of spatially integrated processes because of their ability to localize to different subcellular compartments and bring together important signaling proteins at these sites. However, the role that adaptor proteins play in regulating cell migration is not well understood. Here, we show a novel function for the adaptor protein containing a pleckstrin homology (PH), phosphotyrosine binding (PTB), and leucine zipper motif denoted APPL1 in modulating cell migration. APPL1 impairs the turnover of adhesions at the leading edge of cells thereby inhibiting their migration. The ability of APPL1 to impair migration is dependent on its PTB domain, which interacts with the serine/threonine kinase Akt, suggesting the interaction of APPL1 with Akt is important for its effect on migration. Interestingly, APPL1 decreases the amount of active Akt in cells. Using a mutant-based approach, we further show that APPL1 modulates migration and adhesion dynamics via a mechanism that involves regulation of Akt function. An APPL1 mutant which is unable to localize to endosomal membranes no longer has an effect on migration or adhesion turnover, indicating that APPL1 endosomal localization is required for its ability to regulate these processes. Furthermore, APPL1 is found in vesicular structures containing the non-receptor tyrosine kinase Src. Src has been shown to regulate Akt function through the phosphorylation of two Akt tyrosine residues, and intriguingly, we have found that APPL1 reduces the tyrosine phosphorylation of Akt. Therefore, we propose a model in which APPL1 regulates adhesion dynamics and cell migration by altering Src-mediated tyrosine phosphorylation of Akt. Our results further underscore the importance of adaptor proteins in modulating the flow of information through signaling pathways by demonstrating a critical new function for APPL1 in regulating cell migration and adhesion turnover.

TKS5 regulates invadopodium membrane anchoring in breast cancer cells.

V. Sharma[1], J. Condeelis[1]; [1]Anatomy and Structural Biology, Albert Einstein College of Medicine of Yeshiva University, Bronx, NY

A growing body of research implicates invadopodia in cancer cell invasion and metastasis (Oser et al., 2009, J Cell Biochem.; Stylli et al., 2008, J Clin. Neurosci.). Invadopodia are protrusive structures of cancer cells, 0.5-1 micron in diameter and 1-10 microns long. The primary function of these structures is to degrade ECM and protrude into degraded spaces, which creates a passage (like a tunnel) through the extra-cellular space, which cells utilize to migrate from the site of primary tumor to enter the bloodstream and eventually metastasize at distant sites to make secondary tumors. To understand the signaling pathways during the assembly of invadopodia in breast cancer cells, we did live-cell time-lapse imaging to visualize the order of

arrival of the proteins of the invadopodium precursor, N-WASp, Cortactin and Tks5. Our data indicate that Cortactin and N-WASp arrive together to form the invadopodium precursor core, followed by Tks5 recruitment to the complex. We found that Tks5 is not required for invadopodium precursor formation but is needed for the stabilization and anchoring of invadopodium precursors. Tks5 has been shown to interact with 3' phosphoinositides (Abram et al., 2003, J Biol. Chem.), and recently PI(3,4,5)P3 was shown to localize at invadopodia (Yamaguchi et al., 2011, J. Cell Biol.). We show that PI(3,4)P2 localizes to invadopodial precursors and appears to be the main binding partner ofTks5 as a link between the precursor core and the cell membrane.

351

A novel focal adhesion TRIM protein regulates focal adhesion disassembly.

P. Uchil[1], T. Pawliczek[1], T. Reynolds[1], S. Ding[1], A. Hinz[1], R. Floyd[1], H. Yang[2], Y. Xiong[2], W. Mothes[1]; [1]MMPATH, Yale University, New Haven, CT, [2]MB&B, Yale University, New Haven, CT

The tripartite motif (TRIM) family of proteins play important roles in diverse cellular functions such as cell differentiation, oncogenesis and innate immunity. Here we identify a TRIM protein as a novel component of focal adhesions. This TRIM protein is recruited to focal adhesions by an interaction between its coiled coil domain and the LD2 motif of paxillin. It is recruited to focal adhesions early in a myosin-II-independent manner. But unlike any other focal adhesion component, it remains stably bound, forming a long-lived focal adhesion scaffold. Cells lacking the TRIM protein are impaired in cell migration due to a defect in focal adhesion disassembly. We hypothesize that the TRIM protein senses cues delivered by microtubuli to initiate focal adhesion disassembly because microtubules correctly target focal adhesion, but fail to induce focal adhesion turnover. Given the importance of the TRIM protein in the dynamic turnover of focal adhesions, it is predicted to play a critical role in metastasis and oncogenesis.

352

Fascin phosphorylation is necessary for efficient turnover of focal adhesions.

N. Elkhatib[1], M. Neu[1], D. Louvard[1], D. Matic Vignjevic[1]; [1]Institut Curie, Paris, France

Efficient cell migration depends on phospho-regulation of the actin bundling protein fascin. Cells expressing phospho-mimetic fascin mutant, S39E, had difficulties to polarize and protrude, while cells expressing non-phosphorylatable fascin mutant, S39A, had problems retracting the uropod (Hashimoto et al, 2007). Our hypothesis is that cycles of fascin phosphorylation/dephosphorylation are necessary for directional cell motility: non-phosphorylated fascin for filopodia formation and cell guidance and phosphorylated fascin for focal adhesions (FAs) turnover and cell body retraction. Using TIRF microscopy we found that GFP-tagged wt and S39A mutant fascin, but not S39E, were enriched in the FAs marked with Cherry-tagged vinculin, paxillin, α- actinin or zyxin. In fascin-depleted cells, FAs were thinner and longer with slower turnover rate. The FA turnover rate was rescued by expression of S39E mutant, but not with S39A, suggesting that fascin phosphorylation is required for rapid turnover of FAs. Using a FAs disassembly assay (Ezratty et al, 2005), we found that fascin phosphorylation is required for FAs disassembly after microtubule re-growth. Our current model is that fascin plays a role in FAs assembly by bundling actin filaments and its phosphorylation is required for efficient FAs disassembly.

353

An integrin endocytic recycling pathway mediated by FAK and Src controls the polarized reassembly of focal adhesions after their disassembly.

G. Nader[1], E. Ezratty[1,2], G. Gundersen[1]; [1]Columbia University, New York, NY, [2]Rockefeller University,

Cell migration is a multi-step process that involves focal adhesion (FA) turnover and recycling of integrins. FA disassembly is an endocytic process that involves focal adhesion kinase (FAK), dynamin and clathrin (Ezratty, E. et al., NCB, 2005; JCB, 2009; Chao, W. and Kunz, J., FEBS, 2009). Little is known about the recycling of integrin following FA disassembly and whether FA components might play a role in the trafficking of endocytosed integrin. We used microtubule regrowth to synchronously induce FA disassembly and integrin endocytosis to examine whether endocytic recycling is coupled to FA reassembly. Focal adhesion reassembly commenced 30 min after microtubule-induced FA disassembly and occurred preferentially at the leading edge of cells. Integrin and active FAK were detected in both Rab 5- and Rab11-positive endosomes and FA reassembly required both Rab 5 and Rab 11. Src kinase participates in FA reassembly following disassembly induced by microtubules (Yeo, M. et al., MBC, 2006), so we explored the possible link between FAK and Src during the disassembly/reassembly cycle. Notably, both Src inhibitor (PP2) and FAK inhibitor (PF228) reversely blocked FA reassembly (without affecting disassembly), but only PP2 blocked the recycling of integrins to the cell surface. Furthermore, FAK and Src colocalized at the Rab 11 endocytic recycling compartment in either PP2 or PF228 treated cells. FAK mutants FAK-Y397F (autophosphorylation/Src binding site mutant) and FAK-K454R (kinase dead) rescued FA disassembly but not reassembly in FAK-/- cells, further suggesting that FAK kinase activity is essential for FA reassembly but not for disassembly. Constitutively active (activation loop mutant K578E/K581E) but not wild type FAK rescued the reassembly defect in Src, Yes and Fyn null cells (SYF cells), showing that Src functioned in FA reassembly through FAK. Consistent with this interpretation Src was transiently associated with the newly formed FAs. These results provide the first evidence that FAK and Src kinase activities contribute to FA reassembly by controlling the recycling of integrins from a Rab 11 compartment. This recycling pathway may direct integrin recycling to the leading edge thus contributing to the polarized formation of FAs in migrating cells.

354

Microenvironmental control of cell migration: Myosin IIA is required for efficient migration in fibrillar environments through control of cell adhesion dynamics.

A. D. Doyle[1], M. L. Kutys[1], M. A. Conti[2], K. Matsumoto[1], R. S. Adelstein[2], K. M. Yamada[1]; [1]Laboratory of Cell and Developmental Biology, NIH/NIDCR, Bethesda, MD, [2]Laboratory of Molecular Cardiology, NIH/NHLBI

Recent evidence suggests that organization of the extracellular matrix (ECM) into aligned fibrils or fibril-like ECM topographies promotes rapid migration in fibroblasts. However, the mechanisms of cell migration altered by these changes in microenvironmental topography remain unknown. Here, using 1D fibrillar migration as a model system, we find that fibroblast leading edge dynamics are enhanced by 1D fibrillar micropatterns and demonstrate a dependence on the spatial positioning of cell adhesions. Although 1D, 2D, and 3D matrix adhesions have similar assembly kinetics, both 1D and 3D adhesions are stabilized for prolonged periods, while both paxillin and vinculin show slower turnover rates in 1D adhesions. Moreover, actin in 1D adhesions undergoes slower retrograde flow than the actin present in 2D lamellipodia, suggesting an increase in mechanical coupling between adhesions and protrusive machinery. Experimental reduction of contractility resulted in loss of 1D adhesion structure and

stability, with scattered small and unstable adhesions and an uncoupling of adhesion protein-integrin stability. Genetic ablation of myosin IIA or IIB isoforms revealed that myosin IIA is required for efficient migration in restricted environments as well as adhesion maturation, while myosin IIB helps to stabilize adhesions beneath the cell body. These data suggest that restricted cell environments such as 1D patterns require cellular contraction via myosin IIA to enhance adhesion stability and coupling to integrins behind the leading edge. This increase in mechanical coupling allows for greater leading edge protrusion and rapid cell migration.

355

Adhesion and Protrusion Signatures Predict Cell-to-cell Variability in Response to EGF.

Y. Hou[1], N. Romsey[1], S. Hedberg[2], I. Schneider[1]; [1]Iowa State University, Ames, IA, [2]Univesity College London, United Kingdom

Cell migration plays an essential role in many biological processes, such as cancer metastasis, wound healing and immune response. Migration occurs through autocatalytic cycles of protrusion, focal adhesion (FA) assembly, FA maturation, FA disassembly and retraction. Epidermal growth factor (EGF) has been shown to enhance the migration rate in many cell types; however it is not known how it regulates FA dynamics, spatial patterns of protrusion or the coupling between these processes. We use total internal reflection fluorescence (TIRF) microscopy and image analysis to quantify FA characteristics, FA dynamics and protrusion dynamics under different doses of EGF stimulation. In a metastatic rat adenocarcinoma cell line, we find that the average cell migration rate does not change dramatically with increasing EGF concentration. However, the distribution of cell migration rates becomes broader with increased EGF concentration. If the FA characteristics, FA dynamics and protrusion dynamics are grouped based on based on EGF concentration, there are few noticeable differences. However, when cells are grouped according to migration rate, dramatic differences in FA characteristics, FA dynamics and protrusion dynamics are observed. This indicates that EGF stimulates increased migration in a subpopulation of cells and this subpopulation of cells contains certain signatures in FA characteristics, FA dynamics and protrusion dynamics. First, fast moving cells form more FAs with intermediate size and speed. Second, fast moving cells form FAs with low intensity and short lifetime. Third, fast moving cells organize their protrusion into lateral waves, whereas slow moving cells generate very little spatial organization in their protrusion. Furthermore, EGF increases the fraction of fast moving cells with lateral waves. We propose that during cancer progression, EGF induces a subset of cells to enhance their migration rate and this subset of cells is characterized by these adhesion and protrusion signatures. These signatures will be informative in understanding how to control migration responses in fast moving subpopulations of cells.

Structure and Function of the Extracellular Matrix

Growth of lung cancer cells in three-dimensional microenvironments reveals key features of tumor malignancy.

M. A. Cichon[1], D. C. Radisky[1]; [1]Mayo Clinic, Jacksonville, FL

Cultured human lung cancer cell lines have been used extensively to dissect signaling pathways underlying cancer malignancy, including proliferation and resistance to chemotherapeutic agents. However, the ability of malignant cells to grow and metastasize in vivo is dependent upon specific cell-cell and cell-extracellular matrix (ECM) interactions, many of which are absent

when cells are cultured on conventional tissue culture plastic. Previous studies have found that breast cancer cell lines show differential growth morphologies in three-dimensional (3D) gels of laminin-rich (lr) ECM, and that gene expression patterns associated with organized cell structure in 3D lrECM were associated with breast cancer patient prognosis. We show here that established lung cancer cell lines also can be classified by growth in lrECM into different morphological categories and that transcriptional alterations distinguishing growth on conventional tissue culture plastic from growth in 3D lrECM are reflective of tissue-specific differentiation. We further show that gene expression differences that distinguish lung cell lines that grow as smooth vs. branched structures in 3D lrECM can be used to stratify adenocarcinoma patients into prognostic groups with significantly different outcome, defining phenotypic response to 3D lrECM as a potential surrogate of lung cancer malignancy.

357

Impact of tissue tension in pancreatic cancer progression.

J. Lakins[1], H. Laklai[1], H. Moses[2], Y. Miroshnikova[1], V. Weaver[1]; [1]UCSF, San Francisco, CA, [2]Vanderbilt

Pancreatic Ductal Adenocarcinomas (PDAC) present a strong desmoplastic reaction, characterized by significant changes in the tumor microenvironment and the extracellular matrix (ECM), which severely compromises their treatment and surgical resection. The Weaver lab and others have shown in other cancers, that tumor development is accompanied by increased stiffness of the ECM. Understanding the mechanisms by which ECM stiffness regulates tumor development may lead to novel targets for anti-cancer treatment as well as for the diagnosis and early detection of the disease. The objective of this work is to understand what factors might contribute to the stiffening of the ECM during the development of PDAC and whether there is a causal effect to this stiffening. We used the transgenic mice models of PDAC that incorporate the two most common mutations found in human PDAC: Kras activating mutation alone (KrasG12D, which develop precancerous lesions) or in combination with Tgfb-receptor 2 deletion (Tgfbr2+/-, which develop invasive PDAC), using pancreatic epithelial cells specific promoter driven Cre-recombinase mice (Ptf1a-Cre). Initial experiments focused on characterizing collagen status, mechanical properties and mechano-signaling at various stages of tumor progression. We also explored the role of stromal fibroblast in driving tissue tension and PDAC.

358

How Deeply Cells Feel: Nuclear Phenotypes Defined by Matrix.

A. Buxboim[1], D. Discher[1]; [1]University of Pennsylvania, Philadelphia, PA

Tissue cells constantly probe their surroundings. They lack eyes to see and ears to hear but sense their microenvironment by adhering and physically deforming, which allows cells to feel into the depths of a matrix. To address how deeply cells feel we cultured mesenchymal stem cells, as prototypical but particularly sensitive adhesive cells, on collagen-coated gels-made microfilms of controlled elasticity (E) and thickness (h). After just 36 hrs in culture, cell spread area was distinctively smaller on thick and soft compared to either thin or stiff films, correlating well with nuclei morphology. Transition from small-to-large spread area transition was obtained at <5 microns gel thickness, which defines a tactile length scale for mechanosensitivity. Matrix-dependent cytoskeletal organization exhibits thickness-dependent nematic and smectic-like assembly, and nuclear component Lamin-A (LMNA), which is widely implicated in cell differentiation, was also found to be different for thin films relative to thick gels of the same E. Transcriptional profiles of many nuclear genes, including LMNA and histones, also showed a

dependence on h. The changes suggest mechanical links to regulation of gene expression by matrix physics

359

Effects of Substrate Rigidity on Fibronectin Matrix Assembly.

C. L. Carraher[1], J. E. Schwarzbauer[1]; [1]Molecular Biology, Princeton University, Princeton, NJ

Fibronectin (FN) is an abundant extracellular matrix protein that cells secrete, bind to and forcefully unfold to assemble into a fibrillar matrix. Increases in both FN production and tissue matrix stiffness have been associated with tumor malignancy and tissue fibrosis; however, little is known about the specific effects of rigidity on the process of cell-mediated FN matrix assembly. To address this question, polyacrylamide gels of varying stiffnesses were prepared to mimic the range of rigidities between softer normal tissues and stiffer diseased tissues, and gels were made cell-adhesive by crosslinking FN to the surfaces. NIH3T3 cells were grown on the gels, and FN matrix assembly was visualized by immunofluorescence or quantified by matrix insolubility in buffered deoxycholate (DOC) detergent at different time points. We found that FN matrix assembly is significantly reduced on softer substrates. To investigate the cause behind this rigidity-dependent decrease in FN matrix assembly, cells on soft substrates were treated with lysophosphatidic acid (LPA), a phospholipid known to increase cell contractility. Addition of LPA rescued FN assembly on soft substrates, indicating that FN matrix assembly can be promoted by increasing the contractile force a cell applies to the substrate. Since cells forcefully extend FN using integrin receptors, we stimulated integrin binding to FN with Mn^{2+} and found that FN matrix assembly was rescued on soft gels by this treatment. These results suggest that FN matrix assembly depends on the strength of integrin binding to FN, and binding may be weak on soft substrates. Integrin binding supports the extension of FN from a compact form to promote fibril formation, and integrin binding strength has been found to be affected by the conformation of FN. Binding of a conformation-dependent antibody against FN revealed that FN conformation varies with gel stiffness, and it appears to assume a more compact conformation on softer substrates. To test whether pre-extending substrate-bound FN on a soft gel affects matrix assembly, FN was partially unfolded by treatment with 1M guanidine hydrochloride. This treatment increased both FN matrix assembly and the number of matrix assembly sites formed by cells. Together, these findings show that cells assemble less FN matrix on softer substrates, and the difference between soft and stiff substrates is due to a deficiency in cells binding to and unfolding FN on softer substrates.

360

Spatial organization of the extra-cellular matrix regulates cell-cell junction positioning.

Q. Tseng[1], E. Duchemin-Pelletier[1], H. Guillou[2], O. Filhol[1], M. Thery[3]; [1]iRTSV, CEA, France, [2]Institut Néel, France, [3]CEA, Grenoble, France

Organization of cells into epithelium depends on cell interaction with both the extracellular matrix (ECM) and adjacent cells. The role of cell-cell adhesion in the regulation of epithelial topology is well described. ECM is better known to promote cell migration and provide a structural scaffold for cell anchoring. We developed a minimal model system to investigate the contribution of ECM to the spatial organization of multicellular structures. Fibronectin micropatterns were used to constrain the location of cell-ECM adhesion and analyze its effect on intercellular junction positioning. We found that ECM geometry affects the degree of stability of intercellular junction positioning and the magnitude of intercellular forces. Intercellular junctions were permanently displaced and experienced large perpendicular tensional forces as long as they were positioned close to ECM. Remarkably, intercellular junctions remained stable solely in regions deprived of ECM where they were submitted to lower tensional forces. Finally,

cells seemed to adapt their position in order to minimize both intra and inter-cellular tension and thereby adopt stable configurations in which overall tension anisotropy was regulated by ECM geometry. These results uncover a new morphogenetic role for ECM in the mechanical regulation of cell positioning.

361

Individual versus collective cell migration of corneal fibroblasts: regulation by matrix composition in 3D culture.

M. Miron-Mendoza[1], M. Petroll[1]; [1]Department of Ophthalmology, UT Southwestern Medical Center at Dallas, Dallas, TX

Extracellular matrix (ECM) supplies both physical and chemical signals to cells and plays a critical role regulating cell migration during wound repair. To study how ECM composition regulates migration of corneal fibroblasts, we created a nested 3D matrix model. In this model, compressed cell-populated collagen buttons are embedded in cell-free collagen or fibrin matrices. Corneal fibroblasts cultured in PDGF migrated out of the button into the acellular outer matrix. Time-lapse DIC imaging and 3D confocal analysis showed that cells migrated into collagen more rapidly than they migrated into fibrin. Furthermore, fibroblasts migrated into and through collagen mostly as individual cells, whereas fibroblasts moved into fibrin as an interconnected meshwork. Confocal reflection microscopy showed that cells remodeled both collagen and fibrin matrices during migration. Addition of fibronectin to matrices increased the rate of cell migration into both collagen and fibrin matrices, but the differences in cell connectivity remained. Spreading and migration of fibroblasts cultured within and on top of un-nested collagen and fibrin matrices showed similar differences in cell connectivity. Cells migrated individually in collagen matrices, but gradually became interconnected and formed clusters in fibrin matrices. On fibrin matrices, cadherin was localized to cell-cell adhesions, and increased fibronectin was secreted as compared to cells on collagen matrices. Our novel findings show that matrix composition plays a critical role modulating the pattern and amount of cell migration in a 3D environment.

362

Characterization of collagen gel pore sizes from confocal reflection images.

A. Mainka[1], N. Lang[1], J. Lange[1], C. Metzner[1], B. Fabry[1]; [1]Biophysics Group, Erlangen, Germany

The ability of tumor cells to invade connective tissue is crucial for the development of metastases. The mechanical tissue properties, in particular stiffness and pore size, crucially influence cell migration e.g. in collagen gel invasion assays and therefore need to be characterized. Here we present a simple and robust method to measure the pore size of collagen networks from confocal 3D image images. Images were recorded in reflection mode, which has the advantage that no fluorescent staining is necessary, but the disadvantage that collagen fibers that are oriented perpendicular to the imaging plane remain invisible. The resulting bias on the pore size can be corrected as follows. Images were binarized to define the solid and the liquid phase and to compute the distribution of distances between randomly chosen points of the liquid phase and their nearest solid obstacle. For collagen networks, this distribution follows a Rayleigh distribution from which the network line density, or average pore, size can be extracted. We show analytically that the fraction of invisible fibers corresponds to a shift of the distribution by a constant factor that only depends on the numerical aperture of the imaging objective and therefore can be easily corrected for. We then applied this method to a range of collagen gels with largely diverging pore sizes that were polymerized under different conditions including collagen concentration and temperature, with the aim to find an image binarization method that is robust against the influence of laser power, gain voltage, and fiber

density. We present an image normalization and thresholding (binarization) procedure that is robust against such variations of imaging parameters.

363

Solid phase binding assays reveal cryptic molecular interactions between Fibronectin Type III modules.

S. A. Williams[1,2], J. E. Schwarzbauer[1]; [1]Molecular Biology, Princeton University, Princeton, NJ, [2]Biological Sciences, New York City College of Technology, City University of New York (CUNY), Brooklyn, NY

Fibronectin fibrillogenesis is a complex, multi-step process that involves the conversion of soluble, compact fibronectin into an insoluble fibrillar matrix. The formation, extension, and augmentation of fibronectin fibrils represent essential steps in the establishment of a mature matrix that is biochemically characterized by its insolubility in the detergent deoxycholate (DOC). These fibrils are formed by various intermolecular fibronectin-fibronectin interactions involving specific domains within fibronectin. Although several fibronectin self-binding sites have been identified, the domains responsible for matrix maturation are largely unknown. In an earlier study (*Mol. Biol. Cell.* 20:S, 454), proteomic analysis was used to identify FN types $III_{4\text{-}6}$ (Hep III) and $III_{12\text{-}14}$ (HepII) as domains potentially associated within small, DOC-insoluble proteolytic fibril fragments. Both domains contain putative FN self-binding sites. To further investigate interactions between $III_{4\text{-}6}$ and $III_{12\text{-}14}$, recombinant FN fragments containing each domain were used in solid phase binding assays. Under non-denaturing conditions, fragments displayed relatively weak binding, however under mildly denaturing conditions produced by addition of guanidine hydrochloride (GdnHCl), we noted a robust increase in binding affinity between $III_{4\text{-}6}$ and $III_{12\text{-}14}$. Peak absorption in the binding assay occurred between 1.5M and 2.0M GdnHCl. Binding was both concentration-dependent and saturable. The results from binding experiments taken together with the previously obtained proteomic data, suggest that these domains contain sites that are involved in fibronectin-fibronectin intermolecular interactions required for DOC-insolubility and matrix fibril stability.

364

Fibronectin assembly and composite matrix remodeling within a micropatterened model of tissue morphogenesis.

W. Legant[1,2], V. Vogel[2], C. Chen[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]ETH Zurich, Zurich, Switzerland

Encapsulations of cells in reconstituted collagen I matrices have served as in vitro models of tissue morphogenesis and cell migration for nearly 50 years. As cells remodel and compact the exogenous collagen matrix, they also assemble a dense network of cell derived fibronectin which has been shown to increase the efficiency of collagen compaction. Moreover, previous studies have shown that individual fibronectin modules within fibers can unfold in response to cell generated tension, revealing cryptic binding sites that may alter cell adhesion and fibronectin fibrillogenesis. Here, we extend previous 2D work using a FRET sensor of fibronectin conformation/tension by combining this assay with a micropatterned approach to culture large arrays of 3D microtissues with well defined mechanical gradients.

We find that as the microtissue remodels, the fibronectin matrix is increasingly unfolded. Surprisingly, the cell assembled fibronectin and the exogenous collagen matrix become spatially segregated rather than forming an intercalated network. Over the course of several days, the initial collagen matrix is compacted into a dense core around which the cells form a fibrous

shell. Moreover, across a single microtissue, we find gradients of F-actin, fibronectin and tenascin C that match the predicted gradients of mechanical stress.

Here, we expand upon recent techniques to measure fibronectin conformation and to culture arrays of micropatterened tissues in order to simultaneously image matrix reorganization, matrix conformation and overall tissue morphogenesis at the length scale of single cells.

365

Study of the promoter of the cancer-associated extracellular matrix protein tenascin-W.

E. Martina[1], F. Chiovaro[1], R. Chiquet-Ehrismann[1]; [1]Friedrich Miescher Institute for Biomedical Research, Basel, Switzerland

The microenvironment hosting a tumor actively participates in the regulation of tumor cell proliferation, migration, and invasion. Among the extracellular matrix proteins enriched in the cancer stroma is tenascin-W, a member of tenascin family. Tenascin-W is expressed transiently in embryonic development and seems to have specific functions in osteogenesis. In the adult, Tenascin-W expression is strongly reduced, being restricted mainly to kidney and periosteum. However, in a large fraction of various types of human tumors tenascin-W is expressed, while in the corresponding normal tissue tenascin-W is not detectable. Immunohistochemistry of glioblastoma samples showed perivascular localization of tenascin-W. Moreover, we demonstrated that exogenous tenascin-W increases in vitro migration and sprouting of HUVEC, suggesting a possible role in tumor angiogenesis. More recently, the association of tenascin-W and tumor blood vessel has been observed in other types of tumor as well. Because of the distinct spatial and temporal changes in tenascin-W expression it is of interest to study its regulation.
The poster summarizes the recent study of the promoter region of human tenascin-W. Transfection of various deletion mutants of the human tenascin-W proximal promoter reporter constructs was performed in osteoblastoma and fibrosarcoma cell lines to identify regulatory elements. Deletion of a 12-bp sequence upstream of the published transcription start site led to a strong induction of the reporter activity.
DNA-pulldown experiments followed by mass spec analysis was performed to identify possible transcriptional repressors that binds to the 12-bp region. The effect of the downregulation by RNA interference of five putative repressors is currently under examination.

366

Gene expression analysis of neutrophils cultured on collagen matrix lacking telopeptides.

K. Morimoto[1], S. Kunii[1]; [1]Genetic Engineering, Kinki University, Kinokawa, Wakayama. Japan

[Background] The neutrophils protect the host by constituting the first line of defense against bacterial and fungal invading. In chemoattractant responses, neutrophils migrate to an inflammatory site in the extracellular matrices packed with type I collagen fibril and others. In particular, neutrophils secrete widely various cytokines, chemokines, and other proteins to regulate immune system. It is worth to investigate whether the telopeptides in collagen fibrils regulate the mRNA expressions of neutrophils or not. In this study, we report that gene expression profiles of neutrophils cultured on actinidain-hydrolyzed collagen (AHCol) lacking of telopeptides by DNA microarray and qRT-PCR.
[Materials & Methods] Pepsin-hydrolyzed collagen (PHCol) and AHCol were prepared from chicken skin according to our procedures (1). Activated neutrophils were collected from a mouse abdominal cavity stimulated by casein solution, and subsequently were cultured on a plate pre-coated with the PHCol or the AHCol. After the incubation period of 1.5 h, the mRNAs

of neutrophils were extracted and analyzed by mouse gene expression microarrays (Agilent Technologies). To compare the activation levels of neutrophils, we quantified some specific mRNA expressions by real time RT-PCR with the specific primer sets.
[Results] The mRNA expression levels of chemokines of neutrophils cultured on the AHCol were drastically decreased than those on the PHCol. Similarly, important cytokines involved in inflammatory response were affected by contacting the AHCol matrix.
[Conclusion] We demonstrated that the scaffold by the AHCol matrix alters signals of immune network in neutrophils.

The role of filamin in cytoskeletal dynamics of differentiated vascular smooth muscle cells.

R. Yamin[1], R. H. Poythress[1], C. M. Gallant[1], K. G. Morgan[1]; [1]Deartment of Health Sciences, Boston University, Boston, MA

Filamin (FLN) is a large non-muscle actin crosslinking protein (MW 240-280 KD). It is known to crosslink actin filaments orthogonally and to stabilize 3D filament structure. Filamin is also known to act as a mechanotransducer, but its role in the vascular smooth muscle contractility is unclear. In this study we used cellular and molecular approaches to study the structure and function of the cortical cytoskeleton in differentiated vascular smooth muscle cells (dVSMC) in order to decipher the composition of filamin in this structure, identify its binding partners, and understand its possible involvement in regulating actin cytoskeleton connections to the adhesion plaques during the cells contractile response to the agonist phenylephrine.

We demonstrate that FLNa is highly expressed in the dVSMCs while FLNb expression is significantly lower. In addition by using deconvolution immunofluorescence experiments we have found that FLNa localizes in punctae consistent with focal adhesions and dense bodies. By quantitative differential centrifugation we have found that there is an agonist-induced redistribution of the FLNa from the cytosol fraction to the cytoskeleton fraction. Furthermore, by immunoprecipitation experiments, we have found that FLNa interacts with α, β, and γ- Actin as well as CaMKII in an agonist-dependent manner.

Our data suggest that FLNa may play a regulatory role in cytoskeletal dynamics during dVSMC contraction.

A novel role for PI3K in mediating the reciprocal relationship between stem cell gene expression and remodeling of the stem cell microenvironment.

K. M. Henderson[1], J. M. Zuidema[2], R. J. Gilbert[2], G. E. Plopper[1]; [1]Biology, Rensselaer Polytechnic Institute, Troy, NY, [2]Biomedical Engineering, Rensselaer Polytechnic Institute

Although there have been recent advances in the application of stem cell technologies, the cyclical relationships between changes in stem cell structure, cell function and the microenvironment remain largely undefined. As stem cells differentiate, cell structures adapt and cause changes to the microenvironment. Inversely, alterations to the stem cell microenvironment, or niche, induce a functional response leading to structural changes. Chemically altering functional protein pathways to activate cell structure changes and monitoring the resulting microenvironmental remodeling provides a method for analyzing cyclical relationship changes between stem cells and the stem cell niche. Phosphoinositide-3 Kinase (PI3K) transduces microenvironmental changes from ECM-binding, transmembrane

receptors through a variety of pathways, including the Rho-family of GTPases which regulate cytoskeletal organization. Inhibition of PI3K with the drug LY294-002 alters stem cell structure through remodeling of the actin cytoskeleton. Cytoskeletal remodeling was imaged using fluorescent confocal microscopy of human Mesenchymal Stem Cells (hMSC) seeded on collagen-I coated plates or encapsulated in 3D collagen-I hydrogels and treated with either LY294-002 or control media. Inhibiting PI3K causes a reciprocal change in the microenvironment due to the altered cellular structures and functions. Quantified changes in hydrogel compaction rates, along with elastic and viscous moduli collected using a rheometer capture altered physical and mechanical changes to the microenvironment of the 3D collagen-hMSC hydrogels. Microarray analysis of both the 2D and 3D treated and control samples revealed dimensionality-dependent changes in stem cell gene expression along five different mesenchymal lineages. Together, these results suggest that functional changes alone do not determine stem cell fate because the cyclical response from the surrounding microenvironment heavily impacts differentiation. Therefore, in addition to its well-known functions controlling the cell cycle and apoptosis, PI3K now plays a role in remodeling the ECM component of the stem cell niche.

A role for estrogen receptor alpha (ERalpha) and estrogen receptor beta (ERbeta) in collagen biosynthesis in mouse skin.

M. Markiewicz[1], S. Znoyko[2], L. Stawski[3], A. Ghatnekar[1], G. Gilkeson[1], M. Trojanowska[3];
[1]Medical University of South Carolina,Charleston,SC, Charleston, SC, [2]Moscow State University, Moscow, Russia, [3]Arthritis Center,Boston University School of Medicine, Boston, MA

Objective: The goal of this study was to investigate the role of ERalpha and/or ERbeta on collagen biosynthesis in the skin using unique genetic models: knockout ERalpha (ERKO-alpha) and ERbeta (ERKO-beta) female mice.
Methods: We first investigated whether ERalpha and ERbetaƒninfluence collagen accumulation in the skin. The collagen content was assessed by the hydroxyproline assay .We also extracted the collagen by acetic acid method with addition of pepsin. Furthermore, we investigated the amounts of newly made soluble (non-crossed-linked) collagens that are not yet incorporated into the large fibrils using acetic acid extraction method. Using qRT-PCR method we measured mRNA levels of small leucine -rich proteoglycans (SLRP¡¦s) contributing to this process.
Results: The hydroxyproline content was two times higher in ERKO-alpha mice while in ERKO-beta mice was decreased (~30%) as compared to control animals. Furthermore, more collagen was extracted from the skin of ERKO-alpha mice (3.1 fold increase) as compared to controls. In contrast, the total collagen content decreased (~40%) in the skin of ERKO-beta mice. In ERKO-alpha mice, the soluble collagen was slightly elevated (1.6 fold increase) most likely reflecting increased synthesis of collagen. Alterations in collagen solubility have suggested changes in the expression level of SLRPs involved in fibrillogenesis. In ERKO-alpha mice, expression levels of Lumican and Decorin were significantly elevated (9.9 folds and 1.9 folds respectively). On the other hand, in ERKO-betaƒnmice, the expression levels of Lumican and Decorin was diminished (2.3 folds and 7.7 folds respectively).These data suggest that the ERbeta loss of function may lead to changes in collagen fibrils shape, diameter and assembly in these mice. Interestingly, we observed an increased mRNA and protein expression levels of MMP3, 8 and MT1, 2, 3-MMP in ERKO-beta mice suggesting elevated collagen degradation while MT2-MMP was significantly decreased in ERKO-alpha animals.
Conclusions: Our data show that the Estrogen Receptor pathway is involved in collagen biosynthesis. Furthermore, our results indicate that ERalpha plays an inhibitory role in collagen synthesis and fibrillogenesis, while data from ERKO-beta mice suggest that ERbeta may play an opposite role in these processes.

Identification of biologically active site in the laminin gamma 1, 2, and 3 chain short arm regions.

Y. Tanaka[1], T. Watari[1], A. Kawami[1], F. Katagiri[1], K. Hozumi[1], Y. Kikkawa[1], M. Nomizu[1]; [1]Tokyo University of Pharmacy and Life Sciences, Hachioji, Japan

Laminins are major components of the basement membrane and have various biological activities such as promotion of cell adhesion, growth, migration, differentiation, and angiogenesis. Laminin is composed of three different subunits α chain, β chain, and γ chain. So far, five α (α1--α5), three β (β1--β3), and three γ (γ1-- γ3) chains were identified. At least sixteen laminin isoforms were reported with the combination of each subunit. These laminin isoforms expresses tissue- and/or developmental stage-specifically. Laminin γ chains have chain specific diverse biological functions. Each laminin γ chain is composed of N-terminus short arm region (EGF-like repeats and globular domains) and a coiled-coil domain, which forms triple-helical assembly. Here, we focused on the short arm region of the laminin γ1, 2, and 3 chains. We have constructed the synthetic peptide library derived from the laminin sequences, and identified cell adhesive peptides. We expanded the synthetic peptide library to add peptides covered short arm region of laminin γ chains sequences, and screened cell adhesive peptides in the library. We prepared synthetic peptide library including 256 peptides derived from three γ chains sequences. All peptides were synthesized by the 9-fluorenylmethoxycarbonyl strategy with C-terminal amide, and purified by reverse-phase HPLC. These peptides were generally 12 amino acids in length and overlapped with neighboring peptides by 4 amino acids. We screened cell attachment activity of the peptides by the peptide-coated plastic plate assay using human fibrosarcoma (HT-1080) cells. Four peptide derived γ1 chain sequence, C16 (KAFDITYVRLKF), C28 (TDIRVTLNRLNTF), C64 (SETTVKYIFRLHE), and C68 (TSIKIRGTYSER)[1], five peptide derived γ2 chain sequence, C2-25 (AKFLGNQQVSYG), C2-29 (VILEGAGLQIRAP), C2-31 (GITKTYTFRLNE) C2-35 (NLTALLIRATYG), and C2-37 (GYIDNVTLVSAR), and four peptides derived from γ3 sequence, C3-24 (APLNGGNVAFSTL), C3-28 (STDILISLDRLN), C3-65 (RVQLQFLLQETS), and C3-68 (AQRLLSNLTALSI), were identified as cell attachment peptides. The corresponding sites to these active peptides are important for the biological activities of the short arm regions of the laminin γ1, 2, and 3 chains.

Corneal epithelial-like cells in total limbal stem cell deficiency in rabbit model.

S. Kameishi[1,2], H. Sugiyama[2], M. Yamato[2], Y. Sado[3], H. Namiki[1], T. Okano[2]; [1]Waseda University, Tokyo, Japan, [2]Tokyo Women's Medical University, Tokyo, Japan, [3]Shigei Medical Research Institute

[Objective]

Corneal epithelial stem cells reside in the basal layer of limbus located at the transitional zone between cornea and conjunctiva. When limbal epithelial stem cells are destroyed, conjunctival tissue covers the surface of cornea, and this condition is known as limbal stem cell deficiency (LSCD). Previous study suggests that invaded abnormal conjunctival epithelial cells are transdifferentiated into corneal epithelial-like cells in rabbit total LSCD model. This study investigated the character of invaded conjunctival epithelial cells and basement membrane in rabbit total LSCD model.

[Methods]
Rabbit LSCD model was prepared by removing corneal and limbal epithelium surgically and chemically. The expressions of cytokeratin 4 (K4), K13, mucin 5 (Muc5), K12, and type IV collagen alpha-chains of the model were investigated for 6 and 12 months.
[Results and Discussions]
Neovascularization and cornea opacification were observed in the cornea surface of LSCD model. The integrity of LSCD model was characterized by observing the expression of conjunctival epithelial cell markers (K4 and K13), goblet cells marker (Muc5), and neovascularization in the corneal stroma. The central cornea of 6- and 12- months follow-up LSCD models were found to have corneal epithelial maker of K12 expressing cells, which were islanded without connecting to the limbal epithelial region.
Native conjunctival basement membrane consists of α1(IV)-α1(IV)-α2(IV) and α5(IV)-α5(IV)-α6(IV) collagens, and corneal basement membrane have α3(IV)-α4(IV)-α5(IV) and α5(IV)-α5(IV)-α6(IV) collagens. However, α2 (IV) collagen was found to be continuously expressed in the basement membrane from conjunctiva to central cornea, including the basement membrane of corneal epithelial-like cells of 6-month follow-up LSCD model. These results suggested that invaded conjunctival epithelial cells might be transdifferentiated into corneal epithelial-like cells. Whereas, in the 12-month follow-up LSCD model, α2 (IV) collagen expression under the corneal epithelial-like cells were weaker than that 6-month follow-up LSCD model. Interestingly, α5 (IV) collagen was strongly expressed under the corneal epithelial-like cells in 6-month follow-up LSCD, compared with conjunctival basement membrane. These observations suggested that basement membrane had a possible ability to regulate cell phenotype.
[Conclusion]
This study demonstrated that abnormal conjunctival cells on the corneal surface of LSCD model were transdefferentiated into corneal epithelial-like cells, and basement membrane had a possible ability to regulate cell phenotype. This study was beneficial to understand human LSCD, epithelial transdifferentiation, and stem cell maintenance.

Orthogonal and reversible control of physical and optical properties of polyethylene glycol (PEG) hydrogel matrix.

C. Petchprayoon[1], G. Marriott[1]; [1]Bioengineering, University of California, Berkeley, Berkeley, CA

Recent studies suggest that dynamic sensing and regulation of the stiffness and viscosity of the extracellular matrix is required for stem cell differentiation and tumor metastasis. An understanding of how changes in physical properties of the micro-environment regulate cell function and behavior requires new experimental approaches that allow for dynamic, high spatial and temporal resolution of physico-chemical properties of the cell matrix. In this study we describe new probes that provide for high fidelity, reversible optical control of the physical and optical properties of soft gel matrices and other biomaterials. Thiol-functinalized 4-arm polyethylene glycol (PEG) monomers are crosslinked using a thiol-reactive homo-bifunctional optical switch, spironaphthoxazine (NISO), to form transparent gels of defined stiffness. The populations of the colorless spiro (SP) and the intensely blue colored merocyanine (MC) states of NISO within the gel are controlled via reversible and efficient optical or opto-thermal driven isomerisation reactions. The thermodynamically-stable SP state of the gel is rapidly turned the MC-state on exposure to 365 nm or 405 nm light. The MC to SP transition is quickly realized by exposing the same MC state to visible light or via a slower thermally-driven isomerisation. NISO-PEG gels are shown to undergo many cycles of high-fidelity, opto-thermal switching between the SP and MC states with little to no evidence of fatigue. Incorporation of collagen or fibronectin onto the surface of, or throughout, the gel supports the growth and microscope imaging of cells while having no impact on the optical switching properties. These new gels

allow for high-resolution and multiscale analyses of the relationship between changes in physical properties of the matrix and cell mechanics and behavior.

Asymmetric Expression/Distribution of Connexins is Essential for Contractile Function in the Mammary Gland.

R. Mroue[1,2], M. Bissell[3]; [1]Life Sciences, Lawrence Berkeley National Laboratory, Berkeley, CA, [2]Comparative Biochemistry, UC Berkeley, Berkeley, CA, [3]Lawrence Berkeley National Laboratory, Berkeley, CA

Intercellular communication is essential for glandular functions and homeostasis. Gap junctions couple cells homotypically and heterotypically and coordinate reciprocal responses between the different cell types. Connexins (Cxs) are the main mammalian gap junction proteins, and their distribution in the heterotypic gap junctions is not always symmetrical; in the mammary gland, Cx26, Cx30 and Cx32 are expressed in the luminal epithelial cells and Cx43 in myoepithelial cells. Expression of all four Cxs peaks during late pregnancy until late lactation suggesting essential roles for these proteins in functional differentiation of the gland. When Cx26 was expressed driven by the keratin 5 promoter in a transgenic mouse model designed to study Cx26 over-expression in skin, K5-Cx26 dams had an unexpected mammary phenotype whereby transgenic dams were unable to feed their pups to weaning age, leading to litter starvation and demise in early to mid-lactation. We thus asked why ectopic expression of the luminal Cx26 to mammary myoepithelial cells impairs mammary function, and by what mechanism. The mammary glands of K5-Cx26 female mice develop normally but pups are unable to receive milk. This is despite the normal levels of beta casein and whey acidic protein present in the mammary glands of transgenic mice, and suggesting a defect in delivery rather than milk production. Primary mammary organoids, isolated from wild-type FVB females, contracted in culture upon treatment with oxytocin; however, primary mammary organoids from the transgenic mice failed to respond to oxytocin. Interestingly, we found that ectopic expression of Cx26 to myoepithelial cells alters the expression of endogenous Cx43 and inhibits gap junction-mediated dye coupling in myoepithelial cells expressing high levels of Cx26. The mammary contractile defect is thus due to Cx26 acting as a dominant negative to Cx43 function and impairing gap junctional coupling, since inhibition of gap junctional communication and knock-down of Cx43 in wild-type organoids similarly impairs contraction in response to oxytocin in culture.

374

The Cytoplasmic Tail of Connexin32 and the Assembly of Gap Junctions.

P. Katoch[1], S. Mitra[1], K. E. Johnson[1], P. P. Mehta[1]; [1]Biochemistry and Molecular Biology, University of Nebraska Med Center, Omaha, NE

The spatio-temporal events and cellular factors required for the de novo formation of a nascent gap junction plaque, its growth, and disassembly are poorly understood. The assembly of gap junctions is a multi-step process, and is initiated when six connexin(Cx)s oligomerize to form connexons, which dock with connexons on contiguous cells to form intercellular channels. A gap junction plaque is formed when several intercellular channels cluster. We previously showed that the carboxy tail (CT) of Cx32, a Cx highly expressed in well-differentiated and polarized cells, may be required to initiate the formation of a gap junction plaque and/or its subsequent

growth. To explore the role of Cx32-CT further, a CT-truncated Cx32 (Cx32Δ220) as well as full length Cx32 (Cx32-FL) were retrovirally introduced in three separate cell-culture model systems. As assessed by quantitative immunocytochemical analyses, our results showed that Cx32Δ220 showed 2-3 fold decrease in gap junction size compared to Cx32-FL. Cell surface biotinylation showed that Cx32Δ220 trafficked normally to the cell surface, however, it was inefficiently assembled into gap junctions as assessed by detergent-solubility assay. Immunocytochemical analysis showed that Cx32Δ220 did not colocalize with markers of the secretory and endocytic pathway. Moreover, expression of Cx32-FL in cells stably expressing Cx32Δ220 increased the size of gap junctions, implying the direct involvement of Cx32-CT in this process. To define which domain of Cx32-CT determined the size of gap junctions, a series of deletion mutants, with progressive truncation of 20 amino acids, was retrovirally expressed in human prostate cancer cell line, LNCaP, in pancreatic cancer cell line, BxPC3, and in RL-CL9 cells. These experiments showed that the domain that determined the size of gap junctions lied between amino-acids 230-250 of Cx32-CT. A protein motif search identified two PKA phosphorylation motifs: RKGS and RLS, with serine residues at positions 233 and 240 that might be phosphorylated. Protein kinase A mediated phosphorylation has previously been shown to increase clustering of cell-cell channels. Our findings thus imply that the PKA phosphorylation motifs in Cx32-CT may regulate gap junction size and growth.

375

The C-Terminus is essential for functional expression and internalization of rCx46.

B. Schlingmann[1,2], P. Schadzek[1], F. Hemmerling[1], S. Busko[1], A. Ngezahayo[1,2]; [1]Institute of Biophysics, Leibniz Univ Hannover, Hannover, Germany, [2]Center for Systems Neuroscience, University of Veterinary Medcine Hannover Foundation, Hannover, Germany

Recent results have shown that a total ablation of the C-terminus of rat lens connexin46 altered formation of functional rCx46 hemichannels. We combined molecular biological, cell imaging and dye transfer techniques to characterize the structures of the C-terminus that are involved in expression and internalization of rCx46. Six mutants rCx4630.3, rCx4630.9, rCx4632.6, rCx4633.5, rCx4635.3, and rCx4636.4 were generated by truncation of the C-terminus at different positions. All mutants were labeled with EGFP and expressed in HeLa cells to analyze the expression and internalization behavior using a confocal laser scanning microscope. The results showed that the rCx46 variants can be classified into three groups, according to the increasing length of the C-terminus. The variants of the first group (rCx4628.2, rCx4630.3, and rCx4630.9) did not form functional gap junction channels, they were found neither in large vesicles nor in cellular compartments. rCx4632.6 and rCx4633.5 form the second group. They formed functional gap junction channels which were clustered in large gap junction plaques. But they were not found in large vesicles and their compartmentalization seemed altered. The last group is composed of rCx4635.3 and longer rCx46 variants. They formed large gap junction plaques and functional gap junction channels as well. They were found in compartments and could be detected in large vesicles. Moreover HeLa cells expressing rCx4635.3 showed a 5.78 times higher rate of vesicle budding from the gap junction plaques in comparison to the 29 amino acid residues shorter variant rCx4632.6. Additionally, in cells pairs expressing rCx4632.6, only 2.91 annular junctions per cell pair were detected while cell pairs expressing rCx4635.3 showed an average of 6.70 annular junctions per cell pair. The results suggest that the first 81 amino acid residues of the C-terminus are necessary for a correct compartmentalization and large vesicle formation of rCx46. Within these 83 residues, the first 51 residues of the C-terminus are enough for formation of functional gap junction channels. However rCx4632.6 showed a reduced vesicle budding and formation of annular junctions compared to rCx4635.3 , we propose that the first 81 amino acid residues in the C-terminus are essential for an annular junction dependent removal of rCx46 gap junction channels.

376

Ultrastructural and Live-Cell Analysis of Dynamin's Role in Gap Junction Plaque Endoexocytosis.

M. Boller[1], K. Schneider[1], B. Nickel[1], T. Shakespeare[2], S. Murray[1]; [1]Univ Pittsburgh Sch Med, Pittsburgh, PA, [2]Biology, Fort Valley State University, Fort Valley, GA

Gap junction-mediated cell-cell communication modulates cell function in most tissues of the body. Such communication is regulated, in part, by the rate of gap junction plaque assembly and removal from the cell surface. While the assembly process has been extensively studied, much less is known about gap junction plaque disassembly. It has been established however that gap junction plaques can be removed from the cell surface by an internalization process (a unique combination of endocytosis and exocytosis, termed “endoexocytosis”) which results in the formation of a cytoplasmic annular gap junction in one of two contacting cells. Both clathrin and dynamin have been demonstrated to play a role in this endoexocytotic process. To increase our knowledge of the details and molecular machinery involved in gap junction plaque endoexocytosis, immunocytochemical, time lapse, and quantum dot transmission electron microscopic (TEM) techniques were used to image SW-13 adrenal cells, which spontaneously internalize connexin 43 (Cx43) gap junction plaques. Ultrastructural evaluation of cell populations in which dynamin was inhibited by treatment with a dynamin GTPase inhibitor (dynasore), or with siRNA knockdown techniques, revealed gap junction plaques with large invaginations. While invaginated gap junction plaque membrane was seen in the diluent-treated control populations, this was rare compared to the number and the size of invaginations observed in dynamin-inhibited cells. Most of the invaginations were not bud-like but instead formed U-shaped structures which had a wide base. These TEM observations would be consistent with failure of the gap junction plaque to form a bud with a constricted neck, in the dynamin inhibited populations. Time lapse imaging however was used to monitor and to confirm that gap junction “buds” formed in the dynamin inhibited populations. These buds failed to be scissored from the plasma membrane. Over time the buds converted to the U-shaped invaginations similar to the structures seen with TEM. The U-shaped areas remained in that configuration for several hours although the morphology of the invagination was altered. While annular gap junctions were observed in both control and dynamin-inhibited cell populations, they were more frequent in control populations. Here we describe, in detail, for the first time the ultrastructural changes during endoexocytosis and demonstrate the changes that occur when dynamin is inhibited. We suggest gap junction buds can form in dynamin inhibited populations but that dynamin plays a pivotal role in scissoring of these buds from the plasma membrane and thus the formation of the annular gap junction vesicle. Information on the molecular machinery needed for gap junction plaque removal from the cell membrane is thought to be critical to an understanding of gap junction processing and cell communication. NSF Grant # MCB- 1023144

377

Endocytosis of Connexin43 and the Dynamics of Gap Junction Assembly.

K. Johnson[1], P. Katoch[1], L. Kelsey[1], P. Mehta[1]; [1]Biochem and Mol. Biology, University of Neb Med Center, Omaha, NE

Connexin(Cx)s, the constituent proteins of gap junctions, are expressed both in a tissue-specific manner as well as redundantly. Redundant and tissue-specific expression implies that distinct mechanisms must exist to regulate the assembly of each Cx into gap junctions. The importance of understanding this is underscored by the fact that the trafficking and assembly of Cxs into gap junctions are defective in different cancers. To explore how the assembly of Cxs is regulated upon arrival at the cell surface, we used two pancreatic cancer cell lines, BxPC3, in which Cx43 is inefficiently assembled and remains intracellular while Cx26 is efficiently

assembled into gap junctions, and Capan-1, in which both Cxs are inefficiently assembled. Cell surface biotinylation showed that Cx43 trafficked normally to the cell surface and was endocytosed by the clathrin-mediated pathway in a Rab5-dependent manner before its assembly into gap junctions. Yeast two hybrid analysis showed that Cx43 interacted with the μ2 subunit of the AP-2 complex via a consensus sorting signal, YKLV, residing in its cytoplasmic tail between amino acid residues 286-289. Retrovirus mediated transduction of mutant Cx43Y286A/V289D, but not of wild type Cx43, induced gap junction assembly in BxPC3 and Capan-1 cells. Phosphorylation of serines in the vicinity of YKLV has been shown to modulate the interaction between the cargo and the AP-2 complex. As assessed by immunocytochemical analysis, we found that transient transfection of mutants Cx43S279A and Cx43S282A, but not of Cx43S279D and Cx43S282D, also induced gap junction assembly in both cell lines. Transient transfection of mutants Cx43Y286/V289D, Cx43S279A and Cx43S282A also prevented endocytosis of Cx43 in single cells. Finally, retrovirally-introduced Cx32 was assembled efficiently into gap junctions in BxPC3 cells. Our findings document that the assembly of Cxs into gap junctions upon arrival at the cell surface is subject to regulatory mechanisms at the site of cell-cell contact that are likely to be Cx specific.

378

Acetylation Modulates Connexin32 Ubiquitination and Turnover.

S. Alaei[1], J. Bulinski[2]; [1]Biological Sciences, Columbia University, New York, NY

Gap junctions (GJ) are dynamic hexameric channels comprised of connexins that allow neighboring cells to communicate through intercellular passage of small molecules such as ions and metabolites. It has long been known that connexins are relatively short half-lived ($t_{1/2}$ =1.5-6h), but the pathways that regulate connexin protein level in order to maintain normal GJ communication under a variety of physiological conditions remain unknown. Using Connexin32 (Cx32) as a model, we are investigating the crosstalk between connexin acetylation and ubiquitination in the regulation of connexin protein level. We have determined that acetylated Cx32 is found both at the cell surface and in the cytoplasm, suggesting that the modification is present for most of the life cycle of Cx32 protein. Our earlier work indicated that pharmacological inhibition of HDACs resulted in increased Cx32 protein level that is independent of transcriptional alterations; further investigation revealed that HDAC6 inhibition in particular plays a role in regulating Cx32 protein level. Pharmacological inhibition of HDAC6 activity results in increased Cx32 at the cell surface, suggesting that deacetylation of Cx32 may be important for Cx32 endocytosis or that Cx32 acetylation promotes trafficking of Cx32 to the cell surface. Cx32 acetylation is increased and ubiquitination is decreased when HDAC6 expression is reduced, suggesting that deacetylation of Cx32 enhances ubiquitination. Analysis of K→R mutants, which eliminate acetylation sites but are unlikely to alter protein structure, has allowed us to identify several acetylated lysines in cytoplasmic domains of Cx32. In K→R mutants, ubiquitination was significantly reduced compared to WT, whereas in K→Q mutants in which Q mimics constitutive acetylation, ubiquitination levels resembled that of WT Cx32. This suggests that acetylation helps recruit ubiquitination machinery to Cx32. Based upon these results, we hypothesize that HDAC6 binding to acetylated Cx32 concurrently recruits ubiquitination machinery that ubiquitinates Cx32 at residues other than the acetylated lysines and augments Cx32 degradation. Current experiments are exploring the possibility of HDAC6-mediated regulation of GJ based cell-cell communication.

379

Internalized Gap Junctions are Degraded by Autophagy.

R. M. Kells[1], A. M. Gumpert[2], J. T. Fong[1], M. M. Falk[1]; [1]Biological Sciences, Lehigh University, Bethlehem, PA, [2]Thomas Jefferson University

Direct intercellular communication mediated by gap junction (GJ) channels is a hallmark of normal cell and tissue physiology. In addition, GJs significantly contribute to physical cell-to-cell adhesion. Clearly, these cellular functions require precise modulation. Typically, GJs represent arrays of hundreds to thousands of densely packed channels, each one assembled from two half-channels (connexons), that dock head-on in the extracellular space to form the channel arrays (termed GJ plaques) that link neighboring cells together. Interestingly, docked GJ channels cannot be separated into connexons under physiological conditions, posing potential challenges to GJ channel function and renewal, and to physical cell-cell separation. We described previously that cells can efficiently internalize entire GJs in a clathrin-mediated endocytic process (Piehl et al., 2007, Mol. Biol. Cell, 18:337-347; Gumpert et al., 2008, FEBS Lett., 582:2887-2892), thus enabling these critical cellular functions. GJ internalization generates unique cytoplasmic double-membrane vesicles, described and termed earlier annular GJs (AGJs) or connexosomes. Here, using expression of fluorescent-tagged Cx43 in HeLa cells, ultrastructural analyses, confocal colocalization microscopy, pharmacological and molecular biological RNA-interference approaches depleting cells of key-autophagic proteins, we provide compelling evidence that GJs, following internalization, are degraded by autophagy. The ubiquitin-binding protein p62/SQSTM1 (sequestosome 1) was identified in targeting internalized GJ vesicles to autophagic degradation. While previous studies identified proteasomal and endo-/lysosomal pathways in GJ degradation, our study provides novel molecular and mechanistic insights into an alternative GJ degradation pathway. Its recent link to health and disease lends additional importance to this GJ degradation mechanism and to autophagy in general.

380

Molecular Mechanisms of Gap Junction Internalization: Involvement of the C-Terminal Domain of Cx43.

J. T. Fong[1], M. M. Falk[1]; [1]Biological Sciences, Lehigh University, Bethlehem, PA

Gap Junctions (GJs) electrically and chemically couple neighboring cells by forming clusters of hydrophilic membrane channels. Connexins (Cxs) are the trans-membrane proteins that form these channels. Complete double-membrane spanning GJ channels are formed when two hexameric hemi-channels (termed connexons) dock in the extracellular space. In addition, GJs significantly contribute to physical cell-to-cell adhesion. Interestingly, docked GJ channels cannot be separated into hemi-channels under physiological conditions, and we have shown that GJs are internalized as a whole, in a clathrin-mediated endocytic process (Piehl et al., 2007; Gumpert et al., 2008). It is known that Cx43 is differentially phosphorylated during its life cycle. For example, mitogen (e.g. EGF) treatment of mouse embryonic stem cells (mESCs) results in increased phosphorylation of Cx43 and a reduction in GJ intercellular communication, suggesting that phosphorylation flags/activates Cx43 for internalization. Clathrin normally does not bind directly to its cargo. Instead, it requires adaptor proteins to link the cargo to clathrin molecules. We found several potential binding sites for (I) the classical clathrin-adaptor protein complex AP-2 (binding motif YXXF), and (II) the alternative clathrin-adaptor Dab2 (binding motif NPXY) in the cytoplasmic regulatory C-terminal domain of Cx43, both shown to be involved in GJ internalization. To characterize the Cx43 internalization signal/s, we mutated the potential binding sites of both adaptor proteins by site-specific mutagenesis. We have generated 9 different Cx43 mutants including 4 tyrosine point mutations (Y to H), 3 small (3-7 amino acids)

and 2 large (36 and 128 amino acid) deletion mutants. Live cell imaging of HeLa cells expressing the mutants exhibit very different cell behavior. Half-live studies revealed that Cx43-delL254-290-GFP and Cx43-delL254-CT-GFP have a significantly longer half-live than full length. Immuno-coprecipitation experiments show that Cx43-delL254-290-GFP and Cx43-delL254-CT-GFP have lost the ability to interact with AP-2, Dab2, clathrin, and dynamin-2. These, and additional analyses elucidate how, mechanistically, clathrin can internalize such large plasma membrane structures, and whether phosphorylation is the signal that triggers GJ internalization.

381

Regulation of photoreceptor gap junction coupling by dopamine and adenosine.

H. Li[1], S. W. Wang[1], J. O'Brien[1]; [1]Dep of Ophthalmology and Visual Science, University of Texas Health Science Center, Houston, TX

Gap junctions in retinal photoreceptors serve to suppress voltage noise and to facilitate entry of rod signals into the cone pathway when rod synapses approach saturation. These synapses are highly plastic and are regulated by light and circadian rhythms. The current study investigates the molecular mechanisms that regulate photoreceptor coupling. Recent studies have revealed an important role of Cx36 phosphorylation at two regulatory sites in regulating cell-cell coupling. Dopamine, as a light signal, has been suggested to cause uncoupling between photoreceptors via its action on D4 receptors, which inhibit adenylyl cyclase and PKA activity. We hypothesized that adenosine, with its extracellular level peaking in the darkness and at night, may serve as a dark signal and co-regulate photoreceptor coupling.

Adult C57BL/6 mice, as well as A1-/- and A2a-/- mice, were maintained under a 12/12h L/D cycle. Some animals were dark-adapted for 6h starting at ZT2h; Corresponding light-adaptation experiments were conducted at the same time. Eyecups were incubated for 30min in oxygenated Ames' medium alone or supplemented with the following drugs: dopamine D4 receptor agonist PD 168077 or antagonist L-745870, adenosine A2a receptor agonist CGS21680 or antagonist 8-(3-Chlorostyryl)caffeine, A1 receptor agonist 2'-MeCCPA or antagonist DPCPX, PKA activator Sp-8-cpt-cAMPS or inhibitor Rp-8-cpt-cAMPS. Cx36 phosphorylation level was evaluated by immunohistochemistry using antibodies for phospho-Cx36 and pan-Cx36. Dopamine and adenosine receptors were localized in retina by in situ hybridization.

Dark-adaptation, in the daytime and at night, increased Cx36 phosphorylation in photoreceptor gap junctions, while light-adaptation decreased phosphorylation. This predicts low photoreceptor coupling in light and enhanced coupling upon dark adaptation, as is observed with other species. Inhibiting D4 receptor activity elevated Cx36 phosphorylation in the light-adapted retina, and this increase was blocked by a PKA antagonist, suggesting that dopamine suppresses coupling by downregulating PKA activity. Activating D4 in dark-adapted retina diminished Cx36 phosphorylation, which was restored by a PKA agonist, in agreement with the previous conclusion. A broad-specificity adenosine receptor agonist CGS21680 increased Cx36 phosphorylation in light-adapted retina. This increase, as well as the increase in Cx36 phosphorylation caused by dark adaptation, were prevented in A1-/- mice. In contrast, in A2a-/- mice, Cx36 phosphorylation was abnormally high in light-adapted retina, but CGS21680 application further enhanced phosphorylation. In situ hybridization experiments showed that both A1 and A2a mRNA were present in inner retinal neurons, but little if any signal was present in photoreceptors. We conclude that adenosine receptors play a role in regulating photoreceptor coupling, but that their actions are at least partially indirect, resulting from regulation of dopamine secretion in the inner retina.

382

Increase of Gap Junction Coupling in Aortic Vascular Smooth Muscle and Endothelial Cells by Dipyridamole.

D. Begandt[1], A. Bader[1], L. Dreyer[1,2], A. Ngezahayo[1,3]; [1]Institute of Biophysics, Leibniz University Hannover, Hannover, Germany, [2]Institute for Multiphase Processes, Leibniz University Hannover, Hannover, Germany, [3]Center for Systems Neuroscience, School of Veterinary Medicine Hannover, Hannover, Germany

Dipyridamole is used in the prevention of primary and secondary stroke as well as for transient ischemic attack. We applied the scrape loading/dye transfer technique on the bovine aortic endothelial cell line GM-7373 and the rat aortic smooth muscle cell line A-10 to analyze whether dipyridamole affects the gap junction coupling of vascular cells. For cells cultivated under control conditions, a Lucifer Yellow diffusion distance of 93 pixels and 81 pixels was found for GM-7373 endothelial cells and A-10 smooth muscle cells, respectively. Presence of 1, 5, 10, 25, 50, 75 and 100 µM dipyridamole for 24 h increased the relative diffusion distance up to 127%, 130%, 137%, 153%, 160%, 173% and 146% in endothelial cells and up to 105%, 117%, 131%, 139%, 161%, 168% and 181% in smooth muscle cells. A significant dipyridamole induced increase of gap junction coupling could be observed after an incubation time of at least 3 h in both cell lines. Within an incubation time of 24 h, the effect of dipyridamole on gap junction coupling increased in both cell types. In order to determine the intracellular mediators of the dipyridamole related effect on gap junction coupling, protein kinase A (PKA) inhibitors like Rp-cAMPS or adenylyl cyclase and PKA activators like forskolin and 8-Br-cAMP were used. We found that presence of 200 µM Rp-cAMPS reduced the dipyridamole evoked increase of the dye diffusion distance. In contrast, activation of adenylyl cyclase or PKA with 100 µM forskolin and 1 mM 8-Br-cAMP, respectively amplified the dye diffusion distance similar to dipyridamole. Accordingly, we propose that dipyridamole increases gap junction coupling by activating a cAMP/PKA dependent mechanism. Whether PKA activates the transcription of connexins, the transport along the ER-Golgi network or modifies the opening state of gap junction channels is under investigation. But preliminary results indicate an effect of dipyridamole on expression of connexin 43 (Cx43) in smooth muscle cells.

383

Multiple binding domains within the ZO-1 scaffolding protein are required for proper junction assembly and function.

L. Rodgers[1], J. Anderson[2], A. Fanning[1]; [1]Cell and Molecular Physiology, UNC-Chapel Hill, Chapel HIll, NC, [2]National Lung, Heart and Blood Institute, NIH

ZO-1 and ZO-2 are cytosolic, multi-domain scaffolding proteins necessary for tight junction (TJ) assembly. They also bind directly to F-actin and numerous cytoskeletal proteins, but the functional relevance of these domains and interactions is poorly understood. In this study we demonstrate that the depletion of both ZO-1 and ZO-2 in Madin-Darby Canine Kidney (MDCK) cells with shRNA constructs leads to three distinct phenotypes: mis-localization of TJ proteins, an increase in paracellular permeability and a dramatic expansion of the contractile array of actomyosin filaments within the Zonula Adherens (ZA). This latter observation suggests the novel hypothesis that assembly and contractility of the ZA is negatively regulated by tight junction ZO proteins. To better understand the synergistic relationship between the tight junction and zonula adherens, we have expressed ZO-1 rescue transgenes in the dKD cells to identify the protein-binding domains that are required for normal TJ and/or ZA assembly. We find that expression of the N-terminal half of ZO-1 protein is sufficient to rescue both TJ and ZA phenotypes observed in the ZO dKD MDCK cells, indicating that direct binding of F-actin to ZO-1 is not required for either TJ or ZA cytoskeletal organization. The PDZ1, PDZ2, SH3 and U6

domains are all required for normal TJ assembly, whereas only the PDZ1 and SH3 domains are necessary for proper ZA assembly. Interestingly, we found that the PDZ3 and GUK domains were not required for the assembly of either junction complex. Based on our results, we conclude that the assembly of a fully functional TJ is dependent on the coordinated interaction of multiple proteins with the N-terminus of ZO-1, and that a smaller subset of these domains also regulates the assembly of the ZA cytoskeleton.

384

Postranslational modifications regulate the subcellular localization of the tight junction protein ZO-2.

M. Quirós[1], L. Alarcon[1], A. Ponce[1], L. Gonzalez-Mariscal[1]; [1]Physiology Biophysic and Neuroscience, Center for Research and Advanced Studies (Cinvestav), México City, Mexico

ZO-2 protein has a dual localization: the tight junction and the nucleus. Here we asked if in confluent cultures ZO-2 travels directly to the plasma membrane and if the putative nuclear localization signals (NLS) present in the sequence of the protein are functional. Employing permeable peptides, one that functions as nPKCε activator (ψεRACK) and other as inhibitor (εV1-2), we show that in sparse cultures the nuclei are respectively devoid or full of ZO-2, confirming the previous observation that nuclear exportation is regulated by nPKCε phosphorylation of nuclear export signal 1. In contrast, treatment of confluent MDCK monolayers with the nPKCå inhibitor does not trigger the accumulation of ZO-2 at the nucleus, suggesting that in confluent cultures the protein is not travelling to the nucleus before reaching the plasma membrane. To test the functionality of the bipartite (bp) NLSs of ZO-2 we microinjected the cytoplasm of sparse cultures with peptides homologous to NLSs chemically coupled to the reporter protein ovalbumin. We observe that while bpNLS1 accumulates ovalbumin at the nucleus, bpNLS2 does not. In silico analysis reveals that S257, S259 and S261 present within bpNLS2 are putative PKC phosphorylation sites, whereas S257 is also a O-GlcNAc target. We demonstrate that nuclear ZO-2 and the amino segment of the protein that contains the NLSs are O-GlcNAc, and show that inhibition of O-GlcNAc glycosidase with PUGNAc diminishes the cellular amount of ZO-2 through a process sensitive to proteosome inhibition. These results suggest that the function of bpNLS2 might be regulated by phosphorylation or O-GlcNAc and that the latter postranslational modification promotes the degradation of the protein at the proteosome.

Tubulobulbar Complexes in Primary Cultures of Rat Sertoli Cells Contain Intercellular Junction Molecules.

M. Du[1], C. Roskelley[1], W. Deng[2], B. Finlay[2], P. Nicholls[3], P. Stanton[3], W. Vogl[1]; [1]Cellular and Physiological Sciences, Univ British Columbia, Vancouver, BC, Canada, [2]Univ British Columbia, Vancouver, BC, Canada, 3Prince Henry's Institute, Clayton, Australia

During spermatogenesis, the regulated turnover of intercellular junctions is crucial for the translocation of spermatocytes from basal to adluminal compartments of the seminiferous epithelium. Tubulobulbar complexes (TBCs) are unique subcellular structures that develop in association with basal junction complexes between Sertoli cells and have been proposed to facilitate junction turnover. We hypothesize that TBCs internalize components of the basal junction complexes, including tight, gap and adhesion junction elements. To test this hypothesis, we have established a primary Sertoli cell culture system in which TBCs or TBC-like structures form in the vicinity of junction complexes between Sertoli cells. Using this culture system, "rod-like" structures that are immunopositive for the intercellular junction elements Claudin-11, Connexin-43 and Nectin-2 occur that extend into Sertoli cells from the cell periphery. These

structures resemble TBCs that form in the intact seminiferous epithelium. These structures also co-localize with F-actin, which is known to associate with the proximal tubular part of TBCs and can be used as a marker for TBCs. Significantly, similar structures in cultured Sertoli cells that express GFP-tagged Claudin-11 and Connexin-43 extend into neighboring non-transfected Sertoli cells. Our results are consistent both with the conclusion that junction elements from neighboring Sertoli cells are found together within TBCs, and with the hypothesis that tubulobulbar complexes may play a role in the turnover of intercellular junctions. Supported by an NSERC Discovery Grant to AWV.

DUSP23 controls the maturation state of cell-cell adhesions by regulating the phosphorylation-dependent dissociation of α-catenin and β-catenin.

L. L. Gallegos[1], M. Sowa[1], J. W. Harper[1], J. S. Brugge[1]; [1]Cell Biology, Harvard Medical School, Boston, MA,

Cadherin-mediated cell-cell adhesion is dynamically regulated by interactions between cadherin-associated proteins β-catenin and α-catenin. These interactions couple E-cadherin to the actomyosin tension-sensing machinery, permitting strengthening and maturation of cell-cell junctions in response to force. A previous screen for genes that affect collective migration in MCF10A cells revealed that knockdown of the 17 kDa dual-specific phosphatase, DUSP23, results in loss of cell-cell adhesion as the cells migrate to fill a scratch wound. In follow-up studies to determine the interaction networks of proteins that regulate cell-cell adhesion using IP/mass spectrometry, we determined that DUSP23 interacts with the cadherin/catenin complex. Furthermore, knockdown of DUSP23 enhances phosphorylation of β-catenin at Tyr 142, and decreases the interaction between α-catenin and β-catenin. Consistent with our observation, biochemical and structural studies from other groups have previously demonstrated that phosphorylation of β-catenin at Tyr 142 disrupts the interaction between α-catenin and β-catenin. Analysis of cell-cell junctions in MCF10A cells depleted of DUSP23 compared to control cells reveals that a significantly higher percentage of DUSP23-depleted cells fail to mature their cell-cell adhesions into linear junctions and instead they remain as immature, zipper-like junctions. Thus, we have revealed a role for the smallest known phosphatase, DUSP23, in regulating the maturation of cell-cell adhesions through modulating the interaction between α-catenin and β-catenin. Studies are ongoing to determine how DUSP23 targets specifically to the adhesion complex, and also to investigate whether the weakening of cell-cell adhesion through loss of DUSP23-dependent regulation of the interaction between α-catenin and β-catenin contributes to invasive activity in 3D culture models and in vivo. Furthermore, we plan to use additional mass spectrometric studies to determine whether other proteins in the DUSP23 interaction network, including EGFR, are DUSP23 substrates.

387

Role of the cytoskeletal protein alphaT-catenin in the heart.

J. van Hengel[1,2], J. Li[3], S. Goossens[1,2], E. Gao[3], L. Cheng[3], K. Tyberghein[1,2], X. Shang[3], R. De Rycke[1,2], F. van Roy[1,2], G. Radice[3]; [1]Department of Molecular Biomedical Research, VIB, Ghent, Belgium, [2]Department of Biomedical Molecular Biology, University Ghent, Ghent, Belgium, [3]Department of Medicine, Center for Translational Medicine, Thomas Jefferson University

Members of the cadherin family of cell adhesion molecules are located in the adherens junction. They interact homophilically to mediate strong cell-cell adhesion and play a key role in the maintenance of tissue structure. AlphaT-catenin is a newly identified cadherin-associated protein that mediates linkage of the cadherin–catenin complex to the actin cytoskeleton. In the

mammalian heart, mixed-type junctional structures (*areae compositae)* are present at the intercalated discs (ICD). We observed alphaT-catenin localized in this novel type of junction, where it associates with endogenous plakophilin-2. To investigate the function of alphaT-catenin in the heart, a murine loss-of-function model was generated.
AlphaT-catenin-null mice are viable but exhibit progressive cardiomyopathy. It has been reported that suppression of PKP-2 activity in cultured cardiomyocytes leads to reduction in Cx43, which affects gap junctional communication. We observed reduced expression of PKP-2 in the ICD of alphaT-catenin-null myocardium. Furthermore, Cx43 was reduced at the ICD, and its co-localization with N-cadherin was also reduced. This indicates that alphaT-catenin might act synergistically with desmosomal PKP-2 to stabilize gap junctions at the *area composita*. This gap junction remodeling was associated with an increase in the incidence of ventricular arrhythmias in alphaT-catenin knockout mice subjected to acute ischemia.
The human alphaT-catenin gene, *CTNNA3*, has been mapped to chromosome 10q21, a region linked to autosomal-dominant dilated cardiomyopathy (DCM). Though genetic screening has not detected an association between *CTNNA3* mutations and DCM to date, *CTNNA3* is considered a candidate cause of this disease.

388

Rac1 Promotes Formation of VE-cadherin Adhesion via IQGAP1-Dependent Mechanism.

N. Daneshjou[1], S. Vogel[1], Y. Komarova[1], A. Malik[1]; [1]Pharmacology, University of Illinois College of Medicine, Chicago, IL

The endothelium lining the blood vessel wall forms a semi-permeable barrier that separates plasma proteins and cells from underlying tissue. Dysfunction of endothelial barrier leads to permeability increase accompanied by protein-rich edema as well as infiltration of blood cells into the interstitial space. The monomeric RhoA-GTPases Rac1, Cdc42, and RhoA play a critical role in regulating endothelial barrier function. Stable Vascular Endothelium (VE)-cadherin homophilic interaction, the main adhesive complex of adherens junction (AJ), causes an increase in the activity of Rac1 and Cdc42, whereas activation of RhoA leads to destabilization of AJs. The purpose of this study was to determine the causal relationship between Rac1 activity at AJs and stability of VE-cadherin mediated adhesion. We utilized a photo-activatable Rac1 probe (mCherry-PA-Rac1), consisting of a constitutively active Rac1 (V12) mutant fused to a photo-activatable LOV (Light Oxygen Voltage) domain of phototropin1 from *Avena Sativa*, as a tool to activate Rac1 locally. We demonstrated that photo-activation of PA-Rac1, but not a light insensitive probe bearing a mutation in the LOV domain (PA-Rac1-C450A), induced VE-cadherin clustering with a rate constant of 0.258 min^{-1} in human dermal microvascular endothelial cells. Interestingly, photo-activation of PA-Rac1 also resulted in junctional accumulation of IQGAP1, a scaffold protein that sequesters GTP-Rac1 and prevents GTP hydrolysis, suggesting that these two events might occur in concert. Furthermore, down regulation of IQGAP1 using the siRNA technique completely inhibited clustering of VE-cadherin upon PA-Rac1 photo-activation although IQGAP1-depleted cells displayed an overall increase in Rac1 activity as demonstrated by Rac1 activation assay. These findings suggest that clustering of VE-cadherin at AJs requires spatial activity of Rac1 and that Rac1 regulates the integrity of VE-cadherin adhesion in an IQGAP1-dependent manner.

Effects of Fluid Shear on Myocytes Expressing ARVC-Causing Mutant Plakoglobin.

V. Hariharan[1], A. Asimaki[2], J. Saffitz[2], H. Huang[1]; [1]Columbia University, New York, NY, [2]Beth Israel Deaconess Medical Center

Introduction: Arrhythmogenic right ventricular cardiomyopathy (ARVC) is typically an autosomal dominant disease characterized by a particularly high incidence of lethal ventricular arrhythmias. Several molecular mechanisms have been proposed for the progressive degeneration of myocardium associated with ARVC. For example, nuclear translocation of plakoglobin (JUP), a structural homologue of ß-catenin, may suppress the canonical Wnt / TCF-Lef pathway, resulting in cell apoptosis. In contrast, the effects of mechanical shear, a force likely experienced by collagen-coupled myocardial sheets in vivo, remains largely unexplored.
Objective: To investigate the effects of steady and oscillatory fluid shear on neonatal rat ventricular myocytes that express ARVC-causing mutant JUP.
Methods: Neonatal rat ventricular myocytes were isolated following established protocol, and cultured on collagen-coated glass slides. Adenoviral infection was used to generate ARVC-expressing cell models, with either wild-type (WT) or mutant plakoglobin (JUP). Cells were sheared under steady and oscillatory flow in a parallel-plate shear chamber at 0.06 Pascal (Pa), and immunostained for JUP or N-cadherin (N-Cad) using established protocol. Samples were imaged on an Olympus IX-81 confocal microscope, and analyzed using quantitative confocal microscopy. Immunoblotting was performed on cardiac myocyte lysates separated by PAGE.
Results & Conclusions: Cardiac cells were responsive to fluid shear stress. Control (no infection) and wild-type (WT) infected cardiac myocytes exhibited junctional reinforcement (i.e. – an increase in the expression level of proteins at cell-cell junctions) of both JUP and PC in response to both steady and oscillatory fluid shear, in addition to ERK 1/2 upregulation. These results are consistent with those previously established using mechanical stretch and demonstrate that fluid shear is a potent mechanostimuli that cardiac cells respond to. We next used mutant JUP to assess whether induction of ARVC-mutant JUP affects mechanoresponse of these cells to fluid shear. In contrast to WT, cells expressing ARVC-causing mutant JUP showed a diminished or totally inhibited ability for junctional remodeling. However, ERK1/2 activation remained unaffected, suggesting that some mechanically-sensitive pathways are not dependent on JUP. Unable to reinforce cell-cell junctions, we hypothesize that myocytes expressing mutant plakoglobin may be more susceptible to alterations in cell-cell interactions when exposed to shear forces, but that not all mechanosensitive pathways are affected in ARVC.

Glycobiology

Micromembrane interactions of Galectin-3.

T. Straube[1], T. von Mach[1], C. Greb[1], W. Ockenga[2], R. Jacob[2]; [1]Cytobiology and Cytopathology, Philipps University of Marburg, Marburg, Germany, [2]Philipps University of Marburg

The β-galactoside-binding lectin galectin-3 is involved in a variety of cellular processes including tumor development, immune-regulation or targeted protein sorting to the apical membrane of polarized epithelial cells. Here, we focused on the membrane interaction of galectin-3 and first employed giant plasma membrane vesicles (GPMVs) from Madine Darby canine kidney (MDCK) cells and large unilamellar vesicles (LUVs). Recombinant galectin-3 binds to GPMVs

and accumulates in liquid disordered domains in a cholesterol-dependent manner. The lectin also interacts with LUVs containing lactosylceramide and cholesterol, which suggests that even in the absence of any glycoprotein galectin-3 binds to lipid domains. In vivo, total internal reflection fluorescence microscopy (TIRFM) depicts galectin-3 binding with caveolin- or flotillin-enriched domains at the apical plasma membrane. This transient interaction with liquid ordered membrane domains is pH-dependent and involves sugar binding, which indicates that the binding of galectin-3 to membrane domains is modulated in living cells. Further studies on galectin-3-glycoprotein binding or oligomerization into cross-linking complexes with multivalent carbohydrates revealed that the environmental pH especially influences lectin-oligomerization with a maximum at pH 6.5. To conclude, interaction of galectin-3 with membrane domains of artificially generated vesicles or with the apical plasma membrane depends on membrane composition and pH.

391

Polymorphic Salivary PNA-Binding Proteins.

R. D. Simmons[1], A. A-T. Williams[1], O. A. Vanderpuye[1], S. O. Oladimeji[2]; [1]Forensic Science, Albany State University, Albany, GA, [2]Biochemistry, Lagos State University, Lagos, Nigeria

Polymorphisms were characterized in salivary glycoproteins binding to the galactose-binding lectin peanut agglutinin. Little knowledge exists on buccal cell glycoproteins and both buccal cell and salivary fluid glycoproteins may be studied as disease biomarkers. PNA reactivity of buccal proteins, cells and salivary fluid was examined by SDS gel electrophoresis and lectin blotting, microtiter plate binding assay and fluorescence microscopy of buccal cells.

In 53 native salivary fluid samples, 84.9% contained an approximately 150,000 Dalton PNA-reactive protein and 15.1% did not. This 150,000 Dalton protein had slightly different electrophoretic mobilities in different samples, being close to 150,000 Daltons in some, greater than 150,000 Daltons or less than 150,000 Daltons in others and sometimes consisted of two closely spaced bands. This protein had different staining intensities in different saliva samples.

Before neuraminidase treatment, only 3 out of 8 salivary fluid samples tested had 150,000 Dalton PNA-binding proteins. After neuraminidase treatment, 7 out of the same 8 samples had PNA-binding proteins and staining of previously reactive samples was increased. No shift in electrophoretic mobility was observed for the 150,000 Dalton protein in reducing conditions versus non-reducing conditions. Microtiter plate assays showed that PNA bound to both buccal cells and salivary fluid. Fluorescence microscopy confirmed that all buccal cells tested bound PNA to their surfaces. It was concluded that buccal cells and salivary fluid contain 150,000 Daltons glycoproteins that vary in amounts of terminal galactose and molecular mass among individuals. These proteins may be further examined for use as biomarkers.

392

Metabolic changes in sialic acid synthesis pathway in DMRV/hIBM model mice with long-term sialic acid treatment.

S. Noguchi[1], M. Malicadan[1], I. Nishino[1]; [1]Natl Inst Neurosci- NCNP, Tokyo, Japan

Distal myopathy with rimmed vacuoles or hereditary inclusion body myopathy (DMRV/hIBM) is an autosomal recessive disorder characterized by muscle atrophy, weakness that initially involves the distal muscles, and presence of accumulated proteins and rimmed vacuoles in myofibers. DMRV/hIBM is secondary to mutations in the *GN*E gene, which encodes an essential enzyme in sialic acid biosynthesis. We recently showed that muscle atrophy and weakness were completely prevented in the DMRV/hIBM mouse after treatment with sialic acid (NeuAc and sialyllactose) and its precursor (ManNAc). In a recent report of neonatal suckling rats, the endogeneous sialic acid synthesis in colon is either inactivated or activated depending on milk

sialic acid level. This finding implies that long-term treatment of DMRV/hIBM patients with sialic acid may affect sialic acid biosynthetic pathway.

In this study, we first analysed the expression of genes encoding the enzymes and transporter in sialic acid biosynthesis pathway in various organs of non-treated wild mouse. The genes involved in synthesis are highly expressed in liver, while those involved in degradation are high in kidney, suggesting that liver is an anabolic organ and kidney is a catabolic organ for sialic acid synthesis. We then examined the expression of genes in skeletal muscle, liver and kidney of DMRV/hIBM mouse after long-term treatment with NeuAc and sialyllactose or ManNAc for more than 300 days and found that the genes for catabolic enzymes were further up-regulated in kidney, while the genes for anabolic enzymes were down-regulated in skeletal muscle. These results suggest that the long-term sialic acid administration may variably influence the effect of treatment depending on the type of compounds administered. We will also discuss the effects of inhibiting catabolic enzymes on sialic acid synthesis in DMRV/hIBM cells.

393

Peracetylated N-acetylmannosamine, a synthetic sugar molecule, unravels important biomarkers in a mouse model of sialic acid deficient myopathy.

M. C. Malicdan[1,2], S. Noguchi[2], T. Tokutomi[3], Y. K. Hayashi[4], Y-I. Goto[5], I. Nishino[4];
[1]NIH/NHGRI, Bethesda, MD, [2]Department of Neuromuscular Research, National Institute of Neuroscience, Kodaira-shi, Japan, [3]Department of Pathology and Laboratory Medicine, National Defense Medical College, Japan, [4]National Institute of Neuroscience, Japan, [5]Department of Mental Retardation and Birth Defect Research, National Institute of Neuroscience, Japan

Distal myopathy with rimmed vacuoles or hereditary inclusion body myopathy (DMRV/hIBM), characterized by progressive muscle atrophy, weakness and degeneration, is due to mutations in GNE, a gene encoding a bifunctional enzyme critical in sialic acid biosynthesis. In the DMRV/hIBM mouse model, which exhibited hyposialylation in various tissue in addition to muscle atrophy, weakness, and degeneration, we recently have demonstrated that the myopathic phenotype was prevented by oral administration of N-acetylneuraminic acid, N-acetylmannosamine and sialyllactose, underscoring the crucial role of hyposialylation in disease pathomechanism. The choice for the preferred molecule, however, was limited probably by the complex pharmacokinetics of sialic acids, and the lack of biomarkers which could clearly show dose-response. To address these issues, we screened several synthetic sugar compounds that could increase sialylation more remarkably and allow demonstration of measurable effects in the DMRV/hIBM mice. In this study, we found that tetra-O-acetylated ManNAc (Ac4ManNAc) increased cell sialylation most efficiently, and in vivo evaluation in DMRV/hIBM mice revealed more dramatic, measurable effect and improvement in muscle phenotype, enabling us to establish analysis of protein biomarkers that can be used for assessing response to treatment. Our results provide a proof of concept in sialic acid-related molecular therapy with synthetic monosaccharides.

394

The bile acid Deoxycholic acid impairs N-linked glycosylation and fucosylation processes in oesophageal epithelial cells.

A-M. Byrne[1], R. Sharma[1], D. Kelleher[1], A. Long[1]; [1]Trinity College Dublin, Dublin, Ireland

It is generally accepted that oesophageal adenocarcinoma arises from a Barrett's metaplastic lesion. Deoxycholic acid (DCA) is a bile acid present in gastric refluxate that alters many cell signalling pathways implicated in oesophageal cancer progression. Altered glycoprotein expression has been demonstrated in tissue from patients with Barrett's oesophagus and oesophageal cancer but the mechanisms regarding such changes are unknown. We had

previously demonstrated DCA-induction of Golgi fragmentation in the HCT116 colonic cell line, therefore we hypothesised DCA could induce Golgi fragmentation in oesophageal cells and impair protein processing, glycosylation and secretion.
We have demonstrated that DCA disrupts Golgi structure and affects protein secretion and glycosylation processes in cell lines derived from normal squamous epithelium (HET1-A) and Barrett's metaplastic epithelium (QH or CP-A). Protein secretion was monitored using a Gaussia Luciferase contruct. Cell surface expression of glycans were identified using carbohydrate-specific probes (WGA, ConA, PNA and UEA) that monitored N-glycosylation, O-glycosylation and core fucosylation in resting and DCA-treated cells. DCA caused a reduction in cell surface expression of (GlcNAc)n,Galß4GlcNAcß6Gal (WGA), GlcNAcßMana6(GlcNAcß2Mana3) Manß4GlcNAc (ConA) and Fuca2Galß4GLcNAcß6r (UEA-1) and altered subcellular localisation of (GlcNAc)n,Galß4GlcNAcß6Gal and GlcNAcßMana6(GlcNAcß2Mana3)Manß4GlcNAc in both cell lines. Furthermore, DCA reduced the expression and cellular localisation of E-cadherin in a manner analogous to treatment of cells with the N-glycan biosynthesis inhibitor tunicamycin. This is the first study to identify an altered Golgi structure and glycomic profile in response to DCA in oesophageal epithelial cells, a process which could potentially contribute to metaplasia, dysplasia and cancer of the oesophagus.

395

Cell surface Calreticulin is a possible ligand for rArtinM on the mast cell surface.

V. C. Barbosa-Lorenzi[1], M. C. Roque-Barreira[1], M. C. Jamur[1], C. Oliver[1]; [1]Biologia Celular e Molecular e Bioagentes Patogênicos, FMRP-USP, Ribeirão Preto, Brazil

Mast cells are essential cells in IgE-associated immune responses. FcεRI crosslinking induces mast cell degranulation and release of mediators. We have previously shown that the lectin ArtinM induces mast cell activation but the mechanisms involved in this activity remain unknown. The aim of this work is to identify the ArtinM ligands present on the mast cell surface and to evaluate the role of these ligands in mast cell activation. For these studies, the rat mast cell line RBL-2H3 and recombinant rArtinM (rArtinM, a monomer) were used. The ability of rArtinM to induce mast cell degranulation was assessed by measuring β-hexosaminidase activity liberation. It was observed that in the presence of IgE, rArtinM was able to induce mast cell degranulation. To identify possible cell surface rArtinM ligands binding assays were performed using plasma membrane enriched cell lysate. This enriched lysate was incubated with biotinylated rArtinM and its ligands were precipitated using agarose-streptavidin. SDS-PAGE analysis revealed a few protein bands, which were extracted from the gel and digested by trypsin. The peptide sequences from these proteins were determined by MS/MS. Sequencing analysis revealed one specific rArtinM-associated protein, cell surface calreticulin (csCRT). It has been shown that csCRT is an important innate immune receptor that serves as a signal transduction receptor for mannose binding lectins. The interaction between csCRT and rArtinM was confirmed by Western Blot and the localization of csCRT was confirmed by immunofluorescence assays. These results demonstrate the presence of csCRT on the mast cell surface and also suggest that rArtinM binds specifically to csCRT. Such an interaction between ArtinM and csCRT may be important in mast cell immune responses and could explain the effects of ArtinM on mast cells.

Vesicle Docking and Fusion

Rab6, Rab8, and MICAL3 cooperate in controlling docking and fusion of exocytotic carriers.

K-L. Yu[1,2], I. Grigoriev[1], E. Martinez-Sanchez[3], A. Serra-Marques[1], J. PerÃ¤nen[4], R-J. Pasterkamp[5], P. van der Sluijs[3], C-C. Hoogenraad[1], A. Akhmanova[1]; [1]Cell Biology, Faculty of Science, Utrecht University, Utrecht, Netherlands, [2]Department of Cell Biology, Erasmus Medical Center, Rotterdam, Netherlands, [3]Department of Cell Biology, University Medical Center Utrecht, Utrecht, Netherlands, [4]Institute of Biotechnology, University of Helsinki, Finland, [5]Department of Neuroscience and Pharmacology, Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, Utrecht, Netherlands

Constitutive exocytosis delivers newly synthesized proteins and lipids from the Golgi apparatus to the cell surface. This process is mediated by vesicles, which bud off from the Golgi apparatus, move along cytoskeletal filaments and fuse with the plasma membrane. We use live cell imaging of individual vesicles with a high spatiotemporal resolution in combination with fluorescence recovery after photobleaching (FRAP) and photoactivation approaches to investigate the involvement of Rab GTPases and their effectors in fusion of secretory vesicles with the plasma membrane. We find that transport and fusion of secretory carriers is controlled by two Rab GTPases, Rab6 and Rab8. Rab6 is a conserved small GTPase that localizes to the Golgi apparatus and cytoplasmic vesicles and controls transport and fusion of secretory carriers. Rab8 is another Rab implicated in trafficking from the trans-Golgi to the plasma membrane. Both Rabs stably associate with exocytotic vesicles but their functions are different: Rab6 regulates vesicle transport and Rab8 recruitment, while, in turn, Rab8 is required for vesicle docking and fusion. We show that Rab8A stably associates with exocytotic vesicles in a Rab6-dependent manner. Rab8A function is not needed for budding or motility of exocytotic carriers but is required for their docking and fusion. These processes also depend on the Rab6-interacting cortical factor ELKS, suggesting that Rab8A and ELKS act in the same pathway. Rab8A and ELKS can be linked by the Rab8 effector, MICAL3, a member of the MICAL family of flavoprotein monooxygenases. Expression of a MICAL3 mutant with an inactive monooxygenase domain resulted in a strong accumulation of secretory vesicles that were docked at the cell cortex but failed to fuse with the plasma membrane, an effect that correlated with the strongly reduced mobility of MICAL3. FRAP-based analysis of protein turnover suggested that the redox activity of MICAL3 is needed to regulate its own turnover and the concomitant remodelling of vesicle-docking protein complexes in which it is engaged. Taken together, our study illustrates the cooperation of two Rab proteins in constitutive exocytosis and implicates a redox enzyme in this process.

397

Mechanisms Controlling the Motility and Fusion of Rab6-positive Exocytotic Carriers.

A. Serra-Marques[1], I. Grigoriev[1], D. E. Gordon[2], A. A. Peden[2], A. Akhmanova[1]; [1]Cell Biology, Faculty of Science, Utrecht University, Utrecht, Netherlands, [2]Clinical Biochemistry, Cambridge Institute for Medical Research, University of Cambridge, United Kingdom

Constitutive exocytosis is an essential cellular process responsible for transport of newly synthesized proteins and other cellular components to the plasma membrane. It is mediated by Golgi-derived vesicles, which move along cytoskeletal filaments and fuse with the plasma membrane. We have previously shown that the small GTPase Rab6 marks the carriers of constitutive secretion, regulating their transport and fusion with the plasma membrane. The

Kinesin-1 Kif5B was shown to stimulate processive transport of Rab6-positive vesicles. Now we show that the kinesin-3 family members Kif1B and Kif1C also play a role in this process, and that in the absence of these kinesins, cytoplasmic dynein assumes a more prominent role, driving faster movements.
Vesicular carriers utilize a complex network of factors, which promote their specific interactions and fusion with the target membranes. Among these factors, a family of proteins called soluble N-ethylmaleimide-sensitive factor (NSF) adaptor proteins receptors (SNAREs) are considered essential. There are three groups of SNAREs: VAMPs, SNAP-25 homologues, and syntaxins; each of the groups contains several mammalian homologues involved in fusion steps between different compartments. Previous studies in our laboratory have shown that the coiled coil protein ELKS/Rab6IP2, which resides in cortical patches localized at the leading edges of migrating cells, promotes docking and fusion of Rab6 vesicles. Interestingly, in the absence of Rab6, the fusion of secretion carriers is accelerated but is much less selective with respect to cell location. This suggests that ELKS/Rab6IP2 and Rab6 cooperate in some specific way with the protein fusion machinery and are likely to interact, directly or indirectly, with SNARE proteins. We are now testing the involvement of specific SNAREs in the fusion of Rab6-positive vesicles, and we have found that specific members of the VAMP (v-SNARE), and SNAP (t-SNARE) families are necessary for fusion of exocytotic carriers.

Munc18b is Essential for Regulated Mucin Secretion in Lung Epithelium.

L. Piccotti[1], Z. Azzegagh[1], P. Bathina[1], T. Michael[1], B. Dickey[1]; [1]Pulmonary Medicine, Md Anderson Cancer Center, Houston, TX

A tight homeostasis of mucus secretion in respiratory airways is fundamental to ensure the protection against inhaled pathogens and particulates and at the same time avoid airway diseases due to hypersecretion.
The molecular mechanism of regulated mucin secretion in lung epithelium is not yet completely understood. In eukaryotic cells Sec/Munc18 proteins are essential for regulated exocytosis; we thus utilized a genetic strategy to investigate in lung epithelium the role of Munc18b, the only isoform expressed at the apical membrane of airway mucous cells. We first generated constitutive and conditional mouse lines null for Munc18b (loss-of-function, LOF) and transgenic mice overexpressing a gain-of-function (GOF) Munc18b; we then measured airway epithelial mucin content by histochemical (Periodic Acid Fluorescent Schiff staining - PAFS) and biochemical (vacuum blot) techniques. We tested spontaneous mucin accumulation (basal secretory defect) in the naïve mice or ATP-induced degranulation (stimulated secretory defect) in mice sensitized and aerosol-challenged with ovalbumin to induce strong mucin production (metaplasia).
Since homozygous Munc18b null mice die at E9.5, we first studied heterozygous mice, detecting a 50% reduction in stimulated mucin secretion, but no mucin accumulation in naïve mice. In order to establish the role of Munc18b in basal secretion, we crossed the conditional allele to CCSP-Cre to delete Munc18b in airway mucous cells. Conditional Munc18b null mice displayed spontaneous mucin accumulation suggesting that Munc18b is essential for basal secretion. This conclusion is supported by the ability of GOF mice to fast resolve metaplasia by basal secretion. Together, these data indicate that Munc18b is a key regulator of mucin secretion in lung epithelium.

399

The Exocyst Subunit Sec6 and the SM Protein Sec1 Act in Concert to Modulate Exocytosis in Yeast.

F. Morgera[1], M. Dubuke[1], M. Sallah[1], P. Gandhi[1], C. Carr[2], M. Munson[1]; [1]Department of Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA, [2]Department of Biochemistry and Biophysics, Texas A&M University, College Station, TX

Trafficking of protein and lipid cargo through the secretory pathway in eukaryotic cells is mediated by membrane-bound vesicles. Secretory vesicle targeting and fusion require the cooperation of multiple protein families. These molecules mediate the recognition step, ensure the fidelity of the process and the subsequent cellular activities, such as proper cell organization, cellular growth and secretion. Membrane fusion is carried out by SNARE complexes, which are formed by SNARE proteins localized on the vesicle and the target membrane. SNARE complex assembly is monitored and regulated by several factors, including the multisubunit tethering complexes and the Sec1/Munc18 family (SM) proteins. Regulation of the yeast secretory pathway relies on critical interactions between the SM protein Sec1, the exocyst complex and SNARE proteins. Our studies show that the exocyst is directly involved in regulating SNARE complexes and membrane fusion through interactions between the Sec6 subunit and the plasma membrane SNARE protein, Sec9. Moreover, we reveal another facet of Sec6 function—it directly binds Sec1, a SNARE regulator of the SM family. The Sec6-Sec1 binding is exclusive of Sec6-Sec9, but compatible with Sec6-exocyst assembly. In contrast, the Sec6-exocyst interaction is incompatible with Sec6-Sec9. Therefore, upon vesicle arrival, Sec6 is proposed to release Sec9 in favor of Sec6-exocyst assembly and to simultaneously recruit Sec1 to sites of secretion for coordinated SNARE complex formation and membrane fusion. Cooperation between the tethering complexes and the SM protein have been shown to be important for proofreading SNARE complexes and/or for SNARE complex formation, suggesting that Sec1-Sec6-exocyst may add further regulation and specificity to the fusion process.

Mechanisms of collective force production by SNAREpin clusters on the pathway to fusion.

B. Stratton[1], J. M. Warner[1], G. Wei[1], H. Chong[1], E. Karatekin[2], B. O'Shaughnessy[1]; [1]Chemical Engineering, Columbia University, New York, NY, [2]Cell Biology, Yale University

SNARE proteins are thought to constitute the core of the intracellular fusion machinery which additionally may involve several accessory proteins (e.g. Sec/Munc proteins, synaptotagmin). Evidence suggests that target- and vesicle-SNAREs engage one another to assemble single SNARE complexes through a zipping mechanism which pulls the anchoring membranes together, while clusters of multiple SNARE complexes are thought to be required to drive fusion [Montecucco et al, Trends in Biochem. Sci., 2005]. In order to isolate SNARE mechanisms in controlled experiments many studies have employed the vesicle-supported bilayer (SBL) assay [Fix et al, Proc. Nat. Acad. Sci., 2004]. Here we present a combination of modeling of basic SNARE mechanisms with image analysis which allows us to quantitatively relate experiment to the model. The model determines the collective force exerted by a cluster of SNARE complexes based on the coarse-grained SNARE structure and the complexation energy previously measured. We propose a cluster drives fusion if it contains enough SNAREs to produce sufficient force above a threshold value, estimated from the threshold forces that drove fusion in protein-free, soft-supported SBL-SBL systems [Wong et al, Biophys. J., 1999]. Hence we determined the number of SNARE complexes required for fusion and find it depends strongly on the vesicle size. The model predicts the SNARE complex requirement for fusion of a 50-nm

vesicle is consistent with the reported requirement of 5-11 complexes [Karatekin et al, Proc. Nat. Acad. Sci., 2010]. We extended the model of the experiments to calculate the opened and closed times of a flickering fusion pore based on the measured lipid flux from the vesicle into the SBL. To test the model, quantitative image analysis of the experiments was required. We developed an image analysis routine which accounts for TIRF effects, polarization, and fluorophore quenching and bleaching which allowed us to precisely measure (i) vesicle size, (ii) fusion times and (iii) lipid flux. We thus measured the dependence of both the fusion times and the subsequent lipid flux on vesicle size and the presence of cholesterol. The model is fit to the lipid flux data to infer that fusion pores in cholesterol-free systems flicker over lipid mixing times of ~10-100 ms, but spend more time closed than open. With cholesterol, lipid mixing was somewhat slower, suggesting that cholesterol favors closed fusion pores.

401

Loss-of-function mutations in SNAP29 result in defects in endocytic recycling and cell motility.

D. Rapaport[1], D. Fuchs-Telem[2,3], E. Sprecher[2,4], M. Horowitz[1]; [1]Cell Research and Immunology, Tel Aviv University, Ramat Aviv, Israel, [2]Dermatology, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel, [3]Sackler Faculty of Medicine, Tel Aviv University, Ramat Aviv, Israel, [4]Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel

Synaptosomal-associated protein SNAP29 is the most ubiquitous target SNARE among the SNAP protein family. Membrane anchored SNAREs assemble into SNARE complexes that bring membranes together to promote fusion. Loss of functional SNAP29 results in the human CEDNIK syndrome (Cerebral Dysgenesis, Neuropathy, Ichthyosis and Keratoderma). Thus far, we identified two mutations among CEDNIK patients: 1. A 1 bp deletion (c. 222delG of the cDNA), found in consanguineous Arab Muslim families from northern Israel, resulting in a premature termination, 75 amino acids downstream the initiator ATG; 2. A 1 bp insertion (c.486insA) found in two sibs from consanguineous parents originating from the Kashmiri region of Pakistan, resulting in a premature termination 5 amino acids downstream the mutation and a truncated protein of approximately 19 kDa.
In SNAP29 deficient cells recycling of transferrin and β1-integrin is impaired. Consequently, impaired β1-integrin recycling affects cell motility as reflected by changes in cell spreading and wound healing. No major changes are detected in exocytosis of VSVG protein from the Golgi apparatus, although the Golgi system acquires a dispersed morphology in SNAP29 deficient cells. Our results emphasize the importance of SNAP29 mediated membrane fusion in endocytic recycling and cell motility.

402

A Novel Role of Syntaxin 3 as a Transcription Regulator.

C. Winterstein[1], B. Pallavi[1], S. Low[1], J. Baggs[3], J. Hogenesch[2], T. Weimbs[2]; [1]University of California Santa Barbara, Santa Barbara, CA, [2]University of Pennsylvania School of Medicine

SNARE proteins mediate membrane fusion events in virtually all cellular membrane trafficking pathways. We have discovered an unexpected, novel function of the SNARE protein syntaxin 3. Syntaxin 3 normally has a C-terminal trans-membrane anchor and is involved in trafficking to the apical plasma membrane domain of polarized epithelial cells. We found that syntaxin 3 undergoes cleavage at an extremely conserved glutamine residue, which removes its trans-membrane domain resulting in a soluble fragment. Furthermore, a novel splice-isoform of syntaxin 3 lacks the trans-membrane anchor, and is expressed in human kidneys. Both, the cleavage fragment and the soluble isoform bind to the nuclear import factor RanBP5, target to the nucleus and co-activate several transcription factors including ETV4. ETV4 is required for

branching morphogenesis in kidney development, and associated with carcinogenesis and tumor metastasis. We found that kidneys from autosomal dominant polycystic kidney disease (ADPKD) patients express a small syntaxin 3 fragment – consistent with soluble syntaxin 3. We hypothesize that cleavage and transcriptional regulation in the nucleus is a novel function and common feature of syntaxin members of SNARE proteins. This may be a novel signaling mechanism that transduces information from cytoplasmic membrane trafficking events to the nucleus to affect changes in gene expression, which introduces a new paradigm of SNARE function.

403

Impaired Transcytosis in Ca^{2+}-depleted Cells Correlates with Decreased Apical Labeling of MAL2 and Syntaxins 2 and 3.

J. O. Omotade[1], A. C. Striz[1], P. L. Tuma[1]; [1]Biology, The Catholic University of America, Washington, DC

Over 15 years ago, transcytosis in MDCK cells was reported to be Ca^{2+}-dependent: thapsigargin enhanced transcytosis while BAPTA impaired it. Furthermore, calmodulin (CaM) antagonists were found to impair the basolateral endosome exit of transcytosing cargo. To date, the Ca^{2+}-dependence of basolateral to apical transcytosis has not been examined in polarized hepatocytes, cells that rely heavily on the transcytotic pathway for the delivery of newly-synthesized apical proteins. We determined that the transcytosis of three classes of newly synthesized apical proteins (GPI-anchored, single spanning and polymeric IgA receptor) was impaired by Ca^{2+} chelation with BAPTA in polarized WIF-B cells. As in MDCK cells, treatment with W7 (CaM antagonist) led to the accumulation of the transcytosing cargo in basolateral endosomes. Because MAL2 regulates transcytosis from the basolateral endosome to the sub-apical compartment, we examined its distributions in Ca^{2+}-depleted cells. After treatment with BAPTA for 1 h, nearly all MAL2 apical labeling was lost. The extent of MAL2 loss from the apical surface markedly coincided with impaired transcytosis. To determine whether diminished apical labeling was specific to MAL2 or was reflecting a general disruption of apical protein retention mechanisms or the disruption of tight junctions, we examined the distributions of a number of apical proteins, basolateral residents and tight junction-associated proteins in BAPTA-treated cells. There were no changes in the distributions of the tight junction markers or basolateral proteins indicating that membrane polarity was maintained in the BAPTA-treated cells. Although most apical proteins examined maintained their steady state apical distributions in Ca^{2+}-depleted cells, the apical labeling of syntaxins 2 and 3 was lost. Because protein levels did not change in BAPTA-treated cells, the decreased MAL2 and synataxins 2 and 3 labeling was not due increased protein degradation, but rather redistribution. Treatment with W7 and KN93 (a CaM kinase II inhibitor) also led to decreased apical labeling of MAL2 and the syntaxins and impaired transcytosis. Together these results suggest that CaM kinase II activation is required for the MAL2-mediated fusion of apically-targeted vesicles with syntaxins 2 and 3. We are actively testing this hypothesis.

405

Otoferlin is a calcium sensor that directly regulates SNARE-mediated membrane fusion.

C. Johnson[1]; [1]Biochemistry, Oregon State University, Corvallis, OR

Otoferlin is a large multi–C2 domain protein proposed to act as a calcium sensor that regulates synaptic vesicle exocytosis in cochlear hair cells. Although mutations in otoferlin have been associated with deafness, its contribution to neurotransmitter release is unresolved. Using recombinant proteins, we demonstrate that the C2 domains of otoferlin sense calcium, and in the presence of membranes, the apparent binding affinities increase by up to sevenfold. Using a

reconstituted membrane fusion assay, we found that five of the six C2 domains of otoferlin stimulate membrane fusion in a calcium-dependent manner. We also demonstrate that a calcium binding–deficient form of the C2C domain is incapable of stimulating membrane fusion, further underscoring the importance of calcium for the protein's function. These results demonstrate for the first time that otoferlin is a calcium sensor that can directly regulate SNARE membrane fusion reactions.

406

Quantitative analysis of syntaxin clusters during insulin granule docking.

N. Gandasi[1], S. Barg[1]; [1]Medical Cell Biology, Uppsala University, Uppsala, Sweden

For insulin to be secreted from pancreatic beta-cells, secretory granules must translocate to and then dock at the plasma membrane. Secretagogues can then trigger exocytosis of these granules, resulting in release of insulin. Only a limited number of granules can dock at any time, suggesting the existence of specialized docking sites where the exocytosis machinery is assembled. This is supported by the finding that SNARE proteins cluster in raft-like nanodomains near docked granules. We have used TIRF imaging and quantitative image analysis to study the association of GFP-labeled syntaxin-1 and L-type Ca^{2+}-channels (CaV1.3) with granules in live Ins1-cells. Both proteins formed small clusters (<100 nm) in the plasma membrane that associated with a subset of the docked granules (~50%). Clusters were stationary over several minutes, but exhibited striking intensity variations with a period of a few seconds. Single-molecule imaging showed that individual molecules of both proteins moved rapidly in the plasma membrane and were occasionally captured beneath a granule, for a short time (<1s). Granules that were associated with a syntaxin cluster were less likely to spontaneously undock, but more likely to undergo exocytosis during stimulation. Syntaxin was recruited to the granule site during docking, and lost during undocking and exocytosis. In summary, granule-associated nanodomains correlate with granule docking and exocytosis. This remarkably dynamic organization is established during or just after granule docking, which may suggest that granules induce the formation of their own docking site. Association of exocytosis-related proteins with granules occurs on a timescale consistent with rapid cellular signaling, and may be important for the short-term regulation of insulin secretion.

Identifying New Sites of Insulin Action in GLUT4 Vesicle Exocytosis.

Y. Xu[1], B. R. Rubin[1,2], C. M. Orme[1,2], A. Karpikov[3], C. Yu[2], J. S. Bogan[1,2], D. K. Toomre[1]; [1]Department of Cell Biology, Yale University School of Medicine, New Haven, CT, [2]Section of Endocrinology and Metabolism, Department of Internal Medicine, Yale University School of Medicine, New Haven, CT, [3]Department of Diagnostic Radiology, Yale University School of Medicine, New Haven, CT

Insulin increases glucose uptake in muscle and adipose tissues, which is accomplished through the mobilization of intracellular GLUT4 storage vesicles (GSVs) to the cell surface. Although insulin has been shown to promote GLUT4 translocation, precisely where insulin acts to control trafficking of GSVs is debated. In this study, by using ultrasensitive total internal reflection fluorescence microscopy (TIRFM) imaging, we quantified the size, dynamics, frequency and spatial localization of single vesicle exocytosis in 3T3-L1 adipocytes. We validated and used VAMP2-pHluorin as a new probe to visualize GSV and studied the spatial distribution of GSV fusion relative to endocytic machinery (clathrin and dynamin). We showed that in unstimulated

TUG shRNA cells, the exocytic rate is similar to that in insulin-stimulated control cells; insulin triggered a transient, two-fold burst of exocytosis in TUG shRNA cells, which was rescued by overexpression of shRNA-resistant TUG. Surprisingly, insulin promoted fusion pore expansion and increased full vesicle fusion, which were blocked by acute perturbation of phospholipase D, reflecting both properties intrinsic to the mobilized vesicles and a novel regulatory site at the fusion pore. Prolonged stimulation caused cargo to switch from 60 nm GSVs to larger exocytic vesicles (~150 nm) characteristic of endosomes, and increased accumulation of GLUT4 and VAMP2 with clathrin patches on the plasma membrane. Dual-color imaging showed that majority of GSVs (~95%) are fuse outside of clathrin and dynamin structures, suggesting a rate limiting endocytic step of regulation by insulin. In summary, our results support a dual brake-accelerator model of GSV translocation, whereby insulin promotes exocytic flux primarily by releasing an intracellular brake (TUG), but also by accelerating plasma membrane fusion and switching vesicle traffic between two distinct circuits. Our data unite the static retention and dynamic equilibrium models, and reveal the fusion pore as a novel site of insulin action, which may be perturbed in type 2 diabetes.

The Potential Roles for PLD-derived Phosphatidic Acid in the Late Stages of Exocytosis.

T. P. Rogasevskaia[1], J. R. Coorssen[2]; [1]Physiology and Pharmacology, University of Calgary, Calgary, AB, Canada, [2]Department of Molecular Physiology, School of Medicine, University of Western Sydney, Campbelltown, Australia

Understanding molecular mechanisms underlying multiple steps of regulated exocytosis has been a major focus for decades. Although essential roles of phospholipases have been excluded from the fusion step per se [1], their upstream and/or modulatory effects have received far less attention. In this regard, phospholipase D (PLD) and its product phosphatidic acid (PA) are of particular interest as the latter may define binding sites for critical proteins. Here, integrating acute treatments [1-6] and selective pharmacological manipulations of sea urchin eggs[7] with quantitative functional/molecular assays [3-7], we have addressed the potential roles for PLD-derived PA in the late stages of exocytosis, including docking and Ca2+triggered fusion. Our data indicate a selective inhibitory effect on the fusion rate when isolated cortical vesicles (CV) are treated with structurally diverse PLD inhibitors, but a consistent inhibitory effect on the extent, Ca2+sensitivity and rate of fusion when these inhibitors are used to treat intact eggs. Docking assays link this inhibition to an alteration in inter-membrane attachment, indicating that a PLD activity may promote CV docking to the plasma membrane (PM). To determine the localization of PLD activity, we labelled sheets of PM with associated docked CV - cell surface complexes (CSC) - and isolated CV with a fluorescent PLD substrate, NBD-PC. High performance thin layer chromatography identified NBD-PA only in the CSC, indicating a PLD activity localized to the inner monolayer of the PM, and presumably closely associated with CV docking sites. This was also consistent with the highest PLD activity being detected on CSC, relative to the intact egg, cytosol or CV membrane when using an alternate assay. Overall, this work with PLD inhibitors indicates upstream roles for PA in docking and/or late priming steps rather than directly in fusion and shed light on the localization of PLD activity with CV docking sites. Alterations in local PA composition may thus modulate fusion, in particular kinetics, through late effects on docking.

Expression of Clusterin decreases with skin dryness and is stimulated by phospholipids.

E. Noblesse[1], M. Juan[1], V. Jeronimo[1], J-H. Cauchard[1], C. Nizard[1], M. Moreau[1], C. Heusèle[1], R. Kurfurst[1], S. Schnebert[1], E. Perrier[1], M. Dumas[1]; [1]LVMH Recherche, St Jean de Braye, France

Clusterin is a 80 kDa glycoprotein widely distributed in mammalian tissues and biological fluids and is implicated in a variety of physiological and pathological processes. It acts as a molecular chaperone to stabilize proteins in a folding competent state and has a role in scavenging extracellular misfolded proteins produced following stress-induced injury. Clusterin gene expression is elevated at sites of tissue remodelling, such as differentiation and apoptosis and has also a role in the clearance of cellular debris and phagocytosis promotion.
Skin dryness is the result of multiparametric disorder implicating the cutaneous barrier, the water transport of and lipidic organization.

Objective

The purpose of this study was, first to demonstrate the effect of cellular debris on gene expression implicated in epidermis differentiation, hydration and inflammation, then characterize the clusterin expression in dry skin versus normal skin and finally modulate this clusterin expression using vesicles containing phosphatidylserin.

Methods

Normal human Keratinocytes (NHK) in culture, were incubated in the presence cellular debris or with vesicular structures (micelles) composed of a mixture of phosphatidyl choline and phosphatidylserine 70% and 30% respectively in weight, during various times. Clusterin expression was quantified by RT-QPCR and western Blot. Gene expression is studied by RT-QPCR.
Tissue clusterin expression is studied on normal skin biopsies issues of patients with clinical normal skin or dry skin. Punch biopsies were performed for further immunohistochemistry analysis. The clusterin immunostaining was performed on cryo-sections with a polyclonal rabbit anti-clusterin antibody, and alexafluor 546 Goat anti-rabbit secondary antibody. The labelled digital pictures obtained by confocal microscopy were quantified by image analysis.

Results

The results of this study highlight a significant effect of the cellular debris on the expression of five genes: a significant decrease of CD44 (hyaluronic acid receptor), filaggrin and aquaporine 9 and a increase in IL1alpha and MMP9 genes. Moreover, immunohistological studies showed that clusterin, which is expressed in the basal layer of the epidermis, is statistically decreased in the dry skin in comparison with the normal skins (- 75.9%).
Cell culture study demonstrated that vesicular structures, are able to stimulate the expression of clusterin at mRNA level (2 times increase at 24h) and protein level (1.8 times increase at 72h).

Conclusion

These results demonstrate that cellular debris are able to modulate genes which are involve in skin differentiation, water homeostasis and inflammation. Moreover, Clusterin expression is significally decreases with dryness and a phospholipids mixture could be used to stimulate its expression to counteract deleterious effects of skin dryness on clusterin and of cellular debris.

410

Cholesterol and low temperature enhance fusion of vesicles to a planar membrane.

D. Woodbury[1], D. Lee[1], M. Lew[1]; [1]Physiology & Develop. Biol, Brigham Young University, Provo, UT

Lipid composition plays an important role in fusion of vesicles to membranes, an essential process for exocytosis. Lipid head group, tail structure, and sterol content all impact the complex phase behavior of membranes. To determine the effect of lipids on fusion rate, we utilized the nystatin/ergosterol fusion assay and stimulated fusion with an osmotic gradient. Using PE/PC planar membranes with increasing concentrations of cholesterol, and keeping vesicle lipids constant (PE/PC/PS/ERG), we observed significantly higher fusion rates. We also observed that lipid phase affects fusion rates by forming DPPC membranes on 5ul glass capillary pipets. Significantly different fusion rates were observed at temperatures above and below the DPPC transition temperature (T_t) of 41°C. Decreasing the temperature below T_t increased the fusion rate. These data are consistent with the hypothesis that vesicle fusion with a membrane is suppressed in a liquid-disordered lipid phase (and/or enhanced by the ripple phase), and suggest cells may have adjusted membrane lipids to reduce membrane fusion.

411

Role for the acto-myosin complex in regulated exocytosis revealed by intravital microscopy.

A. Masedunskas[1], M. Sramkova[1], L. Parente[1], K. Uzzun Sales[1], P. Amornphimoltham[1], T. Bugge[1], R. Weigert[1]; [1]OPCB, NIH/NIDCR, Bethesda, MD

The regulation and the dynamics of membrane trafficking events have been studied primarily in in vitro models that often do not fully reflect the functional complexity found in a living multicellular organism. We have used intravital microscopy in the salivary glands of live rodents to investigate regulated exocytosis, a fundamental process in all the secretory organs. Specifically, we focused on the dynamics and the machinery regulating the fate of large secretory granules (SCGs) after their fusion with the apical plasma membrane (APM). To this aim, we employed a combination of transgenic mice and gene transfection into the SGs of live rats, which enabled us to visualize the SCGs, their limiting membranes, their content and the actin cytoskeleton. We found that after fusion with the plasma membrane, SCGs gradually collapse releasing their content into the lumen of the acinar canaliculi. Furthermrore, we found that after fusion with the APM, F-actin and two of the isoforms of nonmuscle myosin II (IIa and IIb) are recruited onto the SCGs and form a contractile scaffold that is necessary to complete the exocytic process. Our results provide novel information on the machinery controlling regulated secretion and show that intravital microscopy provides unique opportunities to address fundamental questions in cell biology under physiological conditions.

A1 adenosine receptor-mediated modulation of membrane trafficking requires activation of ADAM17 and the subsequent transactivation of EGFR.

H. S. Prakasam[1], G. Apodaca[1]; [1]Medicine, University of Pittsburgh, Pittsburgh, PA

The umbrella cells form the outermost layer of the uroepithelium that lines the renal pelvis, ureters and the urinary bladder. We previously showed that apical addition of adenosine induced apical exocytosis; however, the signaling pathway is not known. Here, we report that specific activation of apically localized A1 adenosine receptors (A1ar) using the agonist CCPA stimulated exocytosis at the apical surface of umbrella cells. The activation of A1ar caused

phosphorylation of epidermal growth factor receptor (EGFR) at tyrosine residue 1173 (Y-1173) and inhibiting EGFR with the small molecule inhibitor AG1478 blocked the exocytosis. The transactivation pathway required HB-EGF as CRM197 an HB-EGF specific inhibitor blocked A1ar-induced exocytosis. A1ar-mediated EGFR- transactivation was also blocked by inhibitors of Gi-proteins, PLC, PKC, MAPK and protein synthesis. Furthermore, by immunolabeling, we show that a disintegrin and a metalloproteinase-17 (ADAM17/ TACE) is richly distributed at the apical domain of umbrella cells and broad-spectrum metalloproteinase inhibitor GM6001 and ADAM17 selective inhibitor Tapi-2 blocked A1AR-mediated vesicular exocytosis. We propose a model whereby activation of Gi-protein coupled A1ar triggers PLC-mediated generation of IP3, which increases intracellular calcium and leads to PKC-mediated activation of ADAM17. Activated ADAM17 in-turn cleaves HB-EGF and triggers EGFR activation leading to MAPK-mediated protein synthesis and exocytosis.

413

Kv2.1 cell surface clusters are insertion and retrieval platforms for ion channel trafficking at the plasma membrane.

E. Deutsch[1], A. Weigel[2], E. Akin[1], P. Fox[1], D. Krapf[2], M. Tamkun[1]; [1]Biomedical Sciences, Colorado State University, Fort Collins, CO, [2]School of Biomedical Engineering, Department of Electrical and Computer Engineering, Colorado State University, Fort Collins, CO

The Kv2.1 delayed rectifier K+ channel regulates electrical activity in nerve and muscle and has been postulated to play a non-conducting role in SNARE-mediated protein fusion in neuroendocrine cells. Kv2.1 is unusual among voltage-gated K+ channels in that it localizes to micron-sized clusters on the cell surface of neurons, atrial myocytes and transfected HEK cells. Within these clusters Kv2.1 is non-conducting. Here we examined the hypothesis that these surface structures are specialized platforms involved in the trafficking of membrane proteins to and from the cell surface. TIRF-based studies indicated that GFP-Kv2.1 containing vesicles directly tether to and deliver cargo in a discrete fashion to the Kv2.1 surface clusters in both transfected HEK and cultured hippocampal neurons. Qdot-based single molecule experiments indicated that the delivery and surface retrieval of Kv2.1 occurs at the perimeter of the surface clusters. Overall, 85±8.4% of newly synthesized channels in HEK cells and 84.9±10.4% in hippocampal neurons were inserted within 0.5 microns of the cluster perimeter even though the Kv2.1 clusters represent only 21.4 ±3.8% of the basal cell surface. When 132 continuously recycling Kv2.1 channels in HEK cells were examined, 96.2% were also inserted at the cluster perimeter. Unlike Kv2.1, the Kv1.4 K+ channel has a homogeneous cell surface expression in transfected cells. Demonstrating that the Kv2.1 clusters represent cell surface platforms for more than just Kv2.1 insertion and retrieval, the non-clustering Kv1.4 K+ channel also inserted into the HEK cell plasma membrane at the Kv2.1 cluster perimeter. Kv1.4 endocytosis also occurred at this region. Together, these results indicate that a non-conducting function of Kv2.1 is to form specialized cell surface microdomains which are involved in membrane protein trafficking. This study is the first to identify stable cell surface sites for membrane protein delivery and retrieval in mammalian cells.

414

Near-membrane dynamics of TRPM8 channels and the effect of agonist stimulation.

C. A. Toro[1], L. Veliz[1], S. Brauchi[1]; [1]Instituto de Fisiologia, Facultad de Medicina, Universidad Austral de Chile, Valdivia, Chile., Valdivia, Chile

Modulation of TRP channel distribution and availability by vesicular translocation has been reported as a regulatory mechanism for TRP channel function. Plasma membrane (PM) vesicle insertion regulates the number of functional thereby dictating total ionic flux and the cellular

consequences of TRP channel function. These consequences will depend on both, the amplitude of current and its ionic composition. Na+ current drives membrane depolarization and may be a trigger for opening other voltage-dependent ion channels, whereas Ca2+ influx drives fundamental cellular signaling cascades that control secretion, protein translocation, and vesicular fusion. Therefore, a tight control of TRP channel trafficking and delivery to various membrane compartments is thus a potentially critical step in regulating the flow of sensory information. Here we show whether agonist treatments affect the membrane dynamics of cold receptors (TRPM8 ion channels). TRPM8-GFP fusion channels were transfected on F11 cells. Through-the-objective TIRF microscopy was used to perform single particle tracking and to record changes in mobility. As the tracking and subsequent analysis of the MSD was slow and tedious, we build our own automatized software for image analysis. We present here a detailed diffusion analysis based on single particle measurements. Our data clearly show that TRPM8 agonists stimulate an increase in receptor density at the PM, and the effect on single vesicle dynamics. These changes are calcium-dependent. Importantly, by the use of the selective blocker BCTC we show that this process is dependent on TRPM8 channel activity. We picture that stimulation of vesicle exocytosis by TRPM8-mediated Ca2+ flux may increase cell-surface expression in a positive feedback loop. Such amplification power may represent a central theme in their function.

The fifth Adaptin and the evolution of the late secretory compartments.

J. Hirst[1], L. Barlow[2], G. Francisco[2], D. Sahlender[1], M. Seaman[1], M. Robinson[1], J. Dacks[2];
[1]CIMR, University of Cambridge, Cambridge, United Kingdom, [2]Department of Cell Biology, Univ Alberta, Edmonton, Canada

Adaptor protein (AP) complexes sort cargo into vesicles for transport from one membrane compartment of the cell to another. Four distinct AP complexes have been identified, which are present in most eukaryotes.

We report the existence of a fifth AP complex, AP-5. Tagged AP-5 localises to a late endosomal compartment in HeLa cells. AP-5 does not associate with clathrin and is insensitive to brefeldin A. Knocking down AP-5 subunits interferes with the trafficking of the cation-independent mannose 6-phosphate receptor and causes the cell to form swollen endosomal structures with emanating tubules. AP-5 subunits can be found in all five eukaryotic supergroups, but they have been co-ordinately lost in many organisms. Concatenated phylogenetic analysis provides robust resolution, for the first time, into the evolutionary order of emergence of the adaptor subunit families, showing AP-3 as the basal complex, followed by AP-5, AP-4, and AP-1 and AP-2.

This provides not only a newly reported, ancient, cellular complex in eukaryotic cells, but insight into the earliest stages of the late secretory system.

In vivo crystallization of human IgG in the endoplasmic reticulum of engineered CHO cells.

H. Hasegawa[1], J. Wendling[2], F. He[2], E. Trilisky[2], R. Stevenson[2], H. Franey[2], F. Kinderman[2], G. Li[2], D. Piedmonte[2], T. Osslund[2], M. Shen[2], R. Ketchem[2]; [1]Amgen Inc., Seattle, WA, [2]Amgen Inc.

Protein synthesis and secretion are essential to cellular life. Although secretory activities may vary in different cell types, what determines the maximum secretory capacity is inherently difficult to study. Increasing protein synthesis until reaching the limit of secretory capacity is one strategy to address this key issue. Under highly optimized growth conditions, recombinant CHO cells engineered to produce a model human IgG clone started housing rod-shaped crystals in the endoplasmic reticulum (ER) lumen. The intra-ER crystal growth was accompanied by cell enlargement and multi-nucleation and continued until crystals outgrew cell size to breach membrane integrity. The intra-ER crystals were composed of correctly folded, endoglycosidase H-sensitive IgG. Crystallizing propensity was due to the intrinsic physicochemical properties of the model IgG, and the crystallization was reproduced in vitro by exposing a high concentration of IgG to a near neutral pH. The striking cellular phenotype implicated the efficiency of IgG protein synthesis and oxidative folding exceeded the capacity of ER export machinery. As a result, export-ready IgG accumulated progressively in the ER lumen until a threshold concentration was reached to nucleate crystals. Using an in vivo system that reports accumulation of correctly folded IgG, we showed that the ER-to-Golgi transport steps became rate-limiting in cells with high secretory activity.

417

Sec16B is involved in the ER export of the peroxisomal membrane proteins Pex3 and Pex16 in mammalian cells.

S. Yonekawa[1], A. Furuno[1], T. Baba[1], Y. Fujiki[2,3], Y. Ogasawara[4], A. Yamamoto[4], M. Tagaya[1], K. Tani[1]; [1]School of life Sciences, Tokyo University of Pharmacy and Life Sciences, Hachiouji, Japan, [2]Department of Biology, Faculty of Science, Kyushu University Graduate School, [3]Core Research of Evolutional Science and Technology, Japan Science and Technology Agency, [4]Faculty of Bioscience, Nagahama Institute of Bio-Science and Technology

Recent work has suggested that some peroxisomal membrane proteins (PMPs), including the PMP import receptors Pex3 and Pex16, are, at least partly, transported from the endoplasmic reticulum (ER) to peroxisomes. The molecular machinery involved in the transport from the ER remains to be identified.

Sec16 is a key molecule in the formation of COPII vesicles, which mediate protein transport from the ER to the Golgi apparatus. Mammals have two Sec16 isoforms: Sec16A, which is a longer primary ortholog of yeast Sec16, and Sec16B, which is a shorter distant ortholog. Previous studies have shown that Sec16B, as well as Sec16A, defines ER exit sites, where COPII vesicles are formed in mammalian cells, and is involved in the transport from the ER to the Golgi apparatus. In this study, we showed that Sec16B plays an important role in the transport of Pex3 and Pex16 from the ER to peroxisomes in mammalian cells.

When overexpressed in HeLa cells, Sec16B was targeted to the entire ER, whereas Sec16A was mostly cytosolic. Overexpression of Sec16B caused Pex3 and Pex16 to be redistributed from peroxisomes to Sec16B-positive ER membranes, concomitantly with a reduction in the number of peroxisomes. Knockdown of Sec16B but not Sec16A by RNA interference inhibited the transport of Pex16 from the ER to peroxisomes, suppressed expression of Pex3, and

caused elongation of peroxisomes. These phenotypes were significantly reversed by the expression of RNAi-resistant Sec16B. Deletion of the C-terminal 348 amino acids of Sec16B abrogated the ability to rescue the Sec16B depletion phenotype, suggesting the importance of the C-terminal region in peroxisome biogenesis. These results suggest that Sec16B is involved in peroxisome biogenesis dependent on the PMP transport pathway from the ER.

418

The delayed ER export of HLA-G is due to its lack of ER export signal, but not to its potential ER retention signal.

S. Cho[1], M. Lee[1], Y. Ko[1], Y. Jun[1]; [1]Cell Dynamics Research Center, School of Life Sciences, Gwangju Institute of Science and Technology, Gwangju, Korea

The cell surface expression of HLA-G, the non-classical major histocompatibility complex class I (MHC-I) molecule specifically expressed in placenta, was reported to be regulated by its dilysine motif present in the cytosolic domain. In contrast to the previous study, we find that the dilysine of HLA-G is not a functional ER retrieval motif as a HLA-G mutant, whose dilysine motif was replaced with alanine residues, did not accelerate its intracellular trafficking. Instead, another HLA-G mutant (HLA-G/A-tail), whose cytosolic tail was replaced with that of HLA-A2.1 with a functional ER export signal, traffics significantly faster than wild-type HLA-G. Interestingly, addition of an ER retention motif at the C-terminal end of HLA-G/A-tail leads to complete ER retention. Finally, addition of 6 amino acids, which includes a functional ER retention motif (KKXX) at the C-terminus, to HLA-G (RAASSD) fully retains HLA-G in the ER. These results are consistent with a previous model whereby a functional dilysine ER retention motif needs to be placed at least 8 amino acids apart from the membrane for stable COPI binding. Therefore, our current study also raises a question on the model where the ER retention motif of HLA-G functions in a peptide-quality-dependent manner.

The Dendritic Endoplasmic Reticulum and Conventional Kinesin Define a Non Canonical Trafficking Modality for GABAB Receptors.

J. I. Valenzuela[1,2], M. Jaureguiberry[1,3], O. Ramírez[2,4], T. Blanpied[5], A. Couve[1,2];
[1]Physiology and Biophysics, Facultad de Medicina, Universidad de Chile, Santiago, Chile, [2]Biomedical Neuroscience Institute (BNI), Facultad de Medicina, Universidad de Chile, Santiago, Chile, [3]School of Biochemistry, Faculty of Biological Science, Universidad Andrés Bello, Santiago, Chile, [4]Anatomy and Development, Facultad de Medicina, Universidad de Chile, Santiago, Chile, [5]Physiology, University of Maryland School of Medicine, Baltimore, MD

The availability of neurotransmitter receptors is regulated by coordinated mechanisms that deliver newly synthesized receptors to the plasma membrane and remove them for storage, recycling or degradation. In neurons, a complex spatial distribution of secretory organelles defines local, non-canonical protein trafficking pathways that comprise the dendritic endoplasmic reticulum (ER) and satellite Golgi outposts. Metabotropic $GABA_B$Rs regulate the efficacy of synaptic transmission throughout the brain, but the mechanisms controlling their biosynthetic route and plasma membrane delivery remain unclear. In this study we examined the trafficking modality of $GABA_B$Rs in dendrites and evaluated the roles of the ER and kinesin-I in this process. The localization, colocalization and mobility of $GABA_B$Rs were evaluated using fixed and live-cell imaging in primary cultures of rat hippocampal neurons under control conditions or after blockade of intracellular trafficking. *De novo* receptor insertion was determined using α-bungarotoxin labeling and single molecule tracking was performed using photoactivated localization microscopy. We show that $GABA_B$Rs insert throughout the somatodenritic plasma membrane and traffic through satellite Golgi outposts. $GABA_B$R1, the

subunit that contains an ER retention motif, colocalizes preferentially with the ER in dendrites and is mobile within this compartment. The transport of dendritic $GABA_BR1$ has a modal velocity of 200 nm/sec and depends on kinesin-I and microtubule acetylation. Taken together, these results indicate that $GABA_BRs$ utilize a non-canonical secretory route in dendrites and uncover a novel role for kinesin-I in the transport of cargo along the dendritic ER. Live-cell imaging of organelle trafficking and before, during and after mitosis.

K. Chambers[1], R. Batchelor[2], M. Janes[2], N. Dolman[2]; [1]Molecular Probes, Life Technologies, Eugene, OR, [2]Molecular Probes, Life Technologies

In mammalian cells the process of mitosis requires substantial trafficking of organelles both before mitotic onset and following separation of daughter cells. Complex organelle morphologies and interactions need to be disassembled then reassembled. Furthermore many organelles show cell-cycle dependent-activity. Intracellular organelles were labeled with targeted fluorescent proteins. Aspects of mitosis were reported by targeted fluorescent proteins to cytoskeletal elements and cell-cycle progression was imaged using FUCCI fluorescent protein biosensor. Cells expressing a fluorescent protein targeted to a particular organelle were combined with either a cytoskeletal targeted fluorescent protein or one of the FUCCI constructs (to delineate G1/S or S/G2/M). Cells were imaged for 24 hours to correlate organelle dynamics with mitotic dynamics, daughter cell separation or cell-cycle progression. Using this approach we show the disassembly of the Golgi apparatus during mitosis and the timing of reformation in G1. Furthermore we show the segregation of endosomal and mitochondrial structures during mitosis and trafficking to reestablish organelle morphology in G1.

Mechanisms of Proglucagon Sorting to the Regulated Secretory Pathway.

L. Guizzetti[1,2], R. McGirr[2], S. Dhanvantari[1,2]; [1]Medical Biophysics, University of Western Ontario, London, ON, Canada, [2]Metabolism/Diabetes and Imaging Programs, Lawson Health Research Institute, London, ON, Canada

Introduction: Prohormones are synthesized in the endoplasmic reticulum, transported through the Golgi and sorted to secretory granules (SGs), where they are processed to mature peptide hormones and stored until a stimulus triggers their release, a process known as regulated secretion. There are several mechanisms by which prohormones are sorted to SGs. One prohormone sorting hypothesis is “sorting-by-entry” whereby prohormones are sorted to SGs via a sorting signal, such as an amphipathic α-helix or di-basic amino acids. Proglucagon is a prohormone that is processed in a tissue-dependent manner, to yield glucagon in pancreatic α-cells, and glucagon-like peptide-1 (GLP-1) and GLP-2 in intestinal L cells and brainstem. We are examining the molecular mechanisms underlying the sorting of proglucagon to SGs. We hypothesize that proglucagon is sorted to SGs via sorting signals comprising either the α-helix structure in glucagon, GLP-1, or GLP-2, or the di-basic amino acid sequence in glucagon.

Results: In order to identify sorting signals within the sequence of glucagon, we have generated fusion constructs, composed of a reporter molecule, Fc, and either wild-type (WT) or mutant glucagon. Glucagon mutations were designed to disrupt either the α-helix (L14P/L26P; LP-Fc) or di-basic amino acids (R17R18Q; RQ-Fc). Stable transfectants using the neuroendocrine cell line, PC12, were generated and verified by Western blot analyses. To measure the extent of regulated secretion, Fc release in response to 55 mM K+ was determined by immunoprecipatation/Western blot. For subcellular localization in SGs, we conducted

fluorescence immunocytochemistry for Fc and an SG marker, chromogranin A. The LP-Fc mutant showed no significant difference in K+-stimulated secretion compared to basal (n=3, t-test), while the RQ-Fc mutant showed a 3-fold increase in K+-stimulated secretion (n=3, $p<0.05$, t-test). Fluorescence immunocytochemistry showed that both WT-Fc glucagon and RQ-Fc mutant significantly co-localized with chromogranin A, while the LP-Fc was localized exclusively to the Golgi. These results indicate that both the WT-Fc glucagon and RQ-Fc mutant are sorted to the regulated secretory pathway while the sorting of the LP-Fc mutant is disrupted.

Conclusion: WT glucagon contains sufficient information for sorting proglucagon to SGs. Specifically, the α-helix within glucagon is a sorting signal while the di-basic amino acid sequence may not be as important for regulated secretion. Further experiments will test the α-helices within GLP-1 and GLP-2 as putative proglucagon sorting signals.

422

PLD2 is important for glycoconjugate trafficking in mast cells.

C. M. Marchini-Alves[1], M. C. Jamur[1], C. Oliver[1]; [1]Department of Cell and Molecular Biology and Pathogenic Bioagents, FMRP-Universidade de Sao Paulo, Ribeirao Preto, Brazil

PLD has been shown to play an important role in vesicle trafficking along the secretory pathway. PLD2, a PLD isoform, was investigated in order to assess its involvement in transport of glycoproteins through the secretory pathway. The mast cell line RBL-2H3 and RBL-2H3 cells that overexpress catalytically active (PLD2CA) and inactive (PLD2CI) forms of PLD2 were used in the study. The glycosylation pathway was investigated using N-acetylmanosamine-azide (ManNAz), which is a metabolic precursor for sialic acid, which was detected with Alexa Fluor 488-alkyne. The cells were pulse labeled with ManNAz for 1h and chased for up to 3 days and the labeling intensity at the plasma membrane was examined. In RBL-2H3 cells the plasma membrane was labeled with ManNAz after 12h of chase, and the labeling remained unchanged until 36h. After 36h of chase, the ManNAz labeling decreased. In CA cells the modified sugar labeled the cell membrane at 12h and the labeling intensity remained the same until 36h of chase. After 36h the modified sugar decreased its labeling intensity in the cell membrane. In CI cells, ManNAz intensity in the cell membrane was higher than the other cell lines after 12h of chase. After this time the labeling intensity decreased, but still had more labeling in the cell membrane than the other cell lines. The same pulse-chase experiment was repeated, but the cells were permeabilized in order to visualize the localization of the modified sugar inside the cells. In RBL-2H3 cells the ManNAz was present in the juxtanuclear region, most probably in the Golgi complex, at 12h. This labeling persisted until 36h and then decreased. In the CA cells the modified sugar was present juxtanuclearly, after the first 12h of chase. After 24h, the intensity of the juxtanuclear labeling decreased, but persisted until 48h. In the CI cells, after the first 12h of chase there was labeling in the juxtanuclear region which remained with the same intensity until 36h of chase. With 60h of chase the intensity of the labeled ManNAz at the cell membrane was the highest when compared to the other cell lines. These observations indicate that in CI cells there is a delay in the synthesis and/or trafficking of the glycosylated proteins when compared to the wild type RBL-2H3 and CA cells. Thus, PLD2 appears to play an important role in glycosylation in RBL-2H3 mast cells. These results provide insights for future studies to elucidate the molecular mechanisms underlying intra-Golgi transport.

423

ALPS motifs and alpha-synuclein bind selectively to different types of vesicles in vitro and in cells.

C. L. Jackson[1], I. Pranke[1], J. Bigay[2], K. Gibson[3], J-M. Verbavatz[3], B. Antonny[2];
[1]Institut Jacques Monod, CNRS & Université Paris Diderot-Paris7, France, [2]Institut de Pharmacologie Moléculaire & Cellulaire, CNRS and Université de Nice Sophia Antipolis, Valbonne, France, [3]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

Membrane curvature sensors have different structures and chemistries. ALPS motifs bind specifically to highly curved membranes due to the fact that they are unbalanced lipid-binding amphipathic helices, having a well-developed hydrophobic face but few charged residues on their polar face. Numerous ALPS motifs are found in proteins that function in the early secretory pathway. A second type of amphipathic helical curvature sensor is exemplified by alpha-synuclein, a causative agent of Parkinson's disease that is localized to synaptic vesicles. alpha-synuclein is also an unbalanced amphipathic helix, but opposite to ALPS motifs, has a well developed polar face and a poor hydrophobic face. Hence both ALPS motifs and alpha-synuclein have a "weakness" that makes positive membrane curvature mandatory for their binding. However, these curvature sensors have opposite chemistries, and direct in vitro comparisons of ALPS motifs and alpha-synuclein demonstrate that they have different lipid requirements for binding, preferring lipid compositions complementary to each one's distinct chemical properties. When expressed in yeast cells, these two curvature sensors were targeted to different classes of vesicles, those of the early secretory pathway for ALPS motifs and to negatively charged endocytic/post-Golgi vesicles in the case of alpha-synuclein. The lipid composition of the vesicles that alpha-synuclein and ALPS motifs associate with in cells correlate well with their in vitro lipid binding properties. These findings show that complementary curvature sensing mechanisms operate in the two major lipid environments of the cell, and that curvature sensors can discriminate between vesicles of different lipid composition.

A Yeast Genomic Screen to Identify Negative Regulators of Kir2.1 Plasma Membrane Residence.

A. R. Kolb[1], P. G. Needham[1], J. L. Brodsky[1]; [1]Biological Sciences, University of Pittsburgh, Pittsburgh, PA

The inward rectifying potassium channel, Kir2.1, functions at the plasma membrane of muscle and neuronal tissues to maintain membrane potential. Gain or loss of function mutations in Kir2.1 cause diseases such as Anderson-Tawil syndrome and short QT syndrome, respectively. Like other complex ion channels, a significant percentage of Kir2.1 is also targeted for ER associated degradation (ERAD). However, the spectrum of cellular determinants that assemble, deliver, and maintain channel plasma membrane residence remain largely unknown.

As in human cells, the yeast, Saccharomyces cerevisiae, must maintain intracellular potassium levels. Yeast express two potassium transporters (Trk1 and Trk2), but in the absence of Trk1 and Trk2 the cells can utilize an exogenously expressed potassium channel to grow on low potassium media.

To identify factors necessary for Kir2.1 plasma membrane residence, we engineered a trk1Î" trk2Î" yeast strain in which Kir2.1 restores growth on low potassium. Thus, yeast growth on low potassium media provides a direct readout for Kir2.1 plasma membrane residence. As a proof of principle that factors could be identified that affect Kir2.1 trafficking, the reporter strain was

crossed to five strains deleted for genes hypothesized to be important for Kir2.1 plasma membrane residence. Yeast deleted for DOA10 grew better and yeast deleted for EMP24 grew less well on low potassium media, suggesting a screen for effectors of Kir2.1 trafficking could be identified. The trk1Î" trk2Î" strain expressing Kir2.1 was then crossed to the yeast deletion collection and the resulting strains were screened on low potassium. Initial results from the screen uncovered nearly all members of the Endosomal Sorting Complex Required for Transport (ESCRT) and the entire retromer complex, as well as members of the transport protein particle (TRAPP) and Conserved Oligomeric Golgi (COG) complexes. Surprisingly, ERAD-associated factors were not identified. Together, these data suggest that Kir2.1 function at the plasma membrane is controlled mainly by later steps in the secretory pathway and not by ERAD.

425

Profragment Chain Topology Controls Early Folding Events of a Nascent Membrane-bound Hydrolase.

M. Behrendt[1], H. Y. Naim[1]; [1]Department of Physiological Chemistry, University of Veterinary Medicine, Hannover, Germany, Hannover, Germany

Many eucaryotic proteins have a complex three-dimensional structure with more than one structural domain and each domain plays a particular role within the intramolecular organization of the polypeptide. The transport-competent precursor of human intestinal lactase phlorizin hydrolase, pro-LPH, encompasses four homologous domains, which presumably have evolved from two subsequent duplications of one ancestral gene. Pro-LPH comprises two intramolecular chaperones, one in its profragment - LPHα - containing domains I and II and one within domain III of the active brush border LPHβ region. The profragment is proteolytically removed in two steps within the Golgi apparatus and by luminal pancreatic trypsin. The role of each profragment domain for the attainment of LPHα chaperone function and the interrelationship between both intramolecular chaperones in the nascent pro-LPH polypeptide has not been elucidated so far. Therefore, we analyzed the early events of its biosynthesis by directed restructuring of the domain composition. Expression in COS-1 cells revealed that removal of domain II results in a diminished phlorizin hydrolase and absent lactase activity, lack of dimerization in the ER, but normal transport kinetics from the ER to the Golgi apparatus. By contrast, deletion of domain I generates a malfolded protein that is blocked in the ER. Moreover, expression of domains I, II, and the profragment alone results in ER-resident proteins. However, the protein containing domains I, II, and III is transport-competent and efficiently secreted. The data presented here propose a model of the early folding events of nascent pro-LPH in which the profragment topological organization precedes the hierarchical intramolecular organization of the whole protein. To our knowledge, this is the first cell biological and biochemical analysis of the early organizational events of a nascent membrane-anchored multi-domain polypeptide.

426

SEC23B is required for development of the murine pancreas, salivary glands and gastric glands.

M. Zhu[1], J. Tao[1], H. Wang[2], M. Vasievich[2], X. Chen[2], G. Zhu[2], D. Ginsburg[2], B. Zhang[1]; [1]Genomic Medicine Institute, Cleveland Clinic Foundation, Cleveland, OH, [2]University of Michigan

In eukaryotic cells, COPII (coat protein complex II) captures cargo into vesicles and mediates vesicle budding from the endoplasmic reticulum (ER). COPII contains 5 core components: SAR1, SEC23, SEC24, SEC13 and SEC31. Mammalian cells express multiple paralogs of COPII proteins, including two SEC23 paralogs, SEC23A and SEC23B. SEC23 is a GTPase-

activating protein (GAP) that activates the SAR1 GTPase and also plays a role in cargo recognition. Recently two human genetic disorders have been associated with defects in SEC23 genes. Cranio-lenticulo-sutural dysplasia (CLSD) is characterized by craniofacial and skeletal malformation due to homozygosity for one of two missense mutations in SEC23A. Mutations in SEC23B cause congenital dyserythropoietic anemia type II (CDAII), defined by moderate anemia, multinucleated erythroblasts, ineffective erythropoiesis and aberrant glycosylation of specific red blood cell membrane proteins. How SEC23B deficiency leads to this selective red blood cell defect in humans remains unclear. Homozygous SEC23B null mutations have never been identified in CDAII patients, suggesting that total loss of SEC23B may be lethal. The objective of this study is to characterize mice completely deficient for SEC23B. Sec23b heterozygous null mice were generated from a gene-trap embryonic stem cell clone. Homozogous Sec23b null pups die shortly after birth, with degeneration of the pancreas, salivary glands and gastric glands. The typical grape-like clusters of acinar cells of the WT pancreas are lost in the Sec23b deficient pancreas, with no discernible islet structure. Zymogen granules are nearly absent in Sec23b deficient pancreatic acini and greatly reduced in salivary glands. The ER is severely distended due to the accumulation of proteins in the lumen. The pro-apoptotic branch of the unfolded protein response pathway is selectively activated in SEC23B deficient pancreas, gastric glands and salivary glands, and these tissues also exhibit positive staining for caspase 3 and TUNEL, suggesting a central role for apoptosis in the degeneration of these tissues in Sec23b deficient embryos. The affected tissues all express high levels of SEC23B, suggesting that professional secretory cells in the mouse may be particularly dependent on SEC23B function. These results suggest distinct and non-overlapping functions for mammalian SEC23A and SEC23B.

427

Biological role and significance of the PAR1 signal peptide.

D. Zampatis[1], N. Tsopanoglou[2], R. Schuelein[1]; [1]Protein trafficking, Leibniz Institute for Molecular Pharmacology FMP, Berlin, Germany, [2]Pharmacology, Medicine school-University of Patras,Greece, Patras, Greece

The G protein-coupled protease-activated receptor 1 (PAR1) is activated by cleavage of its N terminus by thrombin which in turn uncovers a tethered ligand transactivating the receptor. Thrombin cleaves between amino acid residues Arg41 and Ser42 and releases an N-terminal peptide, namely parstatin, which was recently shown to have a regulatory function in angiogenesis and in myocardial ischemia and reperfusion injury. However, the actual length of parstatin was unclear since the receptor also possesses a putative signal peptide (residues 1-21) in its amino terminus according to prediction programs. If functional, this signal peptide should be removed from the receptor following insertion into the membrane of the endoplasmic reticulum and parstatin released from plasma membrane PAR1 would be shorter. Here, we studied the cleavage of the signal peptide of PAR1 and show that it is indeed removed from the N tail resolving the question of parstatin length. Moreover, we show that deletion of the sequence encoding the signal peptide leads surprisingly to a strong decrease in the amount PAR1 mRNA. Transcription itself was not affected and the sequence thus seems to play a role in stabilization of the mRNA secondary structure, a function which was never described before for a G protein-coupled receptor.

428

Novel Regulation of the Golgi Complex and Endosomes by the Cytoplasmic Phospholipase A2 Enzyme PAFAH Ib.

M. Bechler[1], A. Doody[2], K. Ha[2], B. Judson[2], I. Chen[3], W. Brown[2]; [1]Cornell University and University of Edinburgh, Edinburgh, United Kingdom, [2]Cornell University, Ithica, NY [3]Cornell University and University of Michigan

Previous studies have shown that membrane tubule-mediated export from the Golgi complex and endosomal compartments requires cytoplasmic phospholipase A_2 (PLA_2) activity. Here we report that the cytoplasmic PLA_2 enzyme complex Platelet Activating Factor Acetylhydrolase (PAFAH) Ib regulates the trafficking and organization of the mammalian Golgi complex and endosomes by mediating the formation of membrane tubules. PAFAH Ib is comprised of two PLA_2 subunits, α1 and α2, and a dimer of the dynein regulator LIS1. Both α1 and α2 partially localize on Golgi and endosome membranes. Using a variety of in vivo and in vitro approaches, we conclude that the formation of PAFAH Ib-dependent membrane tubules is important for the biogenesis and maintenance of an intact Golgi ribbon, anterograde trafficking through the Golgi stack, and export of itinerant receptors from various endosomal compartments. Although α1 and α2 can form functional homo- and heterodimers, we found that the α1 and α2 catalytic subunits do not have identical functions. Knockdown of the subunits individually had different effects on Golgi structure and function. Finally, we found that α1 and α2 expression levels affect Golgi and endosome organization through interactions with LIS1. Our results demonstrate a cooperative interplay between the PLA_2 activity of α1 and α2 with LIS1 to facilitate the functional organization of the Golgi complex and endosomes, thereby suggesting a model that links continual phospholipid remodeling and membrane tubule formation to dynein-dependent transport. Work supported by NIH grant DK51596 to WJB.

Analysis of the retrotranslocated pool of the ERAD substrate CD3delta.

C. Hoerth[1], H. Lorenz[1]; [1]Univ Heidelberg, Heidelberg, Germany

The quality control mechanism encompassing protein retrotranslocation from the ER and disposal of the faulty polypeptides in the cytosol is known as ER-associated degradation (ERAD). Inefficient degradation of the dislocated proteins by the proteasome has been linked to several disorders, like Alzheimer's disease and the prion diseases. Here, we present data on the retrotranslocated pool of a well-established ERAD substrate, the T cell receptor subunit CD3delta. By applying mono- and dual-labeling approaches, i.e. CD3delta tagged to either one or two fluorescent proteins, the retrotranslocation of CD3delta and the dynamics of its cytosolic pool could be examined by live cell imaging techniques and fluorescence correlation spectroscopy (FCS). Upon dislocation of the type 1 membrane protein, the cytosolic location and aggregation status of CD3delta were investigated. By using reversible proteasome inhibitors the final degradation of cytosolic CD3delta by the recovering proteasome system could be monitored and quantified. The results presented here demonstrate the power of fluorescent protein-based strategies as tools to examine protein turnover pathways.

Rabankyrin-5 regulates retromer function through an interaction with EHD1.

J. Zhang[1], C. Reiling[1], J. Reinecke[1], I. Prislan[2], L. Marky[2], N. Naslavsky[1], S. Caplan[1]; [1]Department of Molecular Biology and Eppley Cancer Center, University of Nebraska Medical Center, Omaha, NE, [2]Department of Pharmaceutical Sciences, University of Nebraska Medical Center, Omaha, NE

Rabankyrin-5 (Rank-5) has been implicated as an effector of the small GTPase Rab5 and plays an important role in macropinocytosis. We have identified Rank-5 as an interaction partner for the recycling regulatory protein EHD1. We have shown this interaction by GST-pulldown, yeast two-hybrid, isothermal calorimetry, and co-immunoprecipitation and found that the binding occurs between the EH-domain of EHD1 and the NPFED motif of Rank-5. Similar to EHD1 and EHD3, Rank-5 co-localizes and interacts with components of the retromer complex and depletion of Rank-5 causes mislocalization of the retromer and affects biosynthetic transport. The effect of Rank-5 on the retromer depends upon the interaction between Rank-5 and EHD1, as rescue experiments with Rank-5 containing mutations in its NPF motif fail to mitigate retromer mislocalization. Finally, we show that depletion of either Rank-5 or EHD1 impairs secretion of VSV-G. Overall, our data indentify a new role of Rank-5 in interacting with EHD1 to regulate retromer function.

Endocytic Trafficking

RNAi-based Functional Profiling Identifies Novel Disease Related Proteins with a Role in Low-density Lipoprotein (LDL) Uptake and Cholesterol Trafficking.

P. Blattmann[1], H. Runz[2], R. Pepperkok[1]; [1]Cell Biology and Biophysics, EMBL Heidelberg, Heidelberg, Germany, [2]Institute of Human Genetics, University of Heidelberg, Heidelberg, Germany

Elevated serum lipid levels are a major risk factor for atherosclerosis and coronary heart disease. To date, over ten proteins which function in cholesterol uptake or trafficking are known to cause lipid disorders such as hypercholesterolemia. Recently, over 120 loci associated for lipid traits and cardiovascular disease were identified in genome-wide association studies (GWAS). The majority of these loci are novel. Variants regulating expression or function of genes encoded in these loci are suspected of being causative in perturbing blood lipid levels in humans. However, most of these genes are uncharacterized or have no known functional role in cellular cholesterol regulation or trafficking. Identifying and characterizing causative genes promises to shed light both on the cell biology of cholesterol trafficking as well as on the pathogenesis of cardiovascular disease.
We have established a high-content screening platform with two functional assays for measuring low-density lipoprotein (LDL) uptake and cellular free cholesterol in tissue culture cells. The combination of automated fluorescent microscopy and image analysis allowed us to obtain multiparametric profiles of siRNA treated cells. Cellular free cholesterol or LDL uptake was affected with at least 2 siRNAs for 40 of the 109 genes encoded in associated loci. Analysis of LDL receptor (LDLR) expression upon siRNA knockdown indicates that most of our candidates exert their effect via pathways independent of LDLR expression level regulation. For 25 of the 40 candidates, our results represent the first demonstration of a functional role in cholesterol metabolism. To further characterize the novel candidates, synthetic genetic interactions were assessed by treating cells with multiple siRNAs.

Our data now allows us to generate hypotheses about how these genes may affect lipid regulatory mechanisms in cells.

432

Rapid Assembly and Internalization of Caveolae Promotes Plasma Membrane Repair in Injured Cells and Muscle Fibers.

M. Corrotte[1], P. de Almeida[1], C. Tam[1], M. Fernandes[1], N. Andrews[1]; [1]Cell Biology and Molecular Genetics, University of Maryland, College Park, MD

Plasma membrane repair is essential for cellular survival after wounding. Muscle tissue is particularly susceptible to injury, and defects in maintaining sarcolemmal integrity lead to severe forms of muscular dystrophy. Mutations in caveolin-3 cause a range of muscle diseases including cardiomyopathy, and muscle fibers from some forms of muscular dystrophy show an increased number of caveolae. The mechanism underlying these observations is still obscure. In this study we show that myotubes share with other cell types a Ca2+ dependent plasma membrane repair mechanism that involves exocytosis of lysosomes, secretion of acid sphingomyelinase, and rapid endocytosis. A few minutes after wounding, injury-induced endosomes appear as large vesicles with properties of early endosomes, and then mature into late endosomes/lysosomes. However, the nature of the vesicles formed immediately after plasma membrane disruption was unknown. By examining fibroblasts and myotubes shortly after wounding, we observed massive de novo formation and internalization of caveolae. This process is required for plasma membrane resealing, and is also triggered by exposure to purified sphingomyelinase, in the absence of wounding. Thus, the accumulation of caveolae observed in muscle fibers from muscular dystrophy patients is likely to reflect an ongoing process of sarcolemmal injury and repair. These findings identify sphingomyelinase-induced caveolae as dynamic endocytic structures with a fundamental role in the restoration of plasma membrane integrity.

Knockdown of all Rab5 isoforms in the liver leads to loss of endosomes and a mis-organization of hepatocellular polarity.

A. Zeigerer[1], J. Gilleron[1], R. Bogorad[2], G. Marsico[1], H. Nonaka[1], V. Kotelianski[2], Y. Kalaidzidis[1], M. Zerial[1]; [1]Max Planck Institut for Molecular Cell Biology and Genetics, Dresden, Germany, [2]Alnylam Pharmaceuticals, Inc.

The liver is a multi-functional organ participating in an immense number of physiological processes, e.g. regeneration, toxicology, bile formation, and lipid and glucose metabolism. All those functions are mainly carried out by hepatocytes, which exhibit a very complex and peculiar polarity with several apical and basolateral sides per cell. Specific trafficking routes and retention mechanisms are necessary to ensure proper function of these distinct membrane domains. The endosomal system plays a key role in maintaining this functional asymmetry or polarity by the formation of spatially distinct intracellular, endocytic networks, which secure the correct sorting and spatial temporal regulation of different transporters and signaling receptors in the liver. We set out at a systems level to dissect the interaction between endocytosis, metabolism and signaling in the liver. Here, we used the state-of-the-art technology of RNA interference in vivo in the liver of adult mice to specifically downregulate all three Rab5 isoforms. By knocking down Rab5, the central component of the endosomal system, we wanted to investigate the effect of alterations in the endocytic network on cellular signaling, hepatocellular polarity, and whole body metabolism. We find that knockdown of Rab5 in vivo leads to a loss of endosomes and to a mis-organization of hepatocellular polarity resulting in a cholestatic phenotype in these mice.

Connections between endocytic membrane trafficking, GPCR signaling and cytokinesis revealed by the small molecule XZ1.

X. Zhang[1,2], A. Bedigian[2], M. Coughlin[1], U. Eggert[1,2]; [1]Harvard Medical School, Boston, MA, [2]DFCI, Boston, MA

Endocytosis and cytokinesis are distinct cellular processes that share certain sub-reactions, but this connection is poorly understood. Endocytic membrane trafficking is essential for cytokinesis and several proteins have been implicated in both processes, including the ESCRT complex, which was discovered in the context of endosomal sorting and is required for abscission, the final step in cytokinesis. We report here new insights into connections between endocytosis and cytokinesis revealed by the small molecule XZ1 and we show that these connections are mediated by G-protein coupled receptor (GPCR) signaling. XZ-1 inhibits cytokinesis, causes tubulation of endocytic compartments and aggregates the ESCRTIII complex. RNAi depletion of GPCR signaling components or the ESCRTIII adaptor protein Vsp4 inhibit XZ1's effects on both cytokinesis and endocytosis, as does inhibition of the vacuolar ATPase, suggesting a common interaction during endocytic sorting. XZ-1 thus reveals, and will help to further elucidate, a complex interaction between cell surface receptors and cytokinesis, mediated by endocytosis.

Endocytic Recycling of the Transferrin Receptor is Regulated by c-Abl Kinase.

H. Cao[1], J. Chen[1], M. McNiven[1,2]; [1]Center for Basic Research in Digestive Diseases, Mayo Clinic, Rochester, MN, [2]Department of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN

Clathrin-mediated endocytosis (CME) of transferrin (Tf) and its cognate receptor (TfR) is a central pathway supporting the cellular internalization of trophic iron. It has generally been assumed that this uptake is a constitutive process that is independent of kinase regulation. Recently we tested if pharmacological inhibition of different non-receptor tyrosine kinases might attenuate TfR endocytosis and found that Tf ligand activates the Src-mediated phosphorylation of a dynamin-cortactin complex to facilitate the internalization of the ligand-receptor. In addition to this finding, a significant endocytic block was observed by treating cells with “Gleevec”, a well-characterized inhibitor of the c-Abl family of tyrosine kinases. Therefore, the **Goal of this study** was to define the role of this kinase family in TfR internalization and traffic. To confirm these initial observations, we subsequently utilized cultured cells transfected to express either WT or kinase dead (K290R and Y412F) c-Abl or c-Abl-/-, Arg-/- cells isolated from KO mice models. Importantly, ligand and TfR internalization were reduced significantly (60-70%) in all of these cell models while re-expression of WT c-Abl restored normal uptake levels in c-Abl-/-, Arg-/- cells. Surprisingly, this attenuated Tf/TfR endocytosis was due largely to a substantial drop (~80%) in the cellular and surface receptor levels, suggesting that the recycling of internalized receptor is compromised. Indeed, IF staining of cells in which c-Abl was inhibited revealed a remarkable colocalization of internalized TfR with the lysosome indicating a mis-sorting step leading to receptor degradation. In support of this finding, TfR levels were increased substantially by treating the kinase inhibited cells with the lysosomal protease inhibitor Leupeptin. These findings are the first to implicate a tyrosine kinase (c-Abl) that insures the normal recycling of the TfR away from the lysosome and back to the cell surface.

Cellular Trafficking of Helical Rosette Nanotubes in Dendritic Cells.

N. House[1], H. Fenniri[2], B. Singh[3]; [1]Toxicology, University of Saskatchewan, Saskatoon, SK, Canada, [2]Chemistry, University of Alberta, Canada, [3]Veterinary Biomedical Sciences, University of Saskatchewan, Canada

Biologically inspired, self-assembling helical rosette nanotubes (HRNs), composed of cytosine and guanine, have multiple desired therapeutic applications including drug delivery and vascular stents. HRN interactions with dendritic cells (DCs), sentinels of the immune system thus potentially the first cell type to encounter HRN upon exposure, are key in determining safety and application viability. Splenic classical and plasmacytoid DCs were isolated from male C57/BL6 mice using magnetic cell sorting. HRN functionalized with the RGD (arginine, glycine, aspartic acid) peptide and coupled with the fluorophore FITC in a ratio of 1:10μM of RGDSK/FITC HRN were delivered to the isolated DCs for 15 minutes at a further 1:10μM dilution in media. Confocal microscopy was used to determine which endocytic pathway (receptor-mediated, clathrin or caveolin-dependent) was utilized and whether the process was energy-dependent. 3-D imaging to characterize HRN intracellular localization and live imaging to view the uptake process in real-time also were completed. HRNs were able to utilize multiple uptake pathways to take residence within clathrin and caveolin-coated vesicles, early endosomes, and lysosomes. In addition, the RGD peptide on the HRN was recognized by αVβ3, an integrin expressed in various cell types including some DC subsets and tumor cells, demonstrating receptor-mediated endocytosis. HRNs co-localized with the major histocompatibility complexes (MHC) I and II indicating possible direct interaction leading to antigen presentation. DC maturation occurred upon HRN exposure as illustrated by the formation of dendrites and presence of maturation markers (such as CD40 and CD83). Cell viability was confirmed through a commercially available kit and visually through microscopy and DAPI staining. These data demonstrate that HRN engage integrin αVβ3 to enter DCs through multiple, presumably redundant, pathways, interact with antigen-presenting molecules and induce maturation of DCs.

Protein Kinase C Delta Regulates Endosomal Trafficking and Volume Recovery in Response to Osmotic Swelling.

E. T. Barfod[1], A. L. Moore[1], S. D. Lidofsky[1]; [1]University of Vermont, Burlington, VT

The metabolic activities of the liver generate intracellular osmotic loads that evoke rounds of swelling and volume recovery with corresponding membrane expansion and compensatory retrieval. How the responsible trafficking events are coordinated is uncertain. We sought to determine the cytoskeletal/membrane regulators in a model of hypotonic challenge in HTC hepatoma cells. In live imaging studies, labeled membrane, internalized after swelling, localized to actin-coated endosomes that were also positive for the trafficking regulator Arf6. In addition, pharmacological inhibition of an Arf6 effector, phospholipase D (PLD), attenuated volume recovery. Because the protein kinase C isoform PKCδ can regulate PLD as part of a complex with Arf6 and PLD, we investigated its actions during osmotic stress. On cell swelling, PKCδ transiently increased in membrane fractions, and rottlerin, a PKCδ inhibitor, blocked volume recovery. Swelling also evoked transient association of GFP-PKCδ with endosomes positive for the membrane marker RFP-farnesyl, or with endosomes positive for RFP-actin. Such endosomes could undergo actin-associated morphologic change after PKCδ association. Since PKCδ can regulate actin polymerization on endosomal membranes through an association with cortactin, we tested PKCδ immunoprecipitates and found cortactin present. PKCδ can be activated directly by Src, which we have shown to be a central cell volume regulator. We have also shown that Src activates the phospholipase C isoform PLCγ, which can activate PKCδ

through lipid hydrolysis. We therefore tested whether Src regulates volume-sensitive membrane trafficking by direct interaction with PKCδ. In immunoprecipitates, PKCδ did not associate with Src but did with focal adhesion kinase (FAK). In addition, immunofluorescence studies showed colocalization of GFP-PKCδ in endosomes with the tyrosine phosphorylated forms of FAK and PLCγ. In live imaging studies, GFP-PKCδ transiently colocalized with an RFP fusion that included the pleckstrin-binding domain of PLCγ. This colocalization was attenuated by the Src inhibitor PP2. By contrast, the PKCδ inhibitor rottlerin did not affect endosomal targeting of PLCγ but suppressed endosomal association of PKCδ and endosomal motility. These findings suggest that Src contributes to hepatocyte volume regulation in part via PLCγ-mediated activation of PKCδ and by regulated motility of actin-coated endosomes. Since PKCδ can modulate actin polymerization through interactions with FAK and with cortactin, we speculate that such interactions coordinate actin and membrane dynamics required for endosomal trafficking during osmotic stress.

Src-Mediated Phosphorylation of CIN85 Regulates Trafficking of the EGF Receptor at the Level of Early Endosomes.

B. Schroeder[1], M. McNiven[1]; [1]Mayo Clinic Rochester, Rochester, MN

Ubiquitination of the epidermal growth factor receptor (EGFR) by cbl and its cognate adaptor CIN85 (cbl interacting protein of 85 kDa) is known to play an essential role in directing this receptor to the lysosome for degradation. Currently, it is unclear where in the endocytic pathway this ubiquitin modification occurs or how it is regulated in response to ligand. In this study we show that EGFR activation leads to a pronounced Src-mediated tyrosine phosphorylation of CIN85. This CIN85 modification is essential for EGFR ubiquitination as impairment of CIN85 phosphorylation by the expression of a phospho-defective mutant (CIN85-4F) inhibits its ability to interact with-cbl and causes a significant reduction in receptor ubiquitination. Importantly, phospho-CIN85 interacts with the Rab5-positive endosome where it mediates the sequestration of the ubiquitinated receptor into intra-luminal vesicles (ILVs) for subsequent degradation. Expression of the phospho-defective CIN85-4F mutant interferes with this process leading to retention of the EGFR in the early endosome and a substantial delay in EGFR degradation. These findings provide novel insights into how CIN85 regulates EGFR traffic at the early endosome in conjunction with the Ub-ligase cbl and how this complex might affect cellular growth. This study was supported by DK44650 and CA104125 to MAM.

A Novel Mechanism Regulates EGF Receptor Trafficking.

N. Lill[1], K. A. Clausen[2], K. Henschel[1], A. Schmenk[1], J. G. Koland[3]; [1]Pathology, The Ohio State University, Columbus, OH, [2]School of Medicine, Wake Forest University, [3]Pharmacology, University of Iowa

The ubiquitin ligase c-Cbl controls epidermal growth factor receptor (EGF-R) signaling by enhancing receptor ubiquitination, downregulation, and lysosomal degradation. Our laboratory previously reported that Cbl does this by controlling EGFR's passage through an intracellular trafficking checkpoint at the limiting membrane of early endosomes. Here, we report further studies of the molecular mechanism by which Cbl controls EGFR fate at endosome limiting membranes. We tested three hypotheses: 1) that ubiquitin in complex with EGFR is sufficient to move receptors from the limiting membranes of endosomes to their luminal vesicles, in the absence of Cbl's ubiquitin ligase activity; 2) that forced retention of ligand-activated EGFR at the limiting membrane of early endosomes prevents their degradation, regardless of whether the receptors are associated with ubiquitin; and 3) that the evolutionarily non-conserved Cbl

sequences C-terminal to amino acid 436 have no impact on EGFR fate at the endosomal trafficking checkpoint. Our studies employed HEK 293 and COS-7 cell systems, EGFR and Cbl expression constructs, ubiquitin fusion proteins, and GFP-tagged wild type and mutant Cbl proteins in assays of receptor downregulation, recycling, marker colocalization, trafficking, and degradation. Based on our data, we reject all three hypotheses. 1) Ubiquitin in complex with EGFR is not sufficient to move receptors from the limiting membranes of endosomes onto their luminal vesicles. This finding contradicts the outcome that was predicted on the basis of yeast trafficking investigations. 2) Forced retention of ligand-activated EGFR at the limiting membrane of early endosomes fails to prevent its degradation, in the absence of additional inhibitory signals. This is consistent with a report that EGFR delivery to the MVB lumen is not essential for receptor degradation. 3) Non-conserved residues in the Cbl C-terminus block EGFR degradation at the endosomal trafficking checkpoint, unless their activity is countered by a conserved functional domain within Cbl 1-436. Through our studies, we have identified a new regulatory mechanism controlling EGFR trafficking and fate.

440

The Saccharomyces cerevisiae Na+ ATPase exporter ENa1 is a yeast epsin-specific endocytic cargo.

A. Sen[1], D. Mukherjee[1], D. Glover[1], C. B. Hannah[1], R. C. Aguilar[1]; [1]Purdue University, West Lafayette, IN

The Epsins are an essential family of endocytic adaptors conserved across evolution. Their endocytic functions have been proposed to be redundant with the ones from other adaptor proteins such as the Ap180s (Maldonado-Baez, Dores). Therefore, to date no physiologically relevant cargo has been identified to depend exclusively on the yeast epsins for internalization. In contrast, mammalian epsin has been reported to be important for the endocytosis of the epithelial sodium channel (ENaC) and epidermal growth factor receptor (EGFR). Although there are no obvious EGFR-homologs in yeast, several ion transporters have been identified, including sodium pumps. Here we report that in budding yeast, internalization of the Na+ ATPase exporter ENa1 (Exitus Natru 1) depends specifically on epsins. Specifically, we determined that while in wild type cells a major fraction of ENa1 is localized in internal structures, in cells lacking both yeast epsins, the transporter predominantly accumulated at the plasma membrane. In contrast, in cells lacking both Ap180s, localization of ENa1 was indistinguishable from wild type. Importantly, the ENa1 localization defect observed in epsin knock-outs could be rescued by re-introduction and expression of either of the two yeast epsin paralogs, Ent1 or Ent2. Further, we established that the C-terminal epsin endocytic determinants are necessary for ENa1 internalization. We anticipate that this finding will provide the basis for more detailed studies of the role of the epsin protein family in endocytosis.

441

Common Membrane Trafficking Defects of Disease Associated Dynamin 2 Mutations.

Y-W. Liu[1], V. Lukiyanchuk[1], S. L. Schmid[1]; [1]The Scripps Research Institute, La Jolla, CA

Dynamin (Dyn) is a multidomain and multifunctional GTPase best known for its essential role in clathrin-mediated endocytosis (CME). Dyn2 mutations have been linked to two human diseases, Centronuclear Myopathy (CNM) and Charcot-Marie-Tooth (CMT) disease. Paradoxically, although Dyn2 is ubiquitously expressed and essential for embryonic development, the disease-associated Dyn2 mutants are autosomal dominant, but result in slowly progressing and tissue-specific diseases. Thus, although the cellular defects that cause disease remain unclear, they are expected to be mild. To gain new insight into potential pathogenic mechanisms we utilized mouse Dyn2 conditional knock-out cells combined with retroviral-mediated reconstitution to

mimic both heterozygous and homozygous states and characterized cellular phenotypes using quantitative assays for several membrane trafficking events. Surprisingly, none of the four mutants studied exhibited a defect in CME, but all were impaired in their ability to support p75/neurotrophin receptor export from the Golgi, the raft-dependent endocytosis of cholera toxin, and clathrin-independent endocytosis of EGFR. While it will be important to study these mutants in disease-relevant muscle and neuronal cells, given the importance of neurotrophic factors and lipid rafts in muscle physiology, we speculate that these common cellular defects might contribute to the tissue-specific diseases caused by a ubiquitously expressed protein.

442

Late stages of antibody transcytosis in the mammalian neonatal small intestine.

M. S. Ladinsky[1], K. E. Huey-Tubman[1], P. J. Bjorkman[1]; [1]Biology, California Institute of Technology, Pasadena, CA

Humoral immunity in neonatal mammals is conferred from mother to young by transport of maternal antibodies in milk across the intestinal epithelium to the bloodstream. This transcytosis is directed by the neonatal Fc receptor (FcRn) in specific cells of the proximal small intestine (duodenum and jejunum). In earlier work (He et al (2008)) we defined structural features of early events in the FcRn transcytotic pathway using electron tomography to follow enhanced, nanogold-labeled Fc in the jejunum of neonatal rats. In conjunction with immuno-EM, this approach allowed us to resolve and identify an intricate series of interconnecting vesicles and tubules through which the Fc-FcRn complex travels from the apical (luminal) to the basolateral (bloodstream) side of the epithelium. We are now using these methods and large-area electron tomography to characterize later stages of FcRn transport and observe where and how Fc exits the basolateral epithelium in route to the bloodstream. Neonatal rats were fed nanogold-tagged Fc. Following short (~10-15min) chase times, samples of jejunum were excised and rapidly cryo-immobilized by high-pressure freezing. Nanogold was enhanced at low temperature during subsequent freeze-substitution (He et al (2007)). Tomography of the embedded tissue detected enhanced Fc-gold in membranous compartments distal from the apical surface. These include multivesicular bodies and tubulovesicular elements analogous to those reported in the earlier study. Gold was detected in lateral intercellular spaces (LIS), but pools of gold were often concentrated in dilated regions of the LIS, typically at the junction of three epithelial cells. As the basolateral LIS is open to the highly vascular lamina propria, these dilated regions may contain Fc exit domains and the pooling effect may be due to eddys in the bulk flow of liquid through the channel.

443

The Insulin Receptor Translocates to the Nucleus to Regulate Cell Proliferation and Liver Regeneration.

M. J. Amaya[1], M. C. F. Castelubеr[2], D. L. Almeida[2], M. C. X. Pinto[2], L. A. M. Arantes [2], L. M. Andrade[2,3], A. C. N. Pinheiro[2], E. A. Fonseca[2], G. B. Menezes[4], A. M. de Paula[5], R. R. Resende[6], M. H. Nathanson[1], M. F. Leite[2,7]; [1]Internal Medicine, Yale University, New Haven, CT, [2]Physiology and Biophysics, Federal University of Minas Gerais, Brazil, [3]René Rachou Research Center, Oswaldo Cruz Foundation, Brazil, [4]Morphology, Federal University of Minas Gerais, Brazil, [5]Physics, Federal University of Minas Gerais, Brazil, [6]Nanobiotechnology Laboratory, Federal University of São João del Rei, Brazil, [7]Howard Hughes Medical Institute

Insulin regulates such varied processes in the liver as glucose metabolism and cell proliferation. Insulin's biological actions are mediated by the Insulin Receptor (IR), a Receptor Tyrosine Kinase. The IR translocates to the hepatocyte nucleus upon stimulation with insulin to initiate inositol 1,4,5-trisphosphate (InsP3)-mediated calcium (Ca2+) signals. The aims of the present

study were to determine the mechanism by which the receptor reaches the nucleus and to understand the physiological role of these InsP3-dependent nuclear Ca2+ signals. Western Blot of non-nuclear and nuclear fractions and confocal immunofluorescence were used to detect the translocation of the receptor to the nucleus of SkHep-1 cells. Cell surface biotinylation and streptavidin pull-down were performed to determine whether the receptors that reach the nucleus originated at the plasma membrane. siRNA knockdown studies were performed to establish the endocytic mechanism of translocation. Nuclear and cytosolic Ca2+ signals were monitored by time-lapse confocal microscopy under control and nuclear InsP3 buffering conditions to assess the importance of nuclear InsP3 in insulin-induced Ca2+ signals. BrdU and partial hepatectomy studies were carried out in rats under control and nuclear InsP3 buffering conditions to analyze the importance of nuclear InsP3 in insulin-induced cell proliferation and liver regeneration. Biotinylated IR was found in the nuclear fractions after insulin stimulation, supporting the conclusion that the receptor translocates from the plasma membrane to the nucleus of SkHep-1 cells. Clathrin heavy chain and caveolin-1 siRNA knockdown each resulted in a decrease in nuclear IR after insulin stimulation, and simultaneous knockdown of both had an additive effect, suggesting that either of these endocytic pathways can participate in translocation of the receptor to the nucleus. Nuclear InsP3 buffering lead to the inhibition of insulin-induced Ca2+ signals throughout the cell. Furthermore, nuclear InsP3 buffering resulted in a decrease in BrdU uptake as well as in liver weight after partial hepatectomy, providing evidence that insulin-induced Ca2+signals depend on nuclear InsP3 and that the Ca2+ signals generated in the nucleus regulate insulin-induced cell proliferation and liver regeneration. Together, these observations demonstrate that insulin induces a subpopulation of IR to move from the plasma membrane to the nucleus in order to mediate insulin’s effects on liver growth and regeneration, and that InsP3 and Ca2+ signaling pathways within the nucleus are responsible for these particular actions of insulin.

444

Cross-talk between Clathrin-dependent and Clathrin-independent Endocytic Entry and Trafficking Pathways.

D. Dutta[1], J. G. Donaldson[1]; [1]Laboratory of Cell Biology, NHLBI, NIH, Bethesda MD, Bethesda, MD

Endocytosis can be divided into two types based on the involvement or not of the clathrin coat. Clathrin-dependent endocytosis (CDE) is reliant on clathrin, adaptor proteins such as AP2 and dynamin whereas clathrin-independent endocytosis (CIE) occurs independently of clathrin, AP2 and dynamin. Much is known about CDE, the molecular machinery and the cargo carried, but increased attention is focusing on CIE, identifying the cargo carried and their intracellular itinerary. We have been studying CIE in human cells and have identified an endosomal sorting system that takes place in HeLa cells that sorts CIE cargo after endocytosis. CIE cargo proteins such as the major histocompatibility complex Class I protein (MHCI) are sorted into endosomes associated with EEA1 and containing transferrin receptor and then are trafficked to late endosomes for degradation or recycled back to the PM via tubular carriers. In contrast, other CIE cargo proteins, such as CD44, CD98 and CD147, avoid trafficking to EEA1-associated endosomes and move directly into recycling tubules. There is some evidence from work in *C. elegans* that these parallel endosomal membrane systems (loaded by CDE and CIE) might communicate and coordinate to maintain plasma membrane homeostasis. Therefore, we set out to examine the effects of blocking CDE on CIE and the subsequent trafficking of CIE cargo proteins. We blocked CDE by expression of the dominant negative form of the adaptor protein AP180 or by si-RNA-mediated depletion of clathrin heavy chain or the mu subunit of AP2. Any of these treatments blocked CDE as assessed by transferrin internalization without affecting internalization of CIE cargo proteins. However, subsequent trafficking of CIE cargo was affected

in cells where CDE was impaired. Most notably the recycling tubules were absent and CD44, CD98, and CD147 now trafficked to EEA1-associated endosomes along with MHCI. They also exhibited increased trafficking to LAMP1-positive compartments and reduced surface expression in cells where CDE was blocked. Similar results of altered trafficking of CIE cargo were observed in the lung epithelial BEAS2B cells. We did not observe any direct colocalization of clathrin or AP2 with CIE endosomal system including the tubules. These observations imply that input from CDE membrane systems affects sorting and itinerary of CIE cargo proteins, supporting the notion of a complex coordination of endosomal trafficking pathways.

445

PKC-Driven Feedback Control of Rapid mu-Opioid Receptor Recycling.

A. Soohoo[1], S. L. Bowersox[1], M. Puthenveedu[1]; [1]Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

Post-endocytic sorting and recycling of G-protein coupled signaling receptors (GPCRs) are critical the re-sensitization of cells to signals. However, little is known about the mechanisms and signals that regulate GPCR recycling.

We have monitored the regulation of individual receptor recycling events mediating the surface insertion of the mu opioid receptor (MOR), a recycling receptor critical for the action of opioid neuropeptides and abused drugs, using Total Internal Reflection Fluorescence (TIRF) Microscopy and multi-color live cell confocal imaging. We determined that Phospholipase C signaling through Protein Kinase C (PKC) regulates the sorting and recycling of MOR. This effect was specific, as PKC signaling did not alter the recycling of other signaling receptors. Further, we have identified the receptor itself as a target for this regulation. Together, our results implicate a PKC-driven positive feedback loop in controlling opioid recycling, and suggest that biochemically diverse mechanisms regulate the post-endocytic sorting of GPCRs in the endosome.

446

NEEP21 and EEA1 early endosome regulators work together to ensure proper trafficking of L1/NgCAM and L1-mediated axon outgrowth.

Z. Lasiecka[1], C. Yap[1], B. Winckler[1]; [1]Neuroscience, University of Virginia, Charlottesville, VA

Neuronal endosomal system is essential for membrane receptor trafficking to and within dendrites and axons, by which it participates in various neuronal functions, such as synaptic plasticity and axon outgrowth. The neuronal endosomal system differs from the canonical endosomal system in other cell types due to unique neuronal function and morphology. Neuronal specializations of the endosomal system include adaptations of cannonical endosomal regulators to neuronal-specific functions as well as introduction of neuronal-specific endosomal regulators. EEA1 (early endosome antigen 1) is an example of a cannonical endosomal regulator, localized to cytoplasmic side of early endosomes, important for homotypic early endosomal fusion in non-neuronal cells. In neurons, EEA1 is localized to the somatodendritic domain where it colocalizes with endocytosed AMPA receptors and endocytosed L1/NgCAM adhesion molecules. NEEP21 (neuron-enriched endosomal protein of 21 kD), an example of a transmembrane neuronal-specific early endosomal regulator localized to Golgi and endosomal compartments in somatodendritic domain, is important for trafficking of L1/NgCAM, AMPAR, and APP. What is the relationship between canonical EEA1-positive endosomes and neuronal-specific NEEP21-positive endosomes, and how they work together to traffic cargo, is not known. To address those questions we carefuly analyzed the colocalization and dynamics of EEA1- and NEEP21-positive compartments as well as dissected the role of those two regulators in trafficking of L1/NgCAM axonal adhesion molecule. We chose L1/NgCAM for our study based

on our previous observations that L1/NgCAM endocytosed in somatodendritic domain, on its way to the axon, colocalizes with both EEA1 and NEEP21 and that NEEP21 function is essential for proper trafficking of L1/NgCAM to the axon. Since L1/NgCAM is known to promote axon outgrowth, a crucial process during development of the nervous system, we used here axon outgrowth as our readout for the role of EEA1 and NEEP21 in L1/NgCAM trafficking. We showed that EEA1 and NEEP21 are localized to two, largerly distinct, populations of early endosomal compartments. EEA1 and NEEP21 labeled compartments have different dynamics, with EEA1-positive endosomes being mostly stationary and NEEP21-positive compartments consisting of both stationary and motile populations. However, we also observed a pool of endosomes containing both EEA1 and NEEP as well as pool of compartments where EEA1 and NEEP21 were positioned adjacent to each other. Live imaging further demonstrated interactions between EEA1-positive and NEEP-positive compartments such as budding/fusion (in case of NEEP21) and recruitment/dissociation (in case of EEA1). Our experiments also show that endocytosed L1/NgCAM colocalizes with both EEA1 and NEEP21 stationary compartments and that both EEA1- and NEEP21-positive endosomes are involved in trafficking of L1/NgCAM from somatodendritic to axonal domain. Expression of dominant negative EEA1 construct, which is known to interfere with EEA1-based homotypic fusion, led to accumulation of L1/NgCAM in somatodendritic endosomes and its misslocalization to somatodendritic membrane. Finally, both, interference with EEA1 and downregulation of NEEP21 led to inhibition of L1-mediated neurite outgrowth, which further demonstrated how the proper trafficking of L1/NgCAM through EEA1- positive and NEEP21-positive somatodendritic endosomal compartments is important for axon outgrowth. In conclusion, these findings point to the existence of neuronal adaptations of early endosomal compartments and the importance of somatodendritic endosomal trafficking of L1/NgCAM in L1-mediated axon outgrowth.

447

Effect of modulating PIP2 on cargo endocytosis and clathrin adaptor recruitment.

B. Docter[2], M. A. Puthenveedu[3], O. A. Weisz[1]; [1]University of Pittsburgh, Pittsburgh, PA, [2]Grand Valley State University, Allendale, MI [3]Carnegie Mellon University, Pittsburgh, PA

Localized synthesis of phosphatidylinositol 4,5-bisphosphate (PIP_2) at clathrin coated pits is crucial for the recruitment of adaptors and other components of the internalization machinery, as well as in regulating actin dynamics during endocytosis. Plasma membrane PIP_2 in nonpolarized cells is generated by 5' phosphorylation of phosphatidylinositol 4-phosphate mediated by any of three phosphatidylinositol 5-kinase type I (PIP5KI) isoforms (α, β, or γ). We found that PIP5KIβ over-expression increased apical endocytosis of the polymeric immunoglobulin receptor (pIgR), but had no effect on basolateral endocytosis. In contrast, overexpression of PIP5KIα and γ had no effect on endocytosis of pIgR from either cell surface domain. Overexpression of each isoform significantly increased PIP_2 levels in non-polarized cells, however only PIP5KIβ significantly increased PIP_2 levels in polarized cells. Increasing PIP_2 by overexpression of PIP5KIβ also decreased current of the apical sodium epithelial channel (ENaC) in polarized cortical collecting duct cells, consistent with an increase in channel endocytosis. In contract, PIP5KIβ increased surface expression of another channel, ROMK (Weixel et al., 2007, JBC, 282, 36534–36542). We hypothesized that differential recruitment of ENaC and ROMK clathrin adaptors to the apical surface in response to elevated PIP_2 could account for this difference in channel response. To test this we performed liposome sedimentation assays with purified recombinant PIP_2 binding domains of epsin and ARH, the ENTH and PTB domains, respectively. Preliminary data indicate that the PTB domain bound to PIP_2 containing liposomes with higher affinity than the ENTH domain, suggesting that increases in PIP_2 may selectively enhance ENTH domain recruitment to membranes.

448

Rab7 mutants involved in Charcot-Marie-Tooth disease exhibit delayed growth factor receptor transport and altered endosomal signaling.

S. BasuRay[1], M. N. Seaman[2], S. Mukherjee[3], A. Wandinger-Ness[1]; [1]Department of Pathology & Cancer Research and Treatment Center, University of New Mexico, Albuquerque, NM, [2]Department of Clinical Biochemistry,Cambridge Institute of Medical Research, University of Cambridge,Cambridge, United Kingdom, [3]Endocrine Division, Mayo Clinic and Foundation, Rochester, MN

Rab7 belongs to the family of small GTPases and is a master regulator of early to late endocytic membrane transport. Four missense mutations in the late endosomal Rab7 GTPase i.e.L129F, K157N, N161T and V162M cause the autosomal dominant peripheral neuropathy Charcot-Marie- Tooth type 2B (CMT2B) disease. As yet, the pathological mechanisms connecting mutant Rab7 protein expression to altered neuronal function are undefined. Here, we analyze the effects of Rab7 CMT2B mutants on epidermal growth factor (EGF) dependent intracellular signaling and trafficking. HeLa cells stably expressing Rab7 CMT2B mutants stimulated with Alexa 555 labeled EGF exhibited delayed association with LAMP1-positive late endosomes and lysosomes and slowed EGF receptor degradation following EGF stimulation. Expression of all Rab7 CMT2B mutants enhanced and prolonged EGFR activation as well as enhancing Erk1/2 activation. Rab7 CMT2B mutant proteins colocalized with the late endosomal/lysosomal marker LAMP1 and exhibited a tight, perinuclear clustering of the endosomes. Interestingly, the nuclear activation of Elk-1, a downstream target of Erk1/2 was decreased by the disease mutants similar to what is reported for cells overexpressing the constitutively active Rab7Q67L mutant. Our results suggest that in the disease state, Rab7 CMT2B mutants impair growth factor receptor trafficking and in turn down-regulate nuclear signaling. In addition, intracellular positioning of signaling endosomes plays a key role in determining the altered endosomal signaling. In conclusion, the data demonstrate a mechanistic link between impaired trafficking by Rab7 CMT2B mutants and altered Erk1/2 signaling from perinuclear, clustered signaling endosomes as a causal effect of disease pathogenesis.

449

The Exocyst Component Exo84 and EHD3 Cooperate in Endosome Recycling.

J. Schmidt[1], J. Rahajeng[2], S. Caplan[2], W. Guo[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]University of Nebraska Medical Center, Omaha, NE

The exocyst is an octameric protein complex mediating the tethering of secretory vesicles to the plasma membrane before fusion. We report that the exocyst subunit, Exo84, interacts with the dynamin-like EHD proteins both in vitro and in cells. Exo84 contains a specific motif with amino acids NPFEDE that is responsible for binding to a hydrophobic pocket within the EH domain of EHD3. In addition, Exo84 and EHD3 co-localize on Rab8-containing endosome membrane tubules, and EHD3 is needed for the recruitment of Exo84 to these tubular structures. Exo84 is known to be a direct downstream effector of the GTPase RalA. Our data show that when RalA is pre-bound to Exo84, Exo84 can no longer bind to EHD3 indicating that RalA and EHD3 compete for Exo84 binding. The interactions and activities of RalA, Exo84, and EHD3 are important for endosome localization and trafficking. We propose a sequence of activation and recruitment of Exo84 to the highly-curved tubular domains of endosomes where fission of transport carriers is coordinated with the targeting and tethering functions of Exo84.

A Model System to Study Turnover of Plasma Membrane Proteins.

D. Karabasheva[1], N. B. Cole[1], J. G. Donaldson[1]; [1]NIH/NLHBI, Bethesda, MD

The turnover of plasma membrane (PM) proteins is an essential and regulated function of cells. Cytoplasmic sorting signals, such as ubiquitination, facilitate the down-regulation of cell surface receptors resulting in their delivery to late endosomal compartments for degradation. Typically, measuring turnover of cell surface proteins entails non-specific labeling of the entire cell surface with biotin, followed by immunoprecipitation and detection with protein-specific antibodies. Here, we take advantage of the SNAP-tag technology that allows labeling of specific fusion proteins on the cell surface. The SNAP-tag is a variant of a 20 kDa DNA repair protein (O6-alkylguanine-DNA alkyltransferase), which can be covalently labeled with fluorescently tagged benzylguanine derivatives (BG). The interleukin 2 receptor alpha subunit/CD25 (also known as Tac) is a type I membrane protein that has been used to identify cytoplasmic sorting sequences in a variety of membrane trafficking studies. When expressed in cells CD25 enters by clathrin-independent endocytosis (CIE), but uses clathrin-dependent endocytosis (CDE) when the C-terminus is modified with dileucine/isoleucine residues. Chimeras of the SNAP-tag with CD25 were expressed in HeLa cells, and an initial PM pool of BG-labeled SNAP-CD25 was followed by immunofluorescence microscopy (with BG-Alexa Fluor 488), and by gel electrophoresis (with BG-IR800) to monitor its degradation in pulse-chase studies. By immunofluorescence microscopy SNAP-CD25 entered cells by CIE, whereas SNAP-CD25-LI entered cells by CDE. SNAP-CD25 exhibited a half-life of 5 h, whereas SNAP-CD25-LI had a half-life of 2.5 h, both of which were extended in the presence of lysosomal inhibitors. Turnover of PM proteins is regulated in part by ubiquitination, typically on cytoplasmic lysine residues. CD25 contains one lysine residue in its cytoplasmic tail, which we mutated to arginine (K to R). SNAP-CD25R entered cells through CIE but its half-life was greater than 8 h. Interestingly, the turnover of SNAP-CD25-GPI, a chimera anchored to the membrane through a GPI anchor and thus lacking a cytoplasmic domain, was also greater than 8 h. These results support a role for ubiquitination in the turnover of CD25. We have extended these assays to examine the turnover of a number of proteins that enter cells by CIE and found that coexpression of known interacting partners of selected cell surface proteins can greatly influence their rates of degradation.

Shank2 traffics with albumin-laden endosomes in human podocytes.

E. Dobrinskikh[1], K. Okamura[1], J. Kopp[2], J. Blaine[1], R. B. Doctor[1]; [1]Department of Medicine; University of Colorado, Denver, Aurora, CO, [2]NIDDK in Bethesda, MD

Podocytes play a key role in forming the glomerular filtration barrier and restricting the unimpeded flux of serum proteins into the nephron. Podocyte clearance of albumin from the glomerular basement membrane is also thought to play an essential role in maintaining the glomerular filtration characteristics but the capacity and mechanisms for albumin clearance by podocytes is undetermined. The present study shows that over 30 min, cultured human podocytes take up significant amounts of albumin in a temperature sensitive manner. Confocal microscopy shows that FITC-albumin co-localize with megalin and the neonatal Fc receptor (FcRn), two receptors implicated in albumin uptake and translocation in renal proximal tubules cells. FITC-albumin also co-localizes with markers for early endosomes (EEA1) and lysosomes (LAMP1). Shank2, a PDZ protein implicated in coordinating epithelial cell endocytosis also co-localizes with FITC-albumin containing endosomes. Image analysis at different focal planes from the basal membrane to the top of the cell after 0, 30, 60 and 120 min following a 10 min FITC-albumin pulse revealed distinct spatiotemporal patterns of Shank2-associated FITC-albumin endosomes with FcRn. These observations indicate that podocytes have a definitive

pathway for albumin endocytosis and that Shank2 is positioned to direct the trafficking of albumin-laden endosomes.

452

Trafficking of GluA2 flip receptors and stargazin upon application of glutamate.

L. M. Stone[1], K. M. Partin[1]; [1]Biomedical Sciences, Colorado State University, Fort Collins, CO

AMPA receptors are post-synaptic, ionotropic glutamate receptors that play a key role in fast excitatory neurotransmission. Individual receptors consist of 4 subunits (GluA1-4) that are one of two splice isoforms: flip or flop. The presence and composition of AMPA receptors at synapses is dynamic, and contributes to synaptic plasticity, long-term potentiation and long-term depression. Altering the normal synaptic composition of AMPA receptors can lead to pathological conditions. For example, decreasing the GluA2 component of AMPA receptors may lead to increased calcium flow into cells, excitotoxicity and subsequent cell death. Abnormal targeting of AMPARs to the cell membrane impacts neuronal signaling and can be caused by defects in transmembrane AMPA receptor regulatory proteins (TARPs) such as stargazin, that normally target the receptors to the membrane. Exposure of AMPA expressing cells to glutamate or other agonists also affects the distribution of AMPARs and provides a way to study receptor and TARP trafficking in response to external stimuli. Previous biochemical analyses suggested that exposure to agonist differentially affects the distribution of AMPA receptors and stargazin, and that glutamate receptors and stargazin separate upon application of agonist (Tomita et al., 2004). To investigate the trafficking of AMPARs and stargazin more closely, we used confocal microscopy of HEK cells expressing yellow fluorescent protein-tagged GluA2 flip wild-type receptors (GluA2i-wt-yfp) and cyan fluorescent protein-tagged stargazin (stg-cfp) and observed the changes in protein distribution following a brief exposure to glutamate mimicking synaptic events. In HEK cells transiently expressing stg-cfp and GluA2i-yfp, stargazin was primarily associated with the membrane, whereas the glutamate receptor was found both cytoplasmically and associated with the membrane. In approximately 50% of the cells examined, the pattern of fluorescence for both proteins remained stable following application of glutamate, resembling the fluorescence pattern of control cells over time. In the remaining cells, the patterns of stg-cfp and GluA2i-wt-yfp changed following exposure to glutamate; membrane-associated GluA2 and stargazin expression was minimal at 10 seconds and 1 minute. GluA2-yfp at the membrane peaked at 5-7 minutes and stargazin-cfp peaked 2-6 minutes following exposure to glutamate. Within the intracellular compartment, the fluorescence intensities of the proteins changed in the presence of glutamate, presumably reflecting the movement of proteins into and out of intracellular compartments. These results suggest dynamic regulation of AMPARs and stargazin trafficking in HEK cells and studies are underway to confirm these findings in neurons.

GIV Spatially Coordinates Gαs and Gαi Signaling to Downregulate EGFR.

A. O. Beas[1], V. Taupin[1], C. Teodorof[1], L. Nguyen[1], M. Garcia-Marcos[1], M. G. Farquhar[1]; [1]Cellular and Molecular Medicine, University of California, San Diego, La Jolla, CA

The heterotrimeric G-proteins Gαs and Gαi regulate the endocytic trafficking of activated EGFR and thereby control the strength, compartmentalization, and duration of signaling. Gαi3 forms a complex with activated EGFR at the PM via GIV, a GEF that activates Gαi3 and regulates receptor dynamics at the PM and endosomes. Gαs also binds GIV, facilitates EGFR degradation, and localizes to endosomes. Here we investigated whether Gαi3 and Gαs differentially regulate EGFR dynamics at the PM and endosomes via interaction with GIV. Depletion of Gαs delays endosome maturation with prolonged retention of EGFR at EEA1 early

endosomes, enhanced membrane association of EEA1, and delayed EGFR degradation. The prolonged stay of EGFR in endosomes results in increased endosome-based signaling including EGFR autophosphorylation, recruitment of SH2-adaptors, and phosphorylation of downstream kinases. The effects of Gαs depletion are reversed by an inactive but not an active Gαs mutant and Gαs-GDP directly binds GIV which localizes to endosomes. Depletion of GIV (like depletion of Gαs) increases the membrane association of EEA1 reflecting a predominant role for the interaction between GDP-bound Gαs and GIV in enhancement of trafficking of EGFR through EEA1 early endosomes. In keeping with previous findings, depleting Gαi3 increases early EGFR signaling at the PM and does not affect signaling from endosomes or the membrane association of EEA1, reflecting Gαi3's predominant role in early EGFR dynamics at the PM. These data support a model in which GIV regulates early, PM-based EGFR dynamics via interaction with Gαi3 and later, endosome-based dynamics via interaction with Gαs.

454

Cortical actin modulates trafficking of the KV2.1 channel to the cell surface.

A. V. Weigel[1], K. Ecklund[2], M. M. Tamkun[2,3], D. Krapf[1,4]; [1]School of Biomedical Engineering, Colorado State University, Fort Collins, CO, [2]Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, [3]Biomedical Sciences, Colorado State University, Fort Collins, CO, [4]Electrical and Computer Engineering, Colorado State University, Fort Collins, CO

The voltage gated potassium channel Kv2.1 forms stable 0.5 – 0.15 μm sized clusters on the cell surface of mammalian cells with a density of 15 – 70 molecules/μm^2. Here we are studying the role of the actin cytoskeleton in cluster maintenance and trafficking. Quantum dot (QD) labeled channels allow us to track individual channels with nanometer accuracy. By simultaneously tagging the channel with GFP describes the characteristics of the channels as an ensemble. We have observed both endocytic and exocytic events with fluorescently labeled Kv2.1 channels. We are able to quantify these events by localizing surface channels manually and automatically using a multi-target tracing algorithm. We see that 96% of the insertion sites of recycled QD labeled channels are localized to the edge of Kv2.1 clusters (n = 127). The few channels that do not arrive directly to a cluster diffuse into a cluster where they become trapped within 10 seconds. Actin depolymerizing agents such as swinholide A and cytochalasin D are seen able to have a direct effect on channel localization and targeting. After the application of 5 μM cytochalasin D channels are no longer targeted to clusters (n = 18). Using 80 μM swinholide A, intact clusters dissociate and therefore newly inserted channels arrive outside of clusters. We further investigate channel trafficking by inhibiting clathrin-dependent endocytic events with 80 μM dynasore. We observe that the rate of recycling events is dramatically reduced with the application of dynasore. Analysis of channel lifetime, i.e. the amount of time a channel spends on the cell membrane shows that recycled channels spend significantly less time on the cell surface than newly synthesized channels, both with and without actin depolymerizers and endocytosis inhibitors. After dynasore is applied the time a channel spends on the membrane is increased by 60% (n = 60) showing that trafficking is mediated by clathrin dependent pathways. In cells with no actin or endocytic inhibitors we see the lifetime of a recycled channel is reduced by 27% as compared to newly synthesized channels. Recycled channels in cells treated with cytochalasin D and swinholide A have lifetimes reduced by 28% and 46%, respectively. These results reveal interesting details about Kv2.1 channel trafficking and targeting as well as the maintenance of clusters.

455

Both class 1A PI3K Subunits, p85 and p110, Regulate Rab-mediated PDGFR Signaling and Trafficking.

D. H. Anderson[1,2], J. N. Nyarko[3], M. D. Chamberlain[3]; [1]Cancer Research Unit, Saskatchewan Cancer Agency, Saskatoon, SK, Canada, [2]Oncology / Biochemistry, University of Saskatchewan, Saskatoon, SK, Canada, [3]Biochemistry, University of Saskatchewan

Activated receptor tyrosine kinases recruit many signaling proteins to activate downstream cell proliferation and survival pathways, including phosphatidylinositol 3-kinase (PI3K) consisting of a p85 regulatory protein and a p110 catalytic protein. We have previously shown the p85α protein has GTPase activating protein (GAP) activity towards Rab5 and Rab4, small GTPases that regulate vesicle trafficking events for activated receptors. Expression of a GAP-defective mutant, p85R274A, caused sustained levels of activated platelet-derived growth factor receptors (PDGFRs), enhanced downstream signaling, and resulted in cellular transformation, through alterations in receptor trafficking. Our objective was to determine if p110 also contributed GAP activity towards Rab5, with p85 providing a catalytic arginine residue (R274) and p110β providing switch stabilization functions specific to the GTP-bound state. To accomplish this goal we set out to compare the results from cells expressing individual p85 defects (lacking GAP activity, R274A, generated previously; or lacking p110-binding ability through deletion of residues 478-513, Δ110) with results from cells expressing a double mutant missing both functions. The enhanced and sustained receptor activation (pTyr) and PDGFR levels observed for late times after PDGF stimulation (60 and 120 min) was the most pronounced in cells expressing the p85Δ110+R274A mutation. In contrast, the sustained MAPK activation (pMAPK) noted in p85R274A-expressing cells, was not observed in p85Δ110+R274A expressing cells, and p85Δ110 expression caused a more transient pMAPK activation profile. We propose that p110β may regulate PDGFR trafficking by providing Rab5-GTP switch stabilization that complements the catalytic arginine residue (R274) within p85, and that p85α and p110β work together as a Rab5 GAP. Supported by the CCS (grant #019040).

456

Identification of a point mutation in Rab11-FIP1A as an inhibitor of plasma membrane recycling.

R. E. McRae[1,2], J. C. Schafer[1,2], J. R. Goldenring[1,2]; [1]Cell and Developmental Biology and Surgery, Vanderbilt University Medical Center, Nashville, TN, [2]Epithelial Biology Center, Vanderbilt University Medical Center, Nashville, TN

Protein trafficking and transport are vital aspects of cellular function as cells interact with their environment by internalization and release of cell surface proteins. Aberrant trafficking contributes to diseases including diabetes insipidus, cystic fibrosis, and Alzheimer's disease. Even though different cargoes, such as channels and receptors, are unique to different cell types, plasma membrane recycling is highly conserved among mammals and regulated by a common set of trafficking proteins including Rab small GTPases and their effectors. Rab11a is involved in recycling and interacts with the Rab11-Family-Interacting-Proteins (FIPs). To study how Rab11-FIP1A interacts with other proteins we identified Threonine 197 as a putative 14-3-3 binding site. Mutating Thr197 to an Alanine caused a dramatic dominant negative phenotype in HeLa cells. The normally perinuclear distribution of GFP-FIP1A was condensed into a membranous cisternum with almost no GFP-FIP1A remaining outside of this site. Also, this condensed GFP-FIP1A (T197A) altered the distribution of proteins in the recycling pathway including endogenous Rab4, Rab5, Rab11a, FIP1C, FIP5, and EEA1. This dominant negative mutation also affects transferrin trafficking in HeLas. While transferrin was taken up and recycled out of cells within 1 hour in non-transfected cells, in GFP-FIP1A transfected cells,

transferrin remained in a perinuclear complex with GFP-FIP1A (T197A). In order to understand this mutation and what role it may have on the structure of the protein, we performed Circular Dichroism (CD) Spectroscopy on recombinant purified FIP1A and FIP1A (T197A). Purified FIP1A (T197A) showed a remarkable change in the structure of FIP1A. The T197A mutation shows a more pronounced alpha helical structure than the wildtype protein, which appears to be comprised of a much more random coil structure. The Rab11-FIP proteins in general have flexible or disordered structures. The results here suggest that the T197A mutant may confer a more ordered confirmation that may reflect an "activated" conformation that is dominant negative for trafficking.

Lipids and Membrane Microdomains

457

Investigating the organisation of lipid rafts in mammalian cells.

R. M. Curnock[1], P. Billcliff[1], R. Rollason[1], G. Banting[1]; [1]Biochemistry, University of Bristol, Bristol, United Kingdom

The lipid raft hypothesis "proposes that the lipid bilayer is not a structurally passive solvent, but that the preferential association between sphingolipids, sterols, and specific proteins bestows cell membranes with lateral segregation potential"1. The physical existence of lipid rafts was demonstrated some time ago2 and there is extensive evidence that lipid rafts are small, and that some types might be highly dynamic (reviewed in1,3,4), with rafts providing physical platforms for a diverse range of fundamental and essential cellular processes. Here, we present evidence that the protein tetherin (aka CD317, HM1.24 antigen, BST-2) is an organiser of lipid rafts. Tetherin possesses a short amino-terminal cytosolic domain that interacts indirectly with the actin cytoskeleton via the proteins RICH2, EBP50 and ezrin5, a conventional non-raft localised transmembrane domain and raft localised carboxyl-terminal glycophosphatidylinositol (GPI) anchor6; the two membrane anchors linked by an extracellular region containing a coiled-coil domain7. Tetherin thus provides a mechanical link between lipid rafts and the actin cytoskeleton5. Fluorescence recovery after photobleaching (FRAP) assays have demonstrated that the lateral diffusion mobility of a GPI anchored reporter protein (YFP-GPI) is increased in cells in which tetherin expression has been knocked down. Consistent with this, data obtained using the fluorescent membrane probe Laurdan have shown that a reduction in membrane order is observed in cells in which tetherin expression has been knocked down. These findings suggest that tetherin limits the lateral diffusional mobility of a raft-localised reporter and that tetherin is playing a role in the organisation of more liquid-ordered membrane domains. The results of single particle tracking studies (presented here) designed to monitor the movement of individual reporter proteins within the plane of the lipid bilayer in control cells and in cells in which the expression of tetherin has been knocked down using siRNA are consistent with tetherin playing a role in organising membrane microdomains.

Tetherin is an organiser of lipid rafts.

P. Billcliff[1], R. Rollason*[1], D. Owen[2], I. Prior[3], K. Gaus[2], G. Banting[1]; [1]School of Biochemistry, University of Bristol, Bristol, United Kingdom, [2]Centre for Vascular Research, University of New South Wales, [3]Department of Physiology, University of Liverpool, United Kingdom*

*Contributed equally to the work presented

Tetherin (Bst2, CD317) has been implicated in preventing the spread of HIV1 virions from infected cells by tethering them to the cell surface. The cytosolic domain of tetherin interacts indirectly with the actin cytoskeleton, and its knockdown in polarised epithelial cells leads to a loss of the sub-apical actin network. Whilst the N-terminus of tetherin interacts with the actin cytoskeleton, the glycophosphatidylinositol (GPI)-anchored C-terminus is localised to lipid rafts; this unusual topology of tetherin enables it to link the actin cytoskeleton to lipid rafts. Moreover, the extracellular region of tetherin forms a parallel coiled-coil dimer, which is likely to limit the free diffusion of proteins into and out of lipid rafts, thereby organising lipid rafts. We therefore set out to examine whether tetherin is involved in lipid raft organisation, and here we present evidence that tetherin is indeed involved in the organisation of lipid rafts. Tetherin has previously been shown to activate the NF-κB pathway and, in line with this, increased expression of tetherin upregulates the activity of an NF-κB activated luciferase reporter, consistent with increased expression of tetherin stabilising lipid raft domains and the signalling complexes associated with them. In addition, using a GPI-YFP reporter construct (a lipid raft marker) in concert with fluorescence recovery after photobleaching (FRAP) assays, the lateral diffusion mobility of GPI-YFP was shown to be increased in cells in which tetherin expression had been knocked down – a result consistent with tetherin playing a role in lipid raft organisation. Further, we have employed the membrane dye laurdan in combination with confocal microscopy to demonstrate that a loss of tetherin expression leads to a reduction in membrane order. Together, the results from FRAP, laurdan and NF-κB activation experiments are consistent with tetherin being a regulator of lipid raft organisation.

459

Clustering and Internalization of Toxic Amylin Oligomers in Pancreatic Cells Requires Plasma Membrane Cholesterol.

S. Trikha[1], A. Jeremic[1]; [1]Department of Biological Sciences, The George Washington University, Washington, DC

Self-assembly of the human pancreatic hormone amylin into toxic oligomers and aggregates is linked to the dysfunction of islet beta-cells and pathogenesis of type-2 Diabetes Mellitus (TTDM). Recent evidence suggests that cholesterol, an essential component of eukaryotic cells membranes, controls amylin oligomerization and aggregation on model membranes. However, the question as to whether cholesterol may also influence amylin interactions with the native

pancreatic membranes and cells remains open. In view of this, the current study was designed to investigate amylin binding and internalization pathways in pancreatic rat insulinoma (RIN-m5F) and human islet cells with depleted, normal and enriched plasma membrane (PM) cholesterol levels, and explored the extent to which PM cholesterol and lipid rafts contribute to amylin uptake and toxicity in these cells. Modulatory effects of cholesterol depleting agents, lovostatin (Lov) and methyl-beta cyclodextrin (BCD), or water soluble cholesterol on PM and cellular cholesterol levels were quantified by the Filipin and Amplex Red fluorometric assays, respectively. The extent of amylin toxicity in controls and treatments were quantified and analyzed using 3-(4, 5-Di methylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT) reduction, Lactate Dehydrogenase (LDH) release and Caspase-3/Annexin V apoptotic assays. Immunofluroscence confocal microscopy and western blot analysis were used to study the internalization and accumulation of amylin monomers and oligomers in cells. Depletion of PM cholesterol by lipid raft disrupting agents, BCD and Lov inhibited the internalization of amylin oligomers in both cell types, which in turn enhanced extracellular oligomer accumulation and potentiated amylin toxicity. Confocal microscopy confirmed binding and accumulation of amylin oligomers and to lesser extent amylin monomers in the lipid rafts of cholesterol-enriched but not cholesterol-depleted cells. Biochemical studies demonstrated the accumulation of toxic amylin oligomers in the medium following depletion of PM cholesterol. Replenishment of PM cholesterol from intracellular cholesterol stores, or by addition of water soluble cholesterol restored amylin oligomer clustering at the PM and internalization, which consequently diminished the cell surface coverage and toxicity of amylin oligomers. In contrast to oligomers, amylin monomers followed clathrin-dependent endocytosis, which is not sensitive to cholesterol depletion. Our studies identify lipid raft-mediated and cholesterol-dependent mechanism for selective uptake and clearance of amylin oligomers, impairment of which greatly potentiates amylin toxicity in pancreatic cells.

The first 5 seconds in the life of an endocytic clathrin coated pit.

E. Cocucci[1,2], F. Aguet[1], T. Kirchhausen[1,2]; [1]Cell Biology, Harvard Medical School, Boston, MA, [2]Program in Cellular and Molecular Medicine at Children's Hospital, Boston, Boston, MA

Formation of endocytic clathrin coated pits and vesicles requires the rapid and highly orchestrated generation of a scaffold made of a very large number of interacting proteins whose assembly results in entrapment of cargoes and membrane deformation. Key for this process is the organized recruitment of clathrin triskelions and AP-2 adaptors. In order to understand the molecular events occurring at the early stages of pit formation we developed a method applicable to living cells and based on total internal reflection fluorescence microscopy that allows visualization and tracking with single-molecule sensitivity and 100 millisecond temporal resolution of clathrin and AP-2 as they are recruited during the first few seconds in the life of a coated pit. By combining this imaging method with newly developed analytical tools to cells expressing fluorescently tagged clathrin and AP-2, we established that coated pits start by the simultaneous recruitment of one clathrin triskelion and two AP-2s. This first recruitment step typically lasts ~2 s, followed by a second step of similar characteristics. We also found that there is no need to pre-cluster AP-2s at the site of coated pit formation and that the presence of the phosphoinositide PIP2 is essential for pit initiation.

LC3II content is increased in livers and lipid droplets (LDs) of ethanol-fed rats.

C. A. Casey[1], B. L. McVicker[2], M. A. McNiven[3], T. M. Donohue[1]; [1]Internal Medicine, VA Medical Center & UNMC, Omaha, NE, [2]Internal Medicine, VA Medical Center, Omaha, NE, [3]Biochemistry, Mayo Clinic School of Medicine, Rochester, MN

Autophagy is a major intracellular catabolic pathway that is critical to cellular quality control and is altered in a variety of pathological states. We are examining the trafficking of lipid droplets (LDs) in liver cells during the development of alcohol-induced fatty liver. Our previous work has demonstrated that ethanol administration slows the rate of protein trafficking in liver cells. Because autophagy involves the movement and fusion of lipid droplets with lysosomes and autophagosomes we examined whether chronic ethanol consumption alters lipophagy (i.e. the autophagic sequestration of lipid droplets). **Methods:** Male, Wistar rats were pair-fed a liquid diet containing either ethanol as 36% of calories or isocaloric carbohydrate for 4-6 wk. Rat liver homogenates were fractionated into post-nuclear supernatants (PNS), mitochondria/lysosomes, cytosols, and microsomes, while LDs were separately isolated from the remaining liver. All fractions were subjected to SDS-PAGE and immunoblotting and probed for the lipidated form of the autophagy marker, Atg 8, the microtubule associated protein 1 light chain 3, known as LC3II. **Results:** In ethanol-fed animals, steatosis was clearly evident, as total liver triglyceride was increased 2-3 fold over pair-fed controls. Chronic ethanol feeding significantly increased LC3II content in liver PNS and microsomal fractions by 30% ($p<0.05$) over those of controls; no change was evident in other subcellular fractions. Additionally, LC3II content associated with LDs from ethanol-fed animals was enhanced 5-fold or more over that of controls. Our findings suggest that chronic ethanol feeding to rats activates autophagosome formation in liver ER membranes, as indicated by a rise in LC3II in total liver and microsome fractions. We propose that the large increase in LD-associated LC3II reflects an attempt by the autophagic machinery to sequester lipid droplets for eventual lipolysis.

Lipid droplets are polarized in fission yeast during G2 phase.

A. Meyers[1], P. Dalhaimer[1]; [1]CBE, Univ. of Tennessee, Knoxville, TN

Lipid droplets (LDs) are now being appreciated as active organelles involved in a variety of cellular processes and not just inert storage depots for neutral lipids. There is evidence that LD dynamics are linked to cell cycle progression in both budding and fission yeast. In fission yeast, S. pombe, the number of lipid droplets follows an oscillatory cycle where the number increases during G2 phase and is roughly halved when the septum forms after M phase. We observe that LDs are strongly polarized to the cell tips in a temperature sensitive mutant (cdc25), whose cell cycle is arrested in late G2 phase at 36 °C well before formation of the septum. Here, we investigate the mechanisms for this distribution. Since LDs associate with microtubules in fly embryos, we tested if these mechanisms were related by disrupting the microtubules with nocodazole. LDs were still polarized in cdc25 after addition of nocodazole. However, the addition of latrunculin A to cdc25 cells caused the LDs to be dispersed throughout the cytoplasm. We conclude that LDs are being actively polarized via the actin cytoskeleton. Future experiments will determine whether this is a myosin-based mechanism, and if so which genes are regulating LD-myosin binding.

Acyl-CoA synthetase 3 is dynamically localized to lipid droplets/ER and functions in fatty acid uptake.

M. Digel[1], B. Rudolph[1], C. Du[1], R. Grossmann[1], M. Becker[1], C. Thiele[2], R. Ehehalt[1], J. Fuellekrug[1]; [1]Univ Heidelberg, Heidelberg, Germany, [2]Life and Medical Sciences (LIMES) Institute, Univ Bonn, Bonn, Germany

Cytosolic lipid droplets are storage organelles for neutral lipids derived from endogenous metabolism. Acyl-CoA synthetase family proteins are essential enzymes in this biosynthetic pathway, contributing activated fatty acids.

Immunofluorescence microscopy showed that ACSL3 is localized to both the endoplasmic reticulum and lipid droplets, with the distribution dependent on the cell type and the supply of fatty acids. ACSL3 was effectively translocated from the ER to nascent lipid droplets as observed by live microscopy. Analysis of the N-terminal hydrophobic domain indicates that it forms an amphipathic helix restricted to the cytosolic leaflet of the ER membrane. N-terminal deletion mutants reduced the efficiency of targeting to lipid droplets. Cellular fatty acid uptake was increased by overexpression and reduced by RNA interference of ACSL3.

In conclusion, the structural organization of ACSL3 allows the fast and efficient movement from the ER to emerging lipid droplets. ACSL3 not only esterifies fatty acids with CoA but is also involved in the cellular uptake of fatty acids, presumably indirectly by metabolic trapping. The unique localization of the acyl-CoA synthetase ACSL3 on lipid droplets suggests a function in the local synthesis of lipids.

Testing the effect of drugs on arrays of NPC1 mutations.

S. Mao[1], N. Pipalia[1] K. Subramanian[2] W. Balch[2] F. Maxfield[1] [1]Biochemistry, Weill Cornell Medical College, New York, NY, [2]The Scripps Research Institute, La Jolla, CA

95% of Niemann–Pick disease type C (NPC) disease is caused by mutations in a transmembrane protein, NPC1, that block efflux of cholesterol from late endosomes and lysosomes. This efflux mechanism keeps the cholesterol content in organelles and organelle membranes low in normal cells. Previous studies have found that histone deacetylase inhibitors (such as LBH589) are able to correct the NPC1 phenotype in human fibroblast cells with an NPC1 I1061T mutation. *NPC1*^{I1061T} is the most common mutation observed in NPC1 patients. However, there are more than 100 different clinical mutations in NPC1 patients. The effects of drugs on NPC1 mutations other than NPC1 I1061T are still unclear. In order to examine the effectiveness of histone deacetylase inhibitor treatment on hundreds of different NPC1 mutations simultaneously, a 384-well plate screen has been designed. The NPC1-null human osteosarcoma cell line (U2OS_shNPC1) is used in the screen. U2OS_shNPC1 cells are transfected with mutated NPC1 and GFP coexpression vector (pMIEG3-NPC1) by reverse transfection, which has been optimized in respect to concentration of DNA and transfection reactant. The mutated NPC1 protein is expressed in GFP positive cells. Using this system, we can test the effects of drug treatments on many different NPC1 mutations. The first application will be to determine which NPC1 mutations can be corrected by histone deacetylase inhibitors. This should help in evaluating whether or not histone deacetylase inhibitor treatment is suitable for patients carrying these mutations.

A novel, apical ceramide-enriched compartment (ACEC) regulates ciliogenesis through a complex with ceramide-associated atypical PKC.

Q. He[1], G. Wang[1], M. Dinkins[1], E. Bieberich[2]; [1]Institute of Molecular Medicine and Genetics, Georgia Health Sciences University, Augusta, GA, [2]Georgia Health Sciences University

The primary cilium is an important sensory organelle, the regulation of which is not fully understood. Using an antibody against the sphingolipid ceramide, we found that in polarized Madin-Darby Canine Kidney (MDCK) cells, an apical ceramide-enriched compartment (ACEC) is located at the base of primary cilia. This novel compartment immunostained for the centrosome marker γ-tubulin, the Rho type GTPase cell division cycle 42 (Cdc42), and atypical protein kinase Cζ/λ (aPKC), a kinase activated by ceramide and associated with a polarity protein complex consisting of partitioning defective Par6 and Cdc42. Inhibition of ceramide biosynthesis with Fumonisin B1 prevented co-distribution of aPKC and Cdc42 in the ACEC and severely impaired ciliogenesis. Cilium formation and co-distribution of aPKC and Cdc42 were restored by incubation with N-acetyl or N-palmitoyl sphingosine (C2 or C16 ceramide), or the ceramide analog N-oleoyl serinol (S18). Using a novel isolation method termed "Lipid-vesicle mediated magnetic activated cell sorting" (LIMACS) we isolated ceramide vesicles from ciliated MDCK cells. Mass spectrometric analysis (sphingolipidomics) showed that these vesicles were highly enriched with ceramide, suggesting that the ACEC is functionally involved in ciliogenesis. We also found that ceramide vesicles were enriched with aPKC, consistent with the observation that aPKC co-distributed with the ACEC at the base of the cilium. Expression of a phosphorylation-incompetent but ceramide-binding mutant of aPKC prevented ciliogenesis, which suggested that binding of aPKC to ceramide at the ACEC is critical for cilium formation or elongation. We will now further determine how the ACEC is formed and how the ceramide-aPKC interaction regulates ciliogenesis. This work is supported by NIH and NSF.

The lipid flippase TAT-5 regulates the budding of extracellular vesicles in *C. elegans* embryos.

A. Wehman[1], B. Grant[2], J. Nance[1]; [1]Developmental Genetics, NYU Medical Center, New York, NY, [2]Rutgers University

During cytokinesis and morphogenesis, embryos undergo dramatic changes in cell shape. While the role of the cytoskeleton in regulating these processes is well known, we understand less about the role of the lipid bilayer in modulating cell shape. For example, the asymmetric partitioning of phosphatidylserine (PS) and phosphatidylethanolamine (PE) to one leaflet of the bilayer can affect membrane curvature and influence dynamic membrane events such as cytokinesis. We identified TAT-5, a P4 ATPase predicted to flip phospholipids to the cytoplasmic leaflet of the bilayer, in an RNAi screen for essential regulators of cell contact-induced polarity in *C. elegans*. Loss of TAT-5 also resulted in defects in plasma membrane dynamics during cytokinesis and morphogenesis.
GFP-tagged TAT-5 localized to the plasma membrane and TAT-5 prevented the externalization of PE, but not PS, on the surface of cells. Since TAT-5 acts at the cell surface, we used electron tomography to examine the three-dimensional structure of the plasma membrane at high resolution. Strikingly, loss of TAT-5 caused the large-scale shedding of budding vesicles from the plasma membrane, which disrupted the structure of cell contacts and likely explains the defects in morphogenesis that we observed in *tat-5* embryos. The robust production of extracellular vesicles in *tat-5* embryos depended on the function of RAB-11, the recycling endosome-associated GTPase, as well as ESCRT complex proteins, which normally function in the formation of multivesicular bodies. Homologs of these proteins regulate viral budding,

suggesting mechanistic similarities between these topologically similar membrane budding events. Our findings define the essential role of a P4 ATPase in the regulation of PE asymmetry and extracellular vesicle budding. Our results also suggest that PE externalization could influence dynamic remodeling of the plasma membrane. No proteins were previously known to regulate extracellular vesicle budding, and our findings may provide novel insights into diseases influenced by extracellular vesicles, including viral spread, blood clotting disorders, and tumor metastasis.

Monitoring of Radioprotective Effects of Amifostine on Rat Liver Microsomal Membrane and Brain Tissue Lipids by FTIR Spectroscopy and Microspectroscopy.

G. Cakmak[1], L. M. Miller[2], M. Severcan[3], F. Zorlu[4], F. Severcan[1]; [1]Department of Biological Sciences, Middle East Technical University, Ankara, Turkey, [2]National Synchrotron Light Source, Brookhaven National Laboratory, Upton, NY, [3]Department of Electrical and Electronics Engineering, Middle East Technical University, [4]Department of Radiation Oncology, Hacettepe University, Turkey

Amifostine is the only approved radioprotective agent by the Food and Drug Administration for reducing the damaging effects of radiation on healthy tissues. The purpose of this study was to investigate the protective effect of amifostine against the deleterious effects of ionizing radiation on rat liver microsomal membranes and white matter (WM) and grey matter (GM) regions of brain tissues at molecular level. Sprague-Dawley rats, which were administered amifostine or not, were whole-body irradiated with a single dose of 800 cGy, decapitated after 24 h and liver microsomal membranes and brain tissues of these rats were analyzed using FTIR spectroscopy and FTIR microspectroscopy. The results of the liver microsomal membrane study [1] revealed that radiation caused a significant decrease in the lipid to protein ratio and the degradation of lipids into smaller fragments that contain less CH2 and more carbonyl esters, olefinic=CH and CH3 groups, which could be interpreted as a result of lipid peroxidation. In addition, radiation altered the secondary structure of proteins by inducing a decrease in the â-sheet structures and an increase in the turns and random coil structures. Moreover, a dramatic increase in lipid order and a significant decrease in the membrane dynamics were observed in the irradiated group. The administration of amifostine before ionizing radiation inhibited all the radiation induced compositional, structural and functional damages in the liver microsomal membranes [1]. Brain FTIR imaging results showed that the total lipid content and CH2 groups of lipids decreased significantly and the carbonyl esters, olefinic=CH, and CH3 groups of lipids increased significantly in the WM and GM after exposure to ionizing radiation, which were interpreted as the byproducts of lipid peroxidation. These changes were more prominent in the WM of the brain. The administration of amifostine before ionizing radiation caused significant protective effect against the radiation induced lipid peroxidation in the WM and GM of the brain. In conclusion, this study indicated that amifostine administration to the rats prior to whole body irradiation protects liver microsomal membrane and brain tissue against the radiation-induced damages. In addition, these results suggest that FTIR spectroscopy together with microspectroscopy provides a novel approach to monitor ionizing radiation induced-damage on biological systems. Supported by TUBITAK (SBAG-2939) and by the METU (BAP-2006-07-02-0001).

Investigation of the Cell Membrane Architecture by Single-Molecule Tracking of Peptidic Toxins.

S. Türkcan[1], J-B. Masson[2], M-R. Popoff[3], J-M. Allain[4], A. Alexandrou[1]; [1]Laboratoire d'Optique et Biosciences, Ecole Polytechnique, Palaiseau, France, [2]Physics of Biological Systems Unit, Institut Pasteur, Paris, France, Metropolitan, [3]Anaerobe Bacteria and Toxins Unit, Institut Pasteur, Paris, France, [4]Laboratoire de Méchanique des Solides, Ecole Polytechnique, Palaiseau, France

The cellular membrane is a vital part of the cell, which plays a crucial role in many cellular processes, such as, signaling and trafficking, and pathologies. This study aims at investigating the membrane architecture by probing the motion of two membrane receptors that are exploited by bacterial toxins.

To investigate the membrane, lanthanide doped nanoparticles ($Y_{0.6}Eu_{0.4}VO_4$) are coupled to two different peptidic pore-forming toxins, the α-toxin of *C. septicum* and the ε-toxin of *C. perfingens* [1]. Single molecule tracking (SMT) of receptor bound labeled toxins in the apical membrane of MDCK cells in a wide-field microscope reveals the receptor motion with sub-diffraction resolution of down to 10 nm. The α and ε-toxin receptors both undergo confined diffusion with similar diffusion coefficients of 0.16 ± 0.14 $\mu m^2/s$ in stable domains of 0.5 μm^2 [2].

To analyze the receptor trajectories, we introduced a novel approach based on an inference method [3]. Our only assumption is that the receptor moves according to the Langevin equation of motion. This method exploits the information of the ensemble of the trajectory and the quality of the extracted values is verified through simulations. Both receptors are confined in a spring-like potential with a spring constant of 0.45 pN/µm.

Tracking after cholesterol depletion by cholesterol oxidase and cytoskeleton depolymerization by Latrunculin B, shows that confinement of single receptors is cholesterol dependent and actin depolymerization does not influence the confinement. We propose that the receptors are confined in lipid rafts and that hydrophobic coupling between the receptor and the surrounding lipids or proteins are sufficient to lead to the observed confinement potentials.

Using the nanoparticle labels as a hydrodynamic force amplifier in a liquid flow, tests the response of the receptor to an external force. SMT shows mainly elastic displacements of the receptor over distances up to 10 times the confining domain diameter. Once the flow stops, the receptors return to their initial position indicating attachment to the cytoskeleton.

Characterization of the ezrin/periaxin/desmoyokin/spectrin/ankyrin-B-based macromolecular complexes in lens fiber cells and their potential role in plasma membrane organization and stability.

R. Maddala[1], V. Rao[1,2]; [1]Ophthalmology, Duke University Medical Center, Durham, NC, [2]Pharmacology, Duke University Medical Center, Durham, NC

Purpose: To identify and characterize the molecular mechanisms regulating fiber cell plasma membrane organization and stability in normal and cataract lenses.

Methods: Lens fiber cell cytoskeletal-protein enriched fractions, immunoprecipitations assays, mass spectrometric–based protein identification and immunofluorescence-based co-localization analyses were performed to isolate and characterize the mouse lens fiber cell membrane-associated macromolecule protein complexes.
Results: Lens fibers of post-natal and adult mice revealed a maturation dependent redistribution of periaxin, a myelin sheath stabilizing protein, clustering discretely at the tricellular junctions in mature fiber cells. Periaxin and desmoyokin, the PDZ-domain proteins were found to co-exist in a macromolecular complex with proteins involved in membrane subdomain organization including NrCAM, ankyrin B, β-spectrin, ezrin, filensin and phakanin. Moreover, lens fiber cells were found to express and distribute contactin-1, Caspr2, βIV-spectrin, dystrophin-glycoprotein complex proteins and ion-channel proteins involved in membrane organization and cytoskeletal scaffolding in neuronal cells.
Conclusions: Taken together, these observations provide some key pieces of evidence in support of a critical scaffolding role for the ezrin/periaxin/desmoyokin/ankyrin-b/spectrin-based macromolecular complexes in regulating membrane cytoarchitecture, tri-cellular junctional stability and membrane subdomain organization in lens fibers. Additionally, these observations paved the way for the intriguing and previously unsuspected possibility of conserved parallel molecular mechanisms regulating membrane stability and organization in lens fibers and myelinating neurons.

Membrane potential-gated re-organization of plasma membrane.

J. Malinsky[1], P. Herman[2], J. Vecer[2], P. Vesela[1], W. Tanner[3]; [1]Microscopy Unit, Institute of Experimental Medicine, Academy of Sciences of the Czech Republic, Prague, Czech Republic, [2]Faculty of Mathematics and Physics, Charles University, Prague, Czech Republic, [3]Institute of Cell Biology and Plant Physiology, University of Regensburg, Regensburg, Germany

The existence of highly ordered, sphingolipid-enriched gel microdomains in the plasma membrane of baker's yeast S. cerevisiae was recently proposed [1]. Using membrane order/fluidity reporter dyes trans-Parinaric Acid (tPA) and 1,6-Diphenyl-1,3,5-Hexatriene (DPH), we studied the stability of these membrane microdomains in response to plasma membrane depolarization. A clear effect on fluorescence lifetime of tPA following various depolarization treatments of living BY4742 S. cerevisiae was detected. DPH fluorescence anisotropy, in addition, reported an increase of the global membrane fluidity in the treated cells – a clear indication of homogenization of the dye microenvironment in the depolarized membrane. We conclude that the non-zero transmembrane potential across the membrane is a prerequisite for the existence of gel sphingolipid microdomains in the yeast plasma membrane. This conclusion complements our earlier observation of membrane depolarization-gated decomposition of ergosterol-rich MCC (Membrane Compartment of Can1) microdomains [2] and accents the primary role of membrane potential in plasma membrane microdomain organization.

Caveolin Targeting to Endo-lysosomal Membranes is Induced by Serum Starvation and Perturbations of Lysosomal pH and Cholesterol Content.

D. I. Mundy[1], W-P. Li[1], K. Luby-Phelps[1], R. G. Anderson[1]; [1]Univ Texas Southwestern Med Ctr, Dallas, TX

Caveolin-1 is an integral membrane protein of plasma membrane caveolae, which represent one of the clathrin independent endocytic pathways. Here we report that caveolin-1 collects at the cytosolic surface of lysosomal membranes when cells are serum starved. We show this is due to an elevation of the intra-lysosomal pH and that ionophores and proton pump inhibitors that dissipate the lysosomal pH gradient also trapped caveolin-1 on LE/lysosomes. Accumulation is both saturable and reversible. At least a portion of the caveolin-1 goes to the plasma membrane upon reversal. Several studies have suggested that caveolin-1 is involved in cholesterol transport or homeostasis within the cell. Strikingly, we find that caveolin-1 also accumulates on LE/lysosomal membranes when cholesterol homeostasis is perturbed either by low concentrations of cyclodextrin or when the export of lysosomal cholesterol is blocked using progesterone or U18666A. Under these conditions, live cell imaging shows cavicles actively docking with lysosomes, suggesting these structures may be involved in delivering caveolin-1. A recent paper suggested that caveolin translocates to lysosomes primarily to be degraded. While this is undoubtedly true when tagged caveolins are transiently over expressed, or when PTRF/cavin1 is knocked down and caveolin enters the cell via the bulk endocytic pathway, this is not the case here. Endogenous caveolin is degraded very slowly (t1/2 ~ 23 hours) and is not normally seen on LE/lysosomes in our cells except after these treatments. In addition we show that neither serum starvation nor U18666A change the turnover rate of the endogenous protein or caveolin-1-GFP that is stably expressed in cells confirming that the accumulation on late endosomes/lysosomes is not a consequence of blocked degradation. Cavicles normally shuttle between membranes without a loss of domain identity and when they accumulate on LE/lysosomes after progesterone or U18666A treatment they appear to retain their identity as punctate structures. In contrast, when lysosomal pH is high the caveolin that is associated with LE/lysosomes is evenly distributed over the membrane surface suggesting the structure of the cavicle/caveolae is significantly different. In addition, when the association of caveolin-1 with LE/lysosomes is reversed after serum starvation caveolin-1 leaves by a process that appears not to involve cavicles and is not inhibited by genistein whereas this inhibitor blocks trafficking to the LE/lysosome. We conclude that caveolin-1 normally traffics to and from the cytoplasmic surface of lysosomes during intracellular cholesterol trafficking. A recent paper questioned the existence of the caveosome and suggested that they were seeing caveolin on LE/lysosomes. In stable cell lines we still find structures that are not labeled with either dextran or lysotracker and behave as described previously. These are independent of the LE/lysosomal structures that were observed in treated cells and suggest that the death of the caveosome may be greatly exaggerated.

472

Cholera toxin B-subunit assembles slowly diffusing domains and induces tubulation of the plasma membrane of intact cells.

C. A. Day[1], A. K. Kenworthy[1]; [1]Dept Mol Physiol Biophys, Vanderbilt School of Medicine, Nashville, TN

Shiga toxin and cholera toxin have the intrinsic capacity to crosslink glycolipids via their multivalent membrane binding B-subunits. Recent models suggest toxin binding induces the formation of membrane domains that drive toxin uptake into host cells by a novel toxin-dependent endocytic pathway. How the structure and dynamics of the toxin-dependent domains

that trigger this pathway are regulated is still poorly understood, especially in intact cells. To address this question, we investigated the properties of toxin/glycolipid complexes formed by cholera toxin B-subunit (CTxB) binding to its glycolipid receptor GM1. As predicted by current models, CTxB accumulated in tubular plasma membrane invaginations in cells under conditions where tubule scission is inhibited by actin disruption or ATP depletion. However, these treatments led to the formation of toxin-independent invaginations and protrusions as well, indicating that multiple mechanisms of membrane deformation are initiated under these conditions. Next, we characterized the dynamics of the CTxB/GM1 complex within the plasma membrane prior to its internalization using confocal FRAP. Compared to the dynamics of a representative GPI-anchored protein, transmembrane protein, and lipid probe, the diffusional mobility of CTxB was highly constrained at the cell surface. We show that actin and ATP-dependent processes, but not caveolae act as major regulators of motion of the CTxB/GM1 complex within the plane of the membrane. These findings identify CTxB-induced domains as slowly diffusing structures, which are strongly confined by the actin cytoskeleton. We speculate that coupling of the CTxB/GM1 complex to actin may regulate its uptake into cells by a toxin-dependent mechanism.

473

Control of membrane traffic and synaptic growth signaling by the neuronal F-BAR/SH3 domain protein Nervous Wreck.

A. N. Becalska[1], K. Miao[1], T. L. Eskin[1], A. A. Rodal[1]; [1]Department of Biology, Brandeis University, Waltham, MA

Internalized receptors exhibit subcellular location-dependent signaling properties as they are trafficked through endosomal compartments. Therefore, modulating the machinery that controls receptor traffic between compartments represents a novel mechanism to tune signal output. Nervous Wreck (NWK) encodes an F-BAR/SH3 protein that regulates the traffic and signaling output of synaptic growth receptors at the *Drosophila* neuromuscular junction through its interactions with the membrane, actin nucleation machinery, and other endocytic proteins including dynamin and Dap160/Intersectin. Recently, we reported that Nwk promotes synaptic membrane traffic through a physical interaction with Sorting Nexin 16 (Snx16), a conserved early endosomal membrane-binding protein. Snx16 promotes synaptic growth signaling by the Wingless and BMP pathways, and our live imaging of *Drosophila* larvae reveals that Snx16-positive early endosomes interact transiently with Nwk-containing recycling endosomes in nerve terminals, leading to signal attenuation (Rodal et al., 2011; J. Cell Biol.). Understanding these cellular dynamics will require a deeper analysis of the membrane deforming activities of Nwk and Snx16. Here, we have further addressed the mechanisms involved, and found that the N-terminal F-BAR domain of Nwk has a novel membrane deforming activity that distinguishes it from two other presynaptically expressed F-BAR proteins in *Drosophila*, dCip4 and Syndapin. We have identified unique structural features of the Nwk F-BAR domain, which may confer its special membrane bending properties. Further, we found that the activities of the Nwk F-BAR domain are regulated by intramolecular interactions and by phosphorylation of the F-BAR domain, suggesting that multiple regulatory inputs into Nwk could serve as a knob or switch for modulating intracellular membrane traffic at synapses.

474

'Lipid Raft' Association Determines the Recycling Kinetics but not the Late Endosomal Trafficking of Endocytosed GPI-Anchored Proteins in Mammalian Fibroblasts.

J. R. Silvius[1], R. Leventis[1], M. Refaei[1]; [1]Biochemistry, McGill University, Montreal, Québec, Canada

We have examined the post-endocytic trafficking of phosphatidylethanolamine-polyethylene (PE-PEG-) -anchored protein conjugates, incorporated into CHO and BHK fibroblasts, to test previous proposals that ordered lipid microdomains play important roles in glycosylphosphatidylinositol-anchored (GPI-) protein sorting within endosomal compartments. In CHO cells internalized PE-PEG-anchored proteins, like GPI-proteins and the transmembrane transferrin receptor, are efficiently returned to the cell surface via recycling endosomes. However, PE-PEG-protein conjugates with 'raft-phobic' short-chain or unsaturated lipid anchors recycle rapidly to the plasma membrane at the fast rate observed for the transferrin receptor, while analogous conjugates with 'raft-philic' long-chain saturated lipid anchors recycle at the much slower rate observed for the GPI-anchored folate receptor. Our findings strongly support previous suggestions that the slow kinetics of surface recycling of endocytosed GPI-proteins rests on their potential to associate with ordered lipid microdomains ('rafts').

In BHK cells GPI-proteins initially present at the cell surface gradually accumulate over long time courses (several hours) in late endosomes/lysosomes, trafficking to which has also been proposed to depend on the 'raft' association of GPI-proteins. We show that after internalization, the GPI-anchored folate receptor is largely recycled to the cell surface but that a smaller but significant fraction is instead trafficked to late endosomes/lysosomes; this 'bifurcated' sorting explains the slow net rate at which GPI-proteins from the cell surface accumulate in late endosomes/lysosomes. PE-PEG-protein conjugates with either long-chain saturated or unsaturated lipid anchors both traffic very similarly to GPI-proteins in these cells, suggesting that 'raft' association does not play a significant role in GPI-protein trafficking to late endosomes/lysosomes in these cells. (Supported by the Canadian Institutes for Health Research).

The Nuclear Envelope and Nuclear Pore Complexes

475

Membrane proteins of the endoplasmic reticulum are required for nuclear pore complex and spindle pole body assembly and function.

A. K. Lloyd[1], R. Dawson[1], S. R. Wente[1]; [1]Vanderbilt Unvi Med Ctr, Nashville, TN

As a critical step in gene expression, mRNA must travel from the nucleus to the cytosol for translation. Movement across the nuclear envelope (NE) requires transport through nuclear pore complexes (NPCs), large macromolecular protein complexes that span NE pores. Indeed, all cellular functions are in part regulated by transport of factors through NPCs. While molecules smaller than ~30kDa diffuse freely through NPCs, large proteins and RNA move through the NPC in a directed manner by active transport. During a cell's lifetime, new NPCs are generated in response to the need for survival and function. Without proper NPC formation, neither RNA nor proteins can be correctly transported through the NE. For a new NPC to form in an intact double membrane NE, the fusion of the inner and outer membrane leaflets must occur. Membrane proteins are predicted to mediate this fusion step. The resulting curved pore membrane is thought to be stabilized by structural NPC components which also provide a

scaffold for additional functional components to assemble. While a small number of membrane proteins have been identified as stable components of the NPC, the mechanism by which these proteins function has yet to be elucidated. Previously, we found that Rtn1 and Yop1, membrane bending proteins of the endoplasmic reticulum (ER), play a role in NPC assembly. S. cerevisiae cells lacking Rtn1 and Yop1 have NPC defects including a clustering to one region of the NE. As the spindle pole body (SPB) is also NE embedded in *S. cerevisiae*, we examined *rtn1Δyop1Δ* cells for altered SPB structure and function. Electron microscope images of *rtn1Δyop1Δ* cells revealed abnormalities in SPB structure. Furthermore, mitotic spindles appeared on average shorter and misoriented in dividing cells. These observations potentially reflect the known dual requirement of the essential membrane protein Ndc1 in both NPC and SPB assembly. Recently, others suggested that NPC and SPB biogenesis could act antagonistically through the recruitment and sequestering of common components such as Ndc1. Using *rtn1Δ yop1Δ* cells, we examined this relationship between SPBs and NPCs. Increased expression of Ndc1 rescued defects in both NPCs and SPBs of *rtn1Δ yop1Δ* cells. However, increased expression of NPC specific interaction partners of Ndc1only rescued defects in NPCs while worsening defects in SPB function. We are currently investigating the roles by which these different ER membrane proteins influence NPC stability and potentially initiate NE fusion for pore formation.

The SUMO proteases SENP1 and SENP2 bind to Nup153 and control a cycle of SUMO modification of this nucleoporin.

K-H. Chow[1], S. Elgort[1], M. Dasso[2], K. Ullman[1]; [1]Oncological Sciences, University of Utah, Salt Lake City, UT, [2]National Institutes of Health

The nuclear rim houses a variety of proteins with diverse regulatory functions, ranging from nucleocytoplasmic trafficking, transcription regulation to coordination of cell cycle progression. Numerous enzymes of the mammalian SUMO modification pathway, including two members of the SUMO protease family, SENP2 and SENP1, localize to the nuclear periphery. The SUMO proteases play roles both in processing SUMO during the biogenesis of this peptide moiety and also in reversing SUMO modification on specific targets to control the activities conferred by this post-translational modification. Although interaction with the C-terminal domain of the nucleoporin Nup153 is thought to contribute to SENP2 localization to the nuclear pore complex, little is known about the binding partners of SENP1 at the nuclear periphery. We have found that Nup153 binds to both SENP1 and SENP2 and does so through a dual platform, involving both the unique N-terminal domain of Nup153 and a specific region within the C-terminal FG-rich region. We have further found that Nup153 is a substrate for sumoylation, with this modification kept in check by these two SUMO proteases. Specifically, either RNAi depletion of SENP1/SENP2 or expression of dominantly interfering mutants of these proteins results in increased sumoylation of endogenous Nup153. SENP1 and SENP2 are themselves subjected to dynamic SUMO modification regulated by their own catalytic activity. Interestingly, whereas sumoylation of Nup153 promotes its interaction with SENP1/2, sumoylation of the protease appears to prevent this interaction. These studies reveal a dynamic mechanism that likely contributes to concentrating SENP1 and SENP2 in proximity to the nuclear pore complex. In the case of SENP2, its association with the pore has been previously shown to restrict its enzymatic activity, regulating its ability to target nucleoplasmic SUMO substrates. We are working to further understand the functional implications of the partnerships between Nup153 and SENP1 and SENP2.

Distribution and Quantification of the Nucleolar Channel System of Human Endometrium.

M. J. Szmyga[1], E. A. Rybak[1], E. H. Banks[1], K. D. Whitney[1], A. J. Polotsky[1,2], D. S. Heller[3], N. Santoro[1,2], U. T. Meier[1]; [1]Albert Einstein College of Medicine, Bronx, NY, [2]University of Colorado-Denver, [3]University of Medicine and Dentistry of New Jersey

The Nucleolar Channel System (NCS) is a membranous organelle unique to the nuclei of human endometrial epithelial cells. NCSs are limited to days 19-24 of an idealized 28-day menstrual cycle, which overlaps with the implantation window. NCS presence is robust and independent of fertility status. Overall, NCSs are specific to healthy human endometrium of the secretory phase; they are absent from proliferative endometrium, from other hormonally sensitive human tissue such as breast tissue, from endometrial carcinoma specimens, or from baboon endometrium. Having recently identified molecular markers for these enigmatic structures revealed a unique composition of only a subset of nuclear envelope antigens, e.g. only some nuclear pore complex and inner membrane proteins. To these we now add the nuclear transport factors Ran, karyopherin α, and karyopherin β1, and, as a first component of NCS cores, γ-tubulin despite the absence of α- and β-tubulin. Whether these recent additions are important for NCS formation and/or their function is under investigation.

A major hurdle in NCS study has been their detection and quantification. The former we have overcome using indirect immunofluorescence against specific nuclear pore complex proteins enriched in NCSs. Quantification of NCSs has been hampered by their small, 1µ-diameter and peak appearance in only about 45% of endometrial epithelial cell nuclei. Thus, grading of uterine specimens for NCS presence is done semi-quantitatively as normal versus low or absent. In this manner, we show that NCSs are distributed uniformly throughout the upper endometrial cavity in the 9 NCS-positive specimens out of 42 uteri analyzed. Specifically, the fundus, left and right cornua, and anterior and posterior body exhibited between 89% and 100% of normal NCS presence. In contrast, the lower uterine segment contained significantly fewer NCSs compared to the other five regions (56% vs. 93%, $P<0.01$). This uniform distribution is consistent with a preferred implantation rate reported for the upper part of the uterus. To study NCS distribution at the level of endometrial biopsies, consecutive paraffin sections were stained for NCSs and for histologic assessment; each containing between 20 and 60 glandular cross-sections. Surprisingly, the number of NCSs varied randomly from gland to gland without a trace of a gradient or pattern. Our findings demonstrate a large local variability of NCS numbers despite their even distribution across the upper endometrial cavity. Although some glands were devoid of NCSs, neighboring glands contained NCSs paving the way for automated NCS counting algorithms on 5 to 10 glandular cross-sections. Presently, we are devising an NCS counting tool that determines the number of NCSs per epithelial cell nuclei by analyzing deconvolved Z-series of glands. This will create the first quantitative and unbiased understanding of NCSs within human endometrium.

Oxidative Stress Signaling to the SUMOylation Machinery in Hutchinson-Gilford Progeria syndrome.

S. Datta[1], B. M. Paschal[1]; [1]Center for Cell Signaling, University of Virginia., Charlottesville, VA

We recently reported that expression of the Progerin form of Lamin A in Hutchinson-Gilford Progeria Syndrome (HGPS) reduces nuclear levels of the SUMO E2, Ubc9, as well as nuclear levels of SUMO2/3-modified proteins (Kelley et al. 2011). Given the important role of SUMOylation in nuclear function, we have studied how Progerin inhibits Ubc9 import by analyzing two, inter-related mechanisms: oxidative stress signaling and disruption of the Ran GTPase gradient. Fibroblasts from HGPS patients have elevated levels of reactive oxygen

species (ROS) as detected with dichlorofluorescein (DCF). Induction of oxidative stress by H_2O_2 causes a rapid and reversible redistribution of Ubc9 to the cytoplasm. We therefore tested whether Progerin affects Ubc9 distribution via oxidative stress signaling using Chinese Hamster Ovary cells pre-adapted to oxidative stress (CHO^r). Progerin expression as well as H_2O_2 treatment in the parental CHO line caused Ubc9 to redistribute to the cytoplasm, while the pre-adapted CHO^r line was resistant to the effects of both. Oxidative stress is known to inhibit Ubc9 activity via oxidation of a catalytic Cys93 and subsequent formation of a thioester with the E2 Uba2. Ubc9 with a Cys93Ser substitution is localized to the nucleus and undergoes redistribution to the cytoplasm in response to Progerin and H_2O_2 addition, suggesting that catalytic function is not required for Ubc9 import and cytoplasmic localization is not caused by oxidation-induced heterodimerization with Uba2. In heterokaryon experiments, Ubc9 from Progerin-expressing "donor" cells was competent for nuclear import into nuclei of "acceptor" cells, consistent with the interpretation that it does not undergo assembly into a cytoplasmic E1-E2 complex that precludes nuclear import. Ubc9 localization defects in HGPS could reflect a response to disruption of the Ran GTPase gradient, since Ubc9 import is Ran-dependent and the Ran gradient is disrupted in HGPS. We tested this hypothesis by siRNA depletion of the Ran import factor NTF2, which resulted in a significant reduction in the nucleocytoplasmic Ran gradient and concomitant inhibition of Ubc9 import. Finally, oxidative stress is sufficient to disrupt the Ran gradient. Our observations suggest the model that Progerin effects on nuclear SUMOylation in HGPS are mediated by oxidative stress signaling (ROS) to the Ran GTPase system and inhibition of Ubc9 import. According to our model, drugs that restore the redox state of the cell are predicted to reverse Progerin effects on the Ran System and SUMOylation.

479

Membrane Attachment of Lamin A Reduces Histone H3 Tail Phosphorylation in Progeria.

M. Chatterjee[1], B. M. Paschal[1]; [1]University of Virginia, Charlottesville, VA

Fibroblasts from patients with Hutchinson-Gilford Progeria Syndrome (HGPS) have a disruption in the nucleocytoplasmic gradient of the Ran GTPase (Kelley et al., 2011). Ran gradient disruption, which can be recapitulated in various cell types by expressing the Progerin form of lamin A, is strictly dependent on Progerin attachment to the inner nuclear membrane, since farnesyl transferase inhibition or mutation of the CAAX motif prevent the effect. The Ran gradient defect in Progerin-expressing nuclei persists in heterokaryon fusions with normal cells, suggesting the molecular defect resides within the nucleus and is not transduced through the cytoplasm, and is relatively stable. A strong candidate for transducing the effect of Progerin on Ran is the nucleotide exchange factor RCC1, a nuclear protein that is required to establish the Ran gradient in both interphase and mitotic cells. FRAP analysis of GFP-RCC1 revealed reduced mobility in response to Progerin expression, suggesting the RCC1 chromatin-binding cycle (which is linked to nucleotide exchange) is altered by Progerin. RCC1 interactions with chromatin can be modulated by posttranslational modifications of histones. Since Progerin expression is known to reduce the levels of epigenetic marks on the N-terminal tail of histone H3, we examined whether Progerin expression affects the level of H3 Ser10 phosphorylation in interphase cells. H3Ser10 phosphorylation was dramatically reduced by Progerin transfection in both HeLa and Cos cells. H3Ser10 phosphorylation was reduced in fibroblasts from 3/3 HGPS patients examined ($p\text{-value}<10^{-4}$), while normal levels of the epigenetic mark were observed in fibroblasts from an unaffected parent of a patient. H3Ser10 phosphorylation was also reduced by inhibiting lamin A cleavage with lopinavir, and Progerin that contains a Cys-Ser substitution in the CAAX motif failed to reduce H3Ser10 phosphorylation. Thus, the Progerin-dependent reduction in H3Ser10 phosphorylation is mediated by constitutive membrane attachment of lamin A. Nuclear levels of RSK2, one of the kinases that deposits the phospho-Ser10 mark in interphase, were reduced only slightly by Progerin. Disruption of the Ran gradient by siRNA

depletion of its import factor NTF2 did not reduce H3 Ser10 phosphorylation, suggesting the effect of Progerin on this chromatin mark is not caused simply by defective import of RSK2 or another H3 Ser10 kinase. Our data on H3 Ser10 together with work from other groups on H3 Lys9 and H3 Lys27 trimethylation shows that lamins attached to the inner nuclear membrane can regulate the epigenetic state of chromatin throughout the nucleus.

Trafficking and retention of the *Caenorhabditis elegans* SUN protein UNC-84.

E. C. Tapley[1], D. A. Starr[1]; [1]Molecular and Cellular Biology, UC Davis, Davis, CA

Nuclear envelope SUN/KASH bridges are conserved across eukaryotes and function to maintain nuclear envelope integrity, transmit forces generated in the cytoplasm to the nuclear lamina, and control the stiffness of the global cytoskeleton. Central to all of these functions is the localization and retention of SUN proteins at the inner nuclear membrane. However, the molecular mechanisms used to actively traffic integral membrane proteins from the peripheral ER to the inner nuclear membrane, and retain them there are mostly unknown. In our model of nuclear migration, the *Caenorhabditis elegans* SUN protein, UNC-84, localizes to the inner nuclear membrane and is retained, prior to recruiting the KASH protein, UNC-83, to the outer nuclear membrane.
To better understand how functional SUN-KASH bridges are assembled, we have identified three types of targeting signals (cNLS, SUN-NELS, and INM-SM) in the cytoplasmic/nucleoplasmic domain of UNC-84 that facilitate its localization and function at the inner nuclear membrane. To distinguish whether these signals function in ER to nuclear envelope targeting and/or retention at the inner nuclear membrane, we are examining the kinetics of ER to NE trafficking of both wild-type and mutant versions of UNC-84 using photoactivation, and examining their mobility at the nuclear envelope in HeLa cells. To identify proteins that interact with the cytoplasmic/nucleoplasmic domain of UNC-84, a yeast two-hybrid screen was performed using UNC-84 1-510 and UNC-84 1-385 as baits. The UNC-84 candidate interacting proteins identified have been implicated in ER to Golgi transport, nuclear architecture, nuclear signaling, and pro-nuclear migration. Elucidating these mechanisms in *C. elegans* and mammalian cell culture will provide novel insight into how nuclear membrane biogenesis relates to normal development and the progression of human disease.

481

Functional Analysis of the Lumenal Domain of the SUN Protein UNC-84.

N. E. Cain[1], E. C. Tapley[1], B. Sosa[2], U. Kutay[3], T. U. Schwartz[2], D. A. Starr[1]; [1]Mol & Cellular Bio, University of California Davis, Davis, CA, [2]Biology, MIT, Cambridge, MA, [3]Biochemistry, ETH Zurich, Zurich, Switzerland

Proper positioning of the nucleus is required for development, cell polarization, fertilization, cell motility, and cell division. In most eukaryotes, a nuclear envelope bridge consisting of an inner nuclear membrane SUN protein and an outer nuclear membrane KASH protein form the LINC complex (for linker of the nucleoskeleton to the cytoskeleton) to link the cytoskeleton to the nuclear lamina. Very little is known about how KASH and SUN protein interact in the perinuclear space or how SUN proteins span the perinuclear space to connect the inner and outer nuclear membranes. We hypothesize that during nuclear migration, the forces generated by microtubule motors are transduced through KASH-SUN bridges across the nuclear envelope to the nuclear lamina. We take advantage of a unique model system that allows quantitative observation of nuclear migration events, hypodermal nuclear migration in *C. elegans*. In this system, the KASH protein UNC-83 and the SUN protein UNC-84 bridge the nuclear envelope and recruit microtubule motors to the surface of the nucleus. Here we report the results of mutational

analysis of the large lumenal domain and SUN domain of UNC-84. We find that the majority of the linker domain between the *trans*-membrane domain and SUN domain is not required to facilitate nuclear migration. However the minimal domain required for function contains a predicted coiled-coil, suggesting that in agreement with the recently solved structure of mammalian Sun2, UNC-84 may function as an oligomer. Based on homology modeling of UNC-84 with the structure of the mammalian Sun2 in complex with the nesprin-2 KASH domain, we have undertaken a structure-function study of the SUN domain of UNC-84. We have mutated several conserved residues in the SUN domain of UNC-84 predicted to mediate interaction with KASH domains. We are currently testing the ability of these mutant SUN proteins to be properly targeted to the nuclear envelope and function during nuclear migration. Understanding how nuclear positioning is accomplished will lead to greater insight into organelle positioning in general, as well as potential therapeutic targets for human diseases.

Modeling the interplay between nuclear pore complex assembly and the cell cycle.

A. Vander Heyden[1,2], B. Castle[2,3], D. Odde[2,3], M. Hetzer[1]; [1]The Salk Institute for Biological Studies, La Jolla, CA, [2]Physiology Course, Marine Biological Laboratory, Woods Hole, MA, [3]Department of Biomedical Engineering, University of Minnesota

Nuclear pore complexes (NPCs) perforate the nuclear envelope (NE) of all eukaryotic cells and control traffic between the cytoplasm and nucleus. Pore assembly is spatially restricted to the NE membrane and temporally restricted to the end of mitosis and to interphase. However, it remains unclear how pore assembly is tuned to the cell cycle to achieve a reproducible density of NPCs. Recent work identifies the core nucleoporin Nup96 as a possible bidirectional regulator of cell cycle progression and nuclear pore complex assembly (1). Nup96 is degraded by the anaphase-promoting complex (APC) during mitosis. Since the APC is activated by cyclin-dependent kinase (Cdk) at the G2/M transition, Nup96 levels are linked to Cdk activity. Conversely, Nup96 inhibits the nuclear export of cyclin D and Cdk6 mRNAs. To understand how Nup96 might influence the oscillations of the cell cycle, we modeled the interactions of Nup96, APC, and activated Cdk using a system of three ordinary differential equations, based on a recent minimal model of the cell cycle (2). We find that a negative feedback loop consisting of APC inhibiting Nup96 and Nup96 inhibiting active Cdk slows the period of the cell cycle. Our model recapitulates the experimentally observed cyclical fluctuations in Nup96 levels and Cdk activity. Nup96 levels plummet during mitosis, but rise again through G1 phase after the APC is inactivated. Activated Cdk accumulates while Nup96 is low but begins to plateau as Nup96 levels rise, with the consequence that higher Nup96 levels slow the cell cycle. Above a certain threshold level of Nup96, the oscillations of Cdk activity halt. This outcome predicts that elevated Nup96 may promote exit from the cell cycle. We next incorporated NPC assembly kinetics into the model, using two additional ordinary differential equations to account for total NPCs and NPCs containing Nup96. Interestingly, we find that the model only recapitulates experimental results showing that Nup96 levels tune the cell cycle if Nup96 can incorporate into all NPCs: those assembled postmitotically and those assembled in interphase. Finally, our model predicts that when the cell cycle is longer, a greater number of NPCs will assemble on the nuclear surface. The predictions of this model have interesting implications for our understanding of Nup96 incorporation into NPCs, regulation of NPC density, and regulation of the cell cycle.

Nesprin-1-dependent recruitment of centrosome proteins to the nuclear surface is essential for nuclear alignment in myotubes.

A. Espigat-Georger[1], C. Chemin[1], A. Merdes[1]; [1]Centre de Biologie du Developpement, University Toulouse III, Toulouse, France

In skeletal muscle cells undergoing differentiation, centrosome proteins relocalize from the pericentriolar material to the outer surface of the nucleus. Using cultures of differentiating mouse C2C12 myoblasts, we are addressing the functional significance of this relocalization: During muscle formation, myoblasts fuse into syncytial myotubes. The multiple nuclei in myotubes are positioned evenly along the fibre, with the exception of clusters of nuclei at the neuromuscular junction. Nuclear positioning is believed to be important for correct muscle function and requires the nuclear envelope protein nesprin-1, since defective nuclear positioning has been found in mice lacking functional nesprin-1, mimicking aspects of Emery-Dreifuss muscular dystrophy. Using RNA silencing of differentiating C2C12 cells, we show that nuclear positioning requires the centrosome protein PCM-1, which is recruited early in differentiation to the nuclear envelope in a nesprin-1-dependent manner. PCM-1 is in turn necessary for the recruitment of components of the dynein/dynactin and kinesin motor complexes, thus suggesting that microtubule motors, bound to the nuclear envelope, transport nuclei along microtubules to position them in the myotube.

Brambleberry, a novel nuclear envelope associated protein, regulates nuclear membrane fusion during cleavage stage development.

E. Abrams[1], H. Zhang[1], F. Marlow[1], L. Kapp[1], M. Mullins[1]; [1]Cell and Developmental Biology, University of Pennsylvania School of Medicine, Philadelphia, PA

Compared to later stages, early blastomeres employ modified cell division mechanics presumably to accommodate the nature of the large cells present following zygote formation. During the cleavage stage in zebrafish, karyokinesis involves a step not found at later stages in development whereby individual chromatin masses surrounded by nuclear envelope, called karyomeres, fuse to form a single mononucleus. Using a genetic approach in zebrafish, we identified *brambleberry* (*bmb*), a maternal-effect mutant that disrupts karyomere fusion resulting in the formation of multiple micronuclei. Positional cloning reveals that *bmb* encodes a conserved novel protein with homology to Kar5p, a protein required for pronuclear fusion in yeast. Similar to yeast, Bmb contains a predicted coiled-coiled domain and two C-terminal transmembrane domains. However, unlike yeast, Bmb contains a highly conserved 69-residue domain near the N-terminus that has not been previously described in any other protein, but is present in many potential Bmb homologues in both invertebrates and vertebrates. To gain further insight into how Bmb functions, we generated Bmb polyclonal antibodies. Immunofluorescence experiments reveal dynamic Bmb localization throughout the cell cycle during the cleavage stage. At late prophase, Bmb protein becomes concentrated adjacent to the condensing chromatin. Subsequently, during metaphase Bmb foci are more evenly distributed in the vicinity of the mitotic spindle and ER. Putative Bmb-associated vesicles then assemble on the separating chromosomes during anaphase. As karyomeres form, Bmb protein is found at the nuclear envelope with prominent puncta evident near karyomere-karyomere interfaces corresponding to pre-, post- and active fusion sites. Our studies identify the first factor acting in karyomere fusion and suggest that specialized proteins and mechanisms are necessary for proper nuclear division in large dividing blastomeres. Moreover, since the nuclear envelope is composed of two distinct membranes, the discovery of Bmb has significant implications for the

study of membrane fusion, as most of our molecular understanding in metazoans is limited to fusion of single membrane structures.

485

Embryonic nucleus formation requires chromatin-induced microtubule disassembly.

J. Z. Xue[1], E. M. Woo[1,2], L. Fish[1], L. Postow[1], B. T. Chait[2], H. Funabiki[1]; [1]Laboratory of Chromosome and Cell Biology, Rockefeller University, New York, NY, [2]Laboratory of Mass Spectrometry and Gaseous Ion Chemistry, Rockefeller University, New York, NY

Chromatin-dependent signals control a variety of vital processes in mitosis. Here we report a novel chromosome-binding protein, Vespera, from *Xenopus* egg extracts, which is exclusively expressed in the early frog embryo and is the homolog of mammalian pluripotency genes *Dppa2* and *Dppa4*. Vespera is SUMOylated upon binding to chromatin by the nuclear matrix-associated E3 ligase PIASy, and this modification is essential for Vespera's activity. Specifically, SUMOylated Vespera destabilizes microtubules in the vicinity of chromosomes, and overexpression of Vespera abolishes metaphase spindle assembly. When Vespera-depleted metaphase extracts are released into interphase to initiate nucleus formation, persistent microtubules are observed, leading to defective nucleus assembly, pinched, lobed nuclear morphology and severely retarded nuclear expansion. Removing persistent microtubules using the drug nocodazole rescues nuclear morphology, and moreover induction of ectopic microtubules using the drug taxol causes the same nucleus assembly defects in control extracts, while it causes no additional defect in Vespera-depleted extracts. Together, these activities of Vespera functionally oppose those of the kinase Aurora B, which instead stabilizes microtubules and inhibits nucleus assembly. Indeed, co-depletion of Aurora B rescues the nucleus assembly defects of Vespera depletion. Similarly, spindle assembly is normally abolished in extracts depleted of Aurora B, but is partially restored by co-depletion of Vespera. Hence, chromatin-induced activation of the antagonistic activities of Vespera and Aurora B finely balances the regulation of microtubule dynamics at mitotic exit, ensuring the critical integrity of nuclear division in the embryo.

486

Do Nuclear Proteins Reorganize During Mitosis to Form an Elastic, Gel-like Spindle Matrix?

C. Yao[1], Y. Ding[1], U. Rath[2], D. J. Sharp[2], J. Girton[1], K. M. Johansen[1], J. Johansen[1]; [1]Biochemistry, Biophysics & Molecular Biology, Iowa State University, Ames, IA, [2]Physiology and Biophysics, Albert Einstein College of Medicine, Bronx, NY

The idea of a spindle matrix has long been proposed in order to account for poorly understood features of mitosis. However, its molecular nature and structural composition have remained elusive. In *Drosophila* we have recently identified four nuclear proteins, Skeletor, Chromator, Megator, and EAST that interact with each other and that redistribute during prophase to form a fusiform molecular complex that persists in the absence of polymerized tubulin. Dual-imaging studies of Chromator-GFP and α-tubulin-mCherry suggests that whereas Chromator reorganizes away from the condensing chromosomes at prophase and fills the entire nuclear space, it does not attain an obvious spindle-like morphology until the microtubules begin invading the nuclear space. This suggests that the spindle matrix may exist as a malleable gel-like structure that reorganizes in response to the incoming microtubules, thereby giving rise to a spindle-like appearance. Furthermore, if microtubules are depolymerized with colchicine just prior to metaphase, we find that the spindle matrix decompresses and coalesces around the chromosomes suggesting that microtubules acts as "struts" stretching the spindle matrix toward the poles with the matrix conferring an elastic inward force. Measurements of fluorescence

intensities across the width of an individual spindle structure immunostained with both anti-α-tubulin and antibodies to the spindle matrix protein Skeletor revealed that the peaks of tubulin labeling are notably distinct from the peaks of Skeletor labeling consistent with what might be observed for a gel-like matrix that embeds the invading microtubule spindle structure. Interestingly, a C-terminal deletion construct of the spindle matrix protein Megator diffuses away from the spindle region during mitosis, indicating that Megator requires its coiled-coil N-terminal domain for spindle matrix localization. In addition, this finding suggests that specific interactions between spindle matrix molecules are necessary for them to form a complex confined to the spindle region. Supported by NSF grant MCB0817107.

The structure and dynamics of nuclear pore proteins in living cells.

C. Atkinson[1], A. Mattheyses[1,2], M. Kampmann[3,4], S. Simon[1]; [1]Laboratory of Cellular Biophysics, The Rockefeller University, New York, NY, [2]Department of Cell Biology, Emory University, Atlanta, GA, [3]Laboratory of Cell Biology, The Rockefeller University, New York, NY, [4]Department of Cellular and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA

Transport across the nuclear membrane occurs through the nuclear pore complex (NPC), which is a large multiprotein complex with a molecular mass greater than 50MDa. The structure of the NPC has been characterized by electron microscopy but the orientation of individual proteins within the complex is unknown. The transport through the NPC is both selective and rapid. This transport involves the phenylalanine glycine repeat nucleoporins (FG nups). However the mechanism by which the FG-nups selectively transport cargo remains unclear. We have developed a theoretical framework which exploits the symmetry of the NPC and its organization in the nuclear envelope in order to resolve the order and disorder of individual protein domains within the complex. Specific domains of individual nucleoporins (nups) were tagged with GFP and examined using fluorescence polarization microscopy to determine their orientation and dynamics. We characterized the domain organization of the FG nups, which are required for transport of cargo through the NPC. This approach revealed both rigid and flexible domains: the tips of the FG domains are relatively disordered compared to the more ordered NPC-anchored domains. We also determined the orientation of several structural nucleoporins with in NPC. This technique allows the collection of structural information in vivo with the ability to probe the organization of protein domains within the NPC. This has particular relevance for the FG domain nups, which are implicated in the mechanism of cargo transport.

488

Sm protein down-regulation leads to defects in nuclear pore complex disassembly and distribution in C. elegans embryos.

D. Joseph-Strauss[1], M. Gorjanacz[2], E. Voronina[3], A. Audhya[4], O. Cohen-Fix[5]; [1]NIH, Bethesda, MD, [2]European Molecular Biology Laboratory, [3]Johns Hopkins School of Medicine, [4]University of Wisconsin-Madison Medical School, [5]NIDDK/NIH

Nuclear pore complexes (NPCs) are large macromolecular structures embedded in the nuclear envelope (NE), where they facilitate exchange of molecules between the cytoplasm and the nucleoplasm. In most cell types, NPCs are evenly distributed around the NE. However, the mechanisms dictating NPC distribution are largely unknown. Here, we used the model organism C. elegans to identify genes that affect NPC distribution during early embryonic divisions. We found that down-regulation of the Sm proteins, which are core components of the spliceosome, but not down-regulation of other splicing factors, led to clustering of NPCs. Down-regulation of Sm proteins also led to incomplete disassembly of NPCs during mitosis, but had no effect on

lamina disassembly, suggesting that the defect in NPC disassembly was not due to a general defect in nuclear envelope breakdown. We further found that these mitotic NPC remnants persisted on an ER membrane that juxtaposes the mitotic spindle. At the end of mitosis, the remnant NPCs moved toward the chromatin and the reforming NE, where they ultimately became NPC clusters. Our results suggest a novel, splicing-independent, role for Sm proteins in NPC distribution and disassembly, and point to a possible link between NPC disassembly in mitosis and NPC distribution in the subsequent interphase.

489

The CTD Phosphatase SCPL-2 regulates the lipid phosphatase Lipin at the nuclear envelope to control nuclear envelope dynamics.

S. Bahmanyar[1], A. Desai[1], J. E. Dixon[2], K. Oegema[1]; [1]Ludwig Institute for Cancer Research, University of California at San Diego, La Jolla, CA, [2]Department of Pharmacology, University of California at San Diego, La Jolla, CA

In budding yeast, the phosphatidic acid phosphatase Pah1, which converts phosphatidic acid to diacylglycerol, and its activating protein phosphatase Nem1 (a member of the small CTD phosphatase family) are required to maintain a spherical nuclear shape. Here, we examine the roles of the metazoan homologs of these enzymes in controlling nuclear structure, using the early *C. elegans* embryo as a model. Prior work in this system showed that partial inhibition of the phosphatidic acid phosphatase LPIN-1^{Pah1} affects nuclear envelope disassembly during mitotic entry (Golden et al. 2009; Gorjánácz and Mattaj 2009). We find that penetrant inhibition of LPIN-1^{Pah1} results in profound defects in endoplasmic reticulum (ER) structure, embryo production, and germline development. Consistent with this, LPIN-1^{Pah1}localizes throughout the ER, including the ER-contiguous nuclear envelope. By contrast, the LPIN-1^{Pah1} activating protein phosphatase SCPL-2^{Nem1} specifically localizes to the nuclear envelope, suggesting that it controls LPIN-1^{Pah1} activity at this subcellular location. Consistent with this, inhibition of SCPL-2^{Nem1} by either RNAi or mutation results in a specific defect in nuclear envelope disassembly resembling that in weak LPIN-1^{Pah1} inhibitions. Quantitative imaging of SCPL-2^{Nem1}-inhibited embryos revealed slowed kinetics of lamin removal and formation of abnormally shaped nuclei after chromosome segregation. However, SCPL-2^{Nem1} inhibition did not significantly affect dispersal of inner nuclear membrane proteins into the ER during envelope disassembly. Prior work in *C. elegans* embryos implicated the transmembrane nucleoporin NPP-12^{gp210} in inner nuclear membrane protein dispersal and nuclear envelope disassembly (Audhya et al. 2007; Galy et al. 2008). Double inhibitions of SCPL-2^{Nem1} and NPP-12^{gp210} showed a strongly additive effect on nuclear envelope disassembly, with lamina and envelope components persisting between the separating chromosomes and blocking cytokinesis. Based on these results, we propose that nuclear envelope-localized SCPL-2^{Nem1} locally controls the lipid phosphatase LPIN-1^{Pah1} and that mitotic entry-coupled regulation of this pathway works in parallel to NPP-12^{gp210}-mediated inner nuclear membrane protein dispersal to ensure timely nuclear envelope breakdown.

Association of persistent DNA breaks with the LINC complex and cytoplasmic microtubules contributes to repair outcome.

M. C. King[1], R. Swartz[1], E. Rodriguez[1], K. Zhang[1]; [1]Cell Biology, Yale University, New Haven, CT

Proteins embedded in the inner and outer nuclear membrane form a complex (the LINC complex) that physically couples the nuclear interior to the cytoplasm. We have shown previously that the nuclear aspect of the LINC complex can associate with chromatin in fission

yeast, mechanically coupling it to the cytoplasmic cytoskeleton. We now show that two types of microtubule-associated LINC complexes exist in *S. pombe*: a centrosomal complex composed of the SUN protein Sad1 and the KASH protein Kms2, and a non-centrosomal complex composed of Sad1 and the KASH protein Kms1. Here, we draw on recent studies in *S. cerevisiae* demonstrating that SUN-domain proteins associate with persistent double-stranded DNA breaks (DSBs) to investigate a potential role for the cytoplasmic cytoskeleton in DNA repair. We show that DNA damage induces a proliferation of non-centrosomal LINC complexes that colocalize with repair foci. Thus, upon LINC complex association, persistent DSBs are subject to both microtubule-dependent mobility and microtubule-generated forces. In the absence of Kms1, the non-centrosomal KASH protein necessary for cytoplasmic microtubule association, DSB repair by homologous recombination becomes less efficient. Further, our genetic analysis shows synthetic enhancing interactions between Kms1 and mediators of homologous recombination as well as synthetic suppressive interactions with other repair pathways. Together, our data support a model in which association of DSBs with the LINC complex regulates the repair process through changes in chromatin mobility and/or associated forces.

491

The C terminal domain of Nup93 is essential for assembly of the structural backbone of the nuclear pore complexes.

R. Sachdev[1], W. Antonin[1]; [1]Friedrich Miescher Laboratory of the Max Planck Society, Tubingen, Germany

Nuclear pore complexes (NPCs) are large macromolecular assemblies that act as gatekeepers for nucleocytoplasmic exchange. They also restrict access to the nucleus by forming a permeability barrier. NPCs are composed of approximately 30 proteins called as nucleoporins (nups). These can be categorized into ones forming the structural skeleton of the pore and others forming the central channel thus imparting functional properties to the pore. During open mitosis in metazoans the nuclear envelope and the NPC breaks down and at the end of mitosis this process is reversed wherein the nucleoporins assemble in an ordered and regulated fashion to form the intact NPC.

We are interested in functionally characterizing the role of one of the structural complexes, the Nup93 complex in NPC assembly. This complex in vertebrates is composed of nucleoporins Nup93, Nup205, Nup188, Nup53 and Nup155. It is known that Nup93 forms two distinct complexes: Nup93-188 and Nup93-205. When depleted individually these complexes are not essential for NPC assembly.

The objective of this study was to know what happens when we deplete both Nup93 containing complexes together, which we did by immunodepleting all three proteins from *Xenopus laevis* egg extracts using antibody against Nup93. This leads to a block in the NE and NPC assembly. This phenotype observed could either be a direct consequence of absence of Nup93 or resulting from co depletion of Nup188 and Nup205. To distinguish these two scenarios we did add back experiments with recombinant Nup93 and concluded that rescue in the block is due to Nup93 alone and not due to the two sub complexes implying that Nup188 and Nup205 together dispensable for NPC assembly.

To know which region of Nup93 contributes to the NPC assembly and function we added back different fragments of Nup93. Surprisingly, the C terminus of Nup93 alone could rescue the phenotype. (Closed nuclear envelope and formation of structural backbone of NPC)

As its known that p62 complex lining the central channel imparts the functional properties to the pore and it interacts with the N terminus of Nup93, we checked this by nuclear import and size exclusion assays. Nuclei where only the C terminus of Nup93 was present were not competent for import and lost their permeability barrier. In contrast nuclei where nup93 full length was added back were transport competent.

492

Phosphorylation of FG nucleoporins by ERK p38 MAP kinases is involved in the regulation of nucleocytoplasmic transport.

H. Kosako[1], N. Tani[1], S. H. Yoshimura[2], S. Kose[3], M. Kawano[1], H. Taniguchi[1], N. Imamoto[3]; [1]Institute for Enzyme Research, The University of Tokushima, Tokushima, Japan, [2]Graduate School of Biostudies, Kyoto University, Kyoto, Japan, [3]Advanced Science Institute, RIKEN, Wako, Japan

In eukaryotic cells, the nuclear pore complex (NPC) is a highly selective, bidirectional transporter for a wide range of material between the nucleus and cytoplasm. It is composed of ~30 different nucleoporins (Nups), and approximately one-third of these Nups are classified as FG Nups due to their content of phenylalanine-glycine repeats, which provide binding sites for nuclear transport receptors (NTRs) during the NPC passage.

Recently, our multi-step phosphoproteomic approach combining IMAC (immobilized metal affinity chromatography) and 2D-DIGE (two-dimensional difference gel electrophoresis) revealed a number of new ERK MAP kinase targets including Nup50. ERK phosphorylation of the FG repeat region of Nup50 reduced its affinity for importin-β family proteins and regulated the permeability properties of the NPC.

Here we show that both ERK and p38 MAP kinases efficiently phosphorylate various FG and non-FG Nups *in vitro*. Phosphate-affinity SDS-PAGE using the Phos-tag ligand followed by Western blotting revealed that these Nups are stoichiometrically phosphorylated by ERK and p38 *in vivo*. Then effects of phosphorylation of different FG repeat regions on interaction with importin-β were analyzed qualitatively and quantitatively. GST pull-down assays showed that interactions of FG Nups with various importin-β family proteins but not with other Nups are sensitive to phosphorylation. Furthermore, MAP kinase activation inhibited nucleocytoplasmic localization of fluorescent reporters in cells. Signal transduction-mediated phosphorylation and regulation of multiple FG Nups may have a broad impact on cellular physiology.

493

Overlapping functions of MAN1 and emerin in Xenopus laevis.

M. Reil[1], M-C. Dabauvalle[1]; [1]Electronmicroscopy, University of Wuerzburg, Biocenter, Wuerzburg, Germany

Members of the family of LEM-domain containing proteins are involved in gene regulation by associations with chromatin, the nuclear lamina and proteins of several signal pathways. The most prominent and eponymous members of this protein family are LAP2, emerin and MAN1, which are integral membrane proteins of the inner nuclear membrane and share the so called LEM-domain.
In human, emerin is encoded by the EMD gene which has been identified as the gene mutated in patients suffering from Emery-Dreifuss muscular dystrophy (EDMD). This disease is characterized by contractions of main tendons, muscle wasting and cardiac arrhythmias. The human protein MAN1 is encoded by the LEMD3 gene. Mutations in this gene cause sclerodermatous bone dysplasias, characterized by increased bone density and skin

aberrations. The physiological role of MAN1 is still unclear but there is evidence that MAN1 has an important role in transforming growth factor-beta signalling.
Apart from their specific roles, it is increasingly supposed that LEM-domain proteins share partially overlapping functions. Here we analyzed the possibility of overlapping functions of MAN1 and emerin during the embryogenesis of Xenopus laevis which is a well established model organism.
Because no commercial antibodies are available for Xenopus specific MAN1 (XMAN1), we first generated specific antibodies against XMAN1. As expected after immunostaining, MAN1 was localized to the inner nuclear membrane of somatic and germline Xenopus nuclei. As shown by immunoblot analysis, XMAN1 is detectable in oocytes and all developmental stages during early embryogenesis of X. laevis. Interestingly, prior studies illustrated that Xemerin is absent in germline and is first detectable at stage 41 of Xenopus development (Gareiss et al., 2005).
Whole-mount immunolocalization experiments showed that at stage 41 onwards both emerin and MAN1 are predominantly colocalized in the somites and the neural tube of embryos. Furthermore it was shown by co-immunoprecipitation studies that Xemerin is able to interact with XMAN1 in vitro (Gareiss et al., 2005). Following it is tempting to speculate that XMAN1 and Xemerin share partially overlapping functions during embryogenesis.
In order to analyze overlapping functions of both proteins during the early development of X. laevis, we performed Knock-down studies by microinjection of Oligo-Morpholinos into a blastomere of stage-2-embryos. We therefore registered a delay in embryonic development and abnormal formations in the caudal limb. However co-injections of truncated isoforms of Xemerin revealed a normal embryogenesis. Our results thus show that emerin and MAN1 have overlapping functions during embryogenesis. This enables an insight into the crosstalk of nuclear envelope proteins.

Gene Structure and Transcription

The action of the sulfur metabolic transcription factors is context-dependent in budding yeast.

R. S. McIsaac[1], A. Petti[1], M. McClean[1], S. Silverman[1], D. Botstein[1]; [1]Princeton University, Princeton, NJ

The sulfur metabolic genes are responsible for the conversion of extracellular sulfur-containing molecules into usable sulfur for the cell. The expression of these genes is coordinated by four DNA-binding cofactors (Cbf1p, Met28p, Met31p, Met32p), and a strong transcriptional activator, Met4p, which lacks a DNA-binding domain. Recently, we characterized a gene induction system, which, upon the addition of estradiol to the culture, results in near-immediate transcription of a single gene of interest with minimal background expression changes. We've constructed strains in which we can induce expression of a single sulfur metabolic transcription factor in both prototroph and methionine-auxotroph backgrounds with this system. Direct targets of these transcription factors are determined from microarray expression profiles as those genes whose expression changes immediately following transcription factor induction. We demonstrate that this rapid induction approach can be used as a discovery tool for establishing a causative regulatory relationship between a factor and its targets. By performing experiments in chemostats, we are able to 1) choose the identity of a single limiting nutrient (i.e., phosphate or methionine) and 2) maintain the culture at a constant growth rate. With this approach we establish that the identity and strength of target regulation can depend on the choice of nutrient limitation. By identifying changes in expression, we are able to improve upon the static

regulatory information provided by other methods and directly probe the existence, strength, and direction of regulation between the sulfur metabolic transcription factors and their targets.

495

Visualization of Promoter-Enhancer Interactions in silent and active loci of a Drosophila Hox gene.

E. Tour[1], W. McGinnis[1]; [1]Cell and Developmental Biology, UCSD, La Jolla, CA

In eukaryotes, gene transcription is controlled by regulatory regions (enhancers), which are often located at significant distances from the promoters they regulate. Multiple lines of evidence support the idea that enhancers interact with promoters, while the intervening DNA loops out, however the exact mechanism and the frequency of this interaction are not fully understood. *Drosophila* Hox gene *Ultrabithorax* (*Ubx*) is regulated by multiple enhancers. Two of these enhancers, *bx* and *abx*, are located 34 kb and 51 kb downstream of the transcription start site, respectively. Using small (less than 4.5 kb) DNA probes and 3-D multiplex in situ hybridization (M-FISH), we detect the interactions between the *bx* and *abx* enhancers and *Ubx* promoter in *Drosophila* embryos, while simultaneously detecting *Ubx* transcription from the locus. In the region where *Ubx* is actively transcribed, *Ubx* locus appears relaxed, consistently with the “beads on string”, i.e. nucleosome-only, level of chromatin compaction, while in the regions where *Ubx* is not transcribed, the chromatin appears significantly more condensed. Looping of the *Ubx* locus that is consistent with enhancer-promoter interactions is detected at a high frequency (60-70% of the loci) in the actively transcribing *Ubx* alleles.

Intragenic Transcription and the Regulation of Protein Function.

K. McKnight[1], H. Liu[2], Y. Wang[1]; [1]Biomedical Sciences, Florida State University College of Medicine, Tallahassee, FL, [2]Department of Pharmacology, University of Texas Southwestern Medical Center

The function of a given gene can be regulated at transcriptional, translational and post-translational levels. Intragenic transcription occurs when initiation of transcription starts from within the coding region but the significance and regulation of intragenic transcription is not well understood. Using budding yeast as a model organism, we found smaller protein isoforms of the conserved spindle midzone protein Ase1 when cells are treated with Hydroxyurea (HU), a drug that inhibits DNA replication and arrests cells in S-phase. We demonstrated that the protein isoforms are not the result of cleavage but of intragenic transcription using Northern Blotting and 5’ Rapid Amplification of cDNA Ends (5’ RACE). After HU treatment, the full length *ASE1* mRNA disappears and a shorter mRNA transcript is present. The result from 5’RACE indicates that the intragenic transcription initiates 756-766 nucleotides downstream of the first start codon. Mutation of the two start codons downstream of the intragenic initiation site abolish generation of the shorter Ase1 isoforms. Interestingly, intragenic transcription of *ASE1* depends on the S-phase checkpoint indicating that it is a regulated process.
Ase1 promotes spindle elongation during anaphase by bundling and stabilizing antiparallel microtubules (MTs) at the spindle midzone. Ase1 proteins can form a homodimer and the domain responsible for dimerization is located within the N-terminal region, while the MT binding domain is at the C-terminal region. The shorter Ase1 protein isoforms resulting from intragenic transcription lack the dimerization domain but contain the intact MT-binding domain. Therefore, we speculated that the shorter Ase1 isoforms play a dominant negative role by competing with the full length Ase1 for MT binding, thereby preventing premature spindle elongation when DNA synthesis is blocked. Using fluorescence microscopy we have shown that cells exhibit slower growth as well as a spindle elongation defect after overexpression of the short isoform of Ase1.

Our results support the hypothesis that intragenic transcription of *ASE1* is induced upon HU treatment in an S-phase checkpoint dependent manner in order to counteract full length Ase1 function. We propose that intragenic transcription may be a new and general way to down-regulate the function of a group of genes in response to growth stress. We have performed a microarray to identify other genes subjected to this regulation and analysis of candidate genes is currently in progress.

497

Transcriptional regulation of Kindlin-2.

A. A. Khan[1], T. Shimokawa[1], S. Strömblad[1], H. Zhang[1,2]; [1]Bioscience and Nutrition, Karolinska Inst, Stockholm, Sweden, [2]Laboratory of Molecular Cell Biology and Tumor Biology, Beijing University, Beijing, China

Introduction: Kindlin family consists of three integrin interacting proteins namely Kindlin-1, Kindlin-2 and Kindlin-3. Kindlin-2 is the most conserved protein in Kindlin family. In contrast to its two tissue specific paralogs, Kindlin-2 is expressed ubiquitously in different parts of the body. Kindlin-2 gene was primarily identified as Mitogen inducible gene (MIG-2) because of its early induction after serum treatment. Kindlin-2 is involved in a number of important processes i.e. cell to cell contact, cell migration, cell cycle regulation, cancer progression and cancer metastasis. **Objective:** Much of the work has been done to explore the functional aspects of Kindlins, however their transcriptional regulation have not been investigated yet. In this study we are trying to elucidate the mechanism of serum based induction of Kindlin-2 and its physiological as well as pathological implications. **Methods:** The main methods we use are the one used commonly in cell signaling and gene regulation based research projects i.e. routine cell culturing, transfection and drug treatments, Luciferase assay, realtime PCR, western blot, flow cytometry and microscopy etc. **Results:** We identified that IGF1 plays an important role in Kindlin-2 transcriptional regulation. Knocking down of IGF1R showed that IGFI induces Kindlin-2 expression through IGF1 receptor. In addition, the preliminary data suggests that IGF1 based Kindlin-2 expression is controlled by P13 kinase pathway. The Luciferase assay for Kindlin-2 promoter in normal as well as cancer cells shows that transcription factor SP1 is responsible for the basal expression of Kindlin-2. However, it seems that Kindlin-2 expression through SP1 dependent core promoter activation is not involved in the serum or IGF1 based Kindlin-2 induction. In addition, we see a peculiar expression pattern of Kindlin-2 gene in prostate cancer (PC3 cells) cells where serum starvation does not seem to affect Kindlin-2 expression, suggesting other factors controlling Kindlin-2 expression in certain types of cancer. **Conclusion:** IGF1 plays important role in regulation of Kindlin-2 expression through PI3-Kinase pathway. The regulation of Kindlin-2 expression through serum as well as IGF1 does not seem to be controlled at transcriptional level. **Future planning:** Currently we are looking into post transcriptional and post translational modifications which may account for serum or growth factor based induction of Kindlin-2. We hope that elucidation of the mechanism of Kindlin-2 regulation at transcriptional, post-transcriptional and post-translational level will open new avenues in delineating the physiological roles of Kindlin-2 i.e. cell migration, cell adhesion, cell cycle, cancer progression and cancer metastasis.

498

Conservation and diversification of cis-regulatory mechanisms of the pax2/5/8 paralog group in chordates.

H. Ochi[1,2], T. Tamai[1], H. Nagano[1], A. Kawaguchi[1], N. Sudou[1,2], H. Ogino[1,2]; [1]Graduate School of Biological Sciences, Nara Institute of Science and Technology, Ikoma, Japan, [2]JST CREST, Chiyoda-ku, Japan

During the chordate evolution, the genome duplications produced a number of paralogous genes. While the evolution of their coding sequences has been extensively studied, it remains unclear how the evolution of their cis-regulatory elements occurred and how such cis-regulatory evolution contributed to the development of gene regulatory networks in modern vertebrates. To address these questions, we are studying regulatory mechanisms of vertebrate pax2, pax5 and pax8 genes. These genes have evolved from a single ancestral gene of early cephalochordates, and exhibit overlapping, yet distinct, expression in the developing neural and nephric tissues, including the ear, brain and pronephros.

We compared human, chicken and Xenopus genomic sequences of pax2/5/8 loci, and identified more than 80 conserved non-coding elements (CNEs). We then subjected them to transgenic Xenopusassay, and detected enhancer activities in 16 CNEs of pax2, 3 CNEs of pax5, and 1 CNE of pax8. These enhancer activities are similar and pleiotropic in the neural and nephric tissues, in spite of the divergent expression of endogenous pax2/5/8 genes, suggesting the conservation of upstream genetic pathways for activation of the paralog members. We also found that one of the pax2 enhancers increases its activity in the pronephros in response to both the down-regulation of pax2 and hypersalinity of the culture medium. We are currently investigating whether other enhancers of pax2/5/8 genes possess similar functions to protect embryos from genetic and/or environmental disturbance.

499

Structural and functional characterization of DAWDLE in *Arabidopsis thaliana*.

L. A. Narayanan[1], D. Chevalier[1]; [1]Biological Sciences, Mississippi State University, Starkville, MS

DAWDLE (DDL) is one of the eighteen genes that encode a protein with a Fork-Head Associated (FHA) domain in *Arabidopsis thaliana*. FHA is a phospho-threonine binding domain found in plant and animal proteins that function in DNA repair and cell cycle regulation. DDL contains an arginine-rich N terminal domain that has sequence similarity with proteins involved in RNA processing. DDL is localized to the nucleus and regulates the level of several small RNAs including microRNAs. Smad Nuclear Interacting Protein 1 (SNIP1), the DDL ortholog in humans and known to regulate RNA stability, is also essential for the production of microRNAs in humans. Our aim is to understand the function of DDL in RNA metabolism in *Arabidopsis*. Two *ddl* T-DNA insertion alleles in the WS-2 ecotype exhibit a strong phenotype that includes pleiotropic developmental defects such as short root and hypocotyl, reduced fertility, and distorted organs. This developmentally delayed phenotype is the result of a reduction of accumulation of small RNAs. In contrast a *ddl* T-DNA insertion allele in the Columbia (Col) ecotype exhibits a weak *ddl* phenotype. The difference of *ddl* phenotype between the two ecotypes is due to a single gene. This natural variation between Col and WS-2 has been mapped to an interval of 0.48 centimorgan on the 5th chromosome. To study the structure-function of DDL, twelve point mutations spanning *DDL* were isolated by Targeting Induced Local Lesions in Genomes (TILLING) analysis and the severity of each point mutation allele is being compared to T-DNA alleles. Traits for comparison include hypocotyl and root development, fertility and microRNA accumulation. To identify DDL interactors, we carried out a suppressor screen and identified a strong, and two weak suppressors of *ddl* that are currently being

mapped. In conclusion, DDL protein being conserved in both animals and plants is expected to play a crucial role in RNA metabolism including that of small RNAs.

Isolation and Purification of HAP1 Promoter, and Transformation into GFP Producing Plasmid.

A. Mervin[1], N. Dixon[1], C-A. Gutekunst[2], F. Norflus[1]; [1]Clayton State University, Morrow, GA, [2]Emory University, Atlanta, GA

Huntington's disease (HD) is an autosomal dominant neurological disorder, leading to progressive degeneration of the nervous system. Usually becoming apparent in mid-life and progressing for 15-20 years, with increased motor and cognitive impairment. Huntington's disease is a type I polyglutamine(CAG) expansion disease. The disease causes severe changes in the striatum Huntington's disease is associated with a mutant huntingtin gene, responsible for producing the huntingtin protein, since HD is a dominant allele disorder it exhibits mendelian inheritance . The focus of the research conducted in the lab was on the HAP1 promoter gene. HAP1 was one of the first proteins identified to interact with mutant huntingtin protein (htt).

HAP1, or htt-associated protein-1 is ubiquitous in the brain and colocalizes with htt in the cytoplasm of neurons. HAP1 and htt are believed to be associated with intracellular trafficking and endocytosis due to their involvement with other trafficking proteins such as dynactin p150 and kinesin light chain. HAP1 is primarily found to be involved with axonal trafficking and endocytosis possibly playing the role as an adaptor protein between cargos and intracellular transporters. It has been found that in some mutations of the disease mutant huntingtin protein binds more tightly to HAP1 and can cause variation in the onset of the disease .

The promoter region governs where initial transcription will begin for a gene. Through the use of PCR, restriction digests, ligation and transformation of bacteria we can learn much more about the promoter of the HAP1 gene. To find the promoter region of the HAP1 gene, we isolate bands of DNA from an agarose gel using electrophoresis. The isolated DNA is then placed into constructs, transformed into bacteria and transfected into cells for viewing fluorescence.

The focus of research for this gene is whether removing its promoter region will still allow this gene to transcribe the protein. To test this idea we will use several different sizes of Rat DNA that contains the HAP-1 gene and insert them into our plasmid to identify whether or not the GFP(Green Fluorescent Protein)gene will be expressed.

Following the transformation, DNA was extracted and a restriction digest performed. By comparing these results to the initial plasmid, we are in the process of determining which region of the HAP1 gene was successfully transformed into bacterial cells. We will then determine which of the constructs retained functional protein production from the HAP1 gene.

Extended Mutation Spectrum of Usher syndrome in Finland.

H. Vastinsalo[1,2], R. Jalkanen[1,2], C. Bergmann[3,4], C. Neuhaus[3], L. Kleemola[5], L. Jauhola[6], H. J. Bolz[3,7], E-M. Sankila[1,8]; [1]Folkhalsan Institute of Genetics, Helsinki, Finland, [2]Department of Medical Genetics, University of Helsinki, Helsinki, Finland, [3]Center for Human Genetics, Bioscientia, Ingelheim, Germany, [4]Department of Human Genetics, RWTH Aachen University, Aachen, Germany, [5]Department of Otorhinolaryngology, Tampere University Hospital, Tampere, Finland, [6]Department of Ophthalmology, Paijat-Hame Central Hospital, Lahti, Finland, [7]Institute of Human Genetics, University Hospital of Cologne, Cologne, Germany, [8]Helsinki University Eye Hospital, Helsinki, Finland

The distribution of the clinical Usher syndrome (USH) types in Finland is 40% USH3, 34% USH1, and 12 % USH2. All USH3 patients carry the founder mutation in clarin 1 (CLRN1) making the molecular diagnostics of USH3 patients simple. However, recently we reported three novel myosin VIIA (MYO7A) mutations in two unrelated USH1 patients. This study was done to further investigate the USH mutation spectrum in Finnish patients. The Asper Ophthalmics USH mutation chip was used to search for known mutations, and to evaluate the chip in molecular diagnostics of Finnish patients. We analyzed samples of nine unrelated USH patients/families without known mutations and two USH3 families with atypically severe phenotype. The chip revealed a heterozygous usherin (USH2A) mutation, p.N346H, in one patient. Further studies done by sequencing of MYO7A and/or USH2A in three index patients revealed two novel heterozygous mutations, p.R873W in MYO7A and c.14343+2T>C in USH2A. We did not identify definite pathogenic second mutations in the patients, but identified several probably non-pathogenic variations that may modify the disease phenotype. For example, we studied a MYO7A splice site change characterized as a polymorphism that, however, leads to altered splicing patterns in the studied region. In four cases, we could not exclude the possibility of digenisms when variations/mutations occurred in two proteins involved in the USH protein interactome. We identified two families segregating genomic variations in both MYO7A and USH2A, and two families with variations in CLRN1 and USH2A. We conclude that compared with the USH3 founder mutation identified in all Finnish USH3 patients, there is considerable genetic heterogeneity of USH1 and USH2 in Finland, making molecular diagnostics and genetic counseling of patients and families challenging.

RTR functions in transcriptional silencing during the division phase of male gametophyte development of *Marsilea vestita.*

C. M. Van der Weele[1], S. M. Wolniak[1]; [1]Cell Biology and Molecular Genetics, University of Maryland-College Park, College Park, MD

The male gametophyte of the water fern *Marsilea vestita* develops from a single cell contained in a desiccated microspore. Development is initiated when the dry spore is placed in water. The single cell in the spore, a meiotic product, then undergoes 9 rapid rounds of mitotic divisions to produce 7 sterile cells and 32 spermatids in less than 5 hours. During the next 5 hours, the spermatids undergo maturation, which culminates in the formation of a complex cytoskeleton and ciliary apparatus. The entire process reaches completion in 11 hours and depends almost entirely on stored transcript and proteins; alpha-amanitin treated spores develop without any anomalies while cycloheximide treated spores fail to progress through the first division cycle. This rapid process depends on precise temporal regulation of translation for the formation of specific proteins required during different phases of development, and on the degradation of proteins that are no longer needed for gamete development. In this study, we describe a protein

we have named RTR, which functions as an essential transcriptional regulator for the temporal and spatial control of transcript abundance during rapid development.

We isolated a transcript for a protein containing a RRM-1 domain (MvU620). Knockdowns of MvU620 by RNAi, resulted in multiple division defects. Cytokinesis was anomalous as the division planes were misplaced, of incorrect shape, incomplete, or absent. Cells with multiple nuclei suggest nuclear division often continued. Despite division defects, the development of spermatogenous cells progressed as cells became rounded, small starch-bearing plastids appeared and gamete nuclei started to elongate. qPCR analyses of RNA isolated early in the division phase showed that in the knockdowns, transcripts of alpha tubulin, G3PDH and a putative nuclear movement protein were up-regulated. Staining with a dichromatic dye, GRSafe, showed a dramatic increase in the abundance of single stranded RNA in the knockdowns, but when spores were treated with the broad-spectrum transcriptional inhibitor Actinomycin D (ActD), or with ActD and dsRNA made from MvU620, the staining patterns were identical to those in untreated cells. These data suggest that MvU620 is involved in transcriptional inhibition during the division phase of spermiogenesis in the male gametophyte, and that in the absence of transcriptional inhibition, early development in the gametophyte is anomalous. We renamed the MvU620 RRM-1 domain containing Transcriptional Regulator RTR. This research was supported by NSF grant 0842525 to S.M.W.

Microarray Analysis to Probe Gene Expression in [PSI+], a Prion-Containing Yeast Cell.

P. Patil[1], J. Schulman[1], B. A. Dennis[2], E. S. Antonio[1], I. M. Evans[1]; [1]Biological Sciences, Rochester Institute of Technology, Rochester, NY, [2]Biomedical Sciences, Rochester Institute of Technology, Rochester, NY

Prions are infectious, self-propagating, aggregated particles devoid of nucleic acid which are composed entirely of abnormally-folded proteins. They are examples of epigenetic protein inheritance. Mammalian prions cause fatal neurodegenerative diseases like Creutzfeldt–Jakob disease (humans) and bovine spongiform encephalopathy (cattle).
Yeast prions model some aspects of mammalian prions and allow for extensive studies of basic mechanisms involving prion-cell interactions. We are using the [PSI+] yeast prion which is a epigenetic modifier of translation termination fidelity resulting in nonsense suppression. [PSI+] is a self-perpetuating amyloid-forming conformation of the eRF3 protein and is coded for by the Sup35 gene
The overall goal is to determine whether the presence of a prion protein in a cell affects the mRNA types and levels present in the cell. Transcriptional (mRNA) profiles were obtained using microarrays. Previous work had not shown large (2x) changes in mRNA when the cells were grown in rich YPD media.
Studies by others have shown that the presence of the [PSI+] prion modulates colony morphology and survivability in a variety of (stressful) growth conditions. Our studies were done in minimal medium containing ornithine, a poor nitrogen source, in an attempt to induce stress in the cells. Microarrays done comparing the transcriptional profile of [PSI+] growing in YPD versus ornithine minimal media showed many transcriptional changes many of which were 2x or greater. When the transcriptional profiles of [PSI+] growing in ornithine minimal medium was compared with that of [psi-], several significant two-fold mRNA changes were observed. These results suggest that the effects of a prion protein on a cell's transcriptional profile may be manifested more in stressful medium conditions. The observed mRNA transcriptional differences may help answer what effect a yeast prion protein has on a cell.

504

Differential role of transcription factor Nkx2-5 in activation of the ANF gene in developing vs. failing heart.

S. Warren[1], R. Terada[1], L. Briggs[1], C. Cole-Jeffrey[1], W-M. Chien[2], E. Weinberg[3], T. Seki[4], M. Chin[2], T. Yang[1], J. Bungert[1], H. Kasahara[1]; [1]Univ Florida, Gainesville, FL, [2]University of Washington School of Medicine, [3]Boston University Medical Center, [4]Georgia Health Science University

Background: Atrial natriuretic factor (ANF) is abundantly expressed in atrial cardiomyocytes throughout ontogeny and in ventricular cardiomyocytes in the developing heart. However, during cardiac failure and hypertrophy, ANF expression can reappear in adult ventricular cardiomyocytes (“re-activation of a fetal cardiac gene program”). Transcription factor Nkx2-5 is one of the major transactivators of the ANF gene during development; but whether Nkx2-5 regulates ANF during cardiac hypertrophy and failure, as well as the identification of its responsive elements in vivo, remain to be elucidated.

Methods and Results: Neonatal cardiomyocytes either expressing or lacking Nkx2-5 isolated from Nkx2-5flox/flox or Nkx2-5flox/flox/Cre mice after maternal injection of tamoxifen were utilized for chromatin immunoprecipitation (ChIP) assay. We identified Nkx2-5 binding to three 5’ regulatory elements (-34, -31 and -21 kb) and the proximal ANF promoter. Chromosome conformation capture (3C) analysis revealed close proximity between the distal elements and the promoter region. A 5.8-kb fragment consisting of these elements transactivated a reporter gene in vivo recapitulating endogenous ANF expression in the inner trabecular layer, which was markedly reduced in Nkx2-5-ablated mice. However, expression of a reporter gene was increased and expanded toward the outer compact-layer in the absence of transcription repressor Hey2 similar to endogenous ANF expression. Functional Nkx2-5 and Hey2 binding sites separated by 59 bp were identified in the -34 kb element in neonatal cardiomyocytes. In adult hearts, this fragment did not respond to pressure-overload, and ANF was induced in the absence of Nkx2-5.

Conclusion: We established a strategy to identify physiologically significant regulatory elements in the ANF gene by ChIP assays with anti-Nkx2-5 antibody. Nkx2-5 likely mediates formation of a chromatin hub in the ANF genomic locus in the developing heart, but this active chromatin hub is not sufficient for the reactivation of ANF expression in the pressure-overloaded heart or during heart failure.

505

Molecular Mechanisms for the Synchronized Transcription of the Three Complement C1q Subunit Genes in Dendritic Cells and Macrophages.

G. Chen[1], C. Tan[1,2], B. Teh[1], J. Lu[1]; [1]Microbiology, National University of Singapore, Singapore, [2]NUS Graduate School for Integrative Sciences and Engineering, National University of Singapore, Singapore, Singapore

Hereditary homozygous C1q deficiency is rare but it almost certainly causes systemic lupus erythematosus (SLE). On the other hand, C1q levels can decline in SLE patients without apparent C1q gene defects and the versatility in C1q production is a likely cause. As an 18-subunit protein, C1q is assembled in 1:1:1 ratio from three different subunits. The three human C1q genes are closely bundled on chromosome 1 (C1qA-C1qC-C1qB) and their basal and IFNγ-stimulated expression, largely restricted to macrophages and dendritic cells (DCs), is apparently synchronized. We cloned the three gene promoters and observed that, while the C1qB promoter exhibited basal and IFNγ-stimulated activities consistent with the endogenous

C1qB gene, the activities of the cloned C1qA and C1qC promoters were suppressed by IFNγ. To certain extents, these were corrected when the C1qB promoter was cloned at the 3Œ end across the luciferase reporter gene. A 53-bp element is essential to the activities of the C1qB promoter and the transcription factors PU.1 and IRF8 bound to this region. By chromatin immunoprecipitation, the C1qB promoter was co-precipitated with PU.1 and IRF8. shRNA knockdown of PU.1 and IRF8 diminished C1qB promoter response to IFNγ. STAT1 instead regulated C1qB promoter through IRF8 induction. Collectively, our results reveal a novel transcriptional mechanism by which the expression of the three C1q genes is synchronized.

506

Clock Gene Expression in Human Keratinocytes.

C. Sandu[1], M. Dumas[2], D. Sambakhe[1], A. Malan[1], C. Nizard[2], S. Schnebert[2], E. Perrier[2], E. Challet[1], P. Pevet[1], M-P. Felder-Schmittbuhl[1]; [1]Neurobiology of Rhythms, INCI, Strasburg, France, Strasbourg, France, [2]Sciences du Vivant, LVMH Recherche, France, Saint Jean de Braye, France

Objectives: Living organisms have developed complex timekeeping systems organized into a circadian clock network allowing their physiology to adapt to the daily environmental changes dictated by the solar cycle. Circadian clocks are cell autonomous systems based on clock proteins interacting within negative feedback loops. They have been described in neuronal and non-neuronal cells and are supposed to ensure adequate daily timing of cellular functions. Several skin functions display daily rhythms: e.g. cell renewal has a maximum at night, but little is known about their control. Here, we investigated the expression of the clock genes *Clock*, *Bmal1*, *Per1*, *Per2*, *Per3*, *Cry1*, *Cry2*, *RevErb-alpha*, *Ror-alpha* and *Ror-beta* in human keratinocytes.
Methods: Primary cultures were established from keratinocytes derived from an abdominal skin biopsy of a healthy 36 year-old donor. Expression profiles of the core clock gene transcripts were assessed over 52 h by qPCR. Data for each gene were fitted to a cosinor-derived sinewave function. All sinewave functions were simultaneously fitted by a non linear least squares regression algorithm which imposed a common endogenous period.
Results: All clock genes (except *Ror-beta*) were expressed in the tested keratinocytes and the expression patterns of their transcripts showed robust circadian rhythmicity (except *Clock*). A common period of 23.06 ± 0.22 h was calculated for the rhythmically expressed genes. Also, as reported for most molecular clockworks, *Bmal1* transcripts oscillated in antiphase with respect to *Per* transcripts. The phases of *Cry* transcripts were opposed approximately 12 h with respect to *Bmal1* while the phase of *Cry1* was 8.5 h phase advanced and the phases of *RevErb-alpha* and *Ror-alpha* were respectively 8 h- and 11 h-delayed.
Conclusion: Our results indicate the presence of an autonomous clock in the keratinocytes. Roles of this clock in the physiology of keratinocytes and skin, as well as the mechanisms by which it is synchronized with environemental changes remain to be determined.

507

Clock Gene Expression in Human Melanocytes.

C. Sandu[1], M. Dumas[2], D. Sambakhe[1], A. Malan[1], C. Nizard[2], S. Schnebert[2], E. Perrier[2], E. Challet[1], P. Pevet[1], M-P. Felder-Schmittbuhl[1]; [1]Neurobiology of Rhythms, INCI, Strasburg, France, Strasbourg, France, [2]Sciences du Vivant, LVMH Recherche, France, Saint Jean de Braye, France

Objectives: Day-time dependent variations were reported in skin functions. The complex cellular organization of skin and the rhythmic processes that take place in this tissue suggest the potential presence of several molecular clocks in the epidermal layer, localized at the

interface between external and internal environments of the body.We investigated the expression of the clock genes *Clock*, *Bmal1*, *Per1*, *Per2*, *Per3*, *Cry1*, Cry2, *RevErb-alpha* and *Ror-beta* in human epidermal melanocytes.
Methods: Primary cultures were established from melanocytes isolated from an abdominal skin biopsy of a healthy 36 year-old donor. Expression profiles of the clock gene transcripts were assessed over 52 h by qPCR. Data for each gene were fitted to a cosinor-derived sinewave function. All sinewave functions were simultaneously fitted by a non linear least squares regression algorithm which imposed a common endogenous period.
Results: Our results show that all clock genes are expressed in the human melanocytes. The expression patterns of *Bmal1*, *Per1*, *Per2*, *Cry1*, *Cry2* and *RevErb-alpha* transcripts showed robust circadian rhythmicity with a common period of 25.22 ± 0.48 h. Phase analysis by adjusting the period to 24 circadian hours showed a phase advance of approximately 7-8 h for *Per1*, *Per2* and *Cry2* and 3 h for *Cry1* as compared to *Bmal1* and a phase delay of approximately 8 h for *RevErb-alpha*.
Conclusion: Our findings indicate the presence of a molecular clock in the human melanocytes that might act locally and possibly interact with other epidermal and/or dermal skin clocks. The role of this circadian clock in the epidermal physiology remains to be determined

508

Clock Gene Expression in Human Fibroblasts.

C. Sandu[1], M. Dumas[2], D. Sambakhe[1], A. Malan[1], C. Nizard[2], S. Schnebert[2], E. Perrier[2], E. Challet[1], P. Pevet[1], M-P. Felder-Schmittbuhl[1]; [1]Neurobiology of Rhythms, INCI, Strasburg, France, Strasbourg, France, [2]Sciences du Vivant, LVMH Recherche, France, Saint Jean de Braye, France

Objectives: Skin performs functions which are critical for the preservation of body homeostasis, in coordination with the environmental changes. Some of these functions undergo daily variations and it is believed that they are controlled by the circadian clocks which are based on negative feedback loop interactions between specific clock proteins. Recent in vitro studies showed circadian expression of a few clock genes in human dermal fibroblasts. We investigated the expression of the all known clock genes *Clock*, *Bmal1*, *Per1*, *Per2*, *Per3*, *Cry1*, *Cry2*, *RevErb-alpha* and *Ror-beta* in human dermal fibroblasts.
Methods: Primary cultures were established from fibroblasts isolated from an abdominal skin biopsy of a healthy 36 year-old donor. Expression profiles of the clock gene transcripts were assessed over 52 h by qPCR. Data for each gene were fitted to a cosinor-derived sinewave function. All sinewave functions were simultaneously fitted by a non linear least squares regression algorithm which imposed a common endogenous period.
Results: Our results show that all canonical clock genes are expressed in the human fibroblasts. The expression patterns of *Bmal1*, *Per1*, *Per2*, *Per3*, *Cry1*, *Cry2* transcripts showed robust circadian rhythmicity with a common period of 22.24 ± 0.39 h. Also, phase analysis showed 11 h delay of *Per1* transcripts as compared to *Bmal1*, while *Per2*, *Per3* and *Cry2* transcripts showed approximately 10 h phase advance and *Cry1* 6.8 h phase advance.
Conclusion: We confirm the presence of a molecular clock in the human fibroblasts, similar to human melanocytes and keratinocytes, and show which are the clock genes involved in time tracking in human fibroblasts. The role of this circadian clock in the dermal (skin) physiology remains to be determined.

509

The Wnt5a alternative promoters A and B are differentially regulated by TNFalpha.

K. S. Katula[1], N. Joyner-Powell[2]; [1]The University of North Carolina Greensboro, Greensboro, NC, [2]Biology, The University of North Carolina Greensboro, Greensboro, NC

WNT5A is an extracellular glycoprotein that activates both canonical and noncanonical Wnt signaling pathways important in development, differentiation, and tissue homeostasis. Wnt5a expression is often misregulated in cancer. The Wnt5A gene of both human and mouse generates multiple transcripts derived, in part, from alternative promoters. In this study, we analyzed the regulation of two of the Wnt5a alternative promoters we term A and B. 2178 bp and 1981 bp of sequences upstream from the human promoters A and B, respectively, were separately cloned in to a luciferase reporter vector and stably transfected in to NIH3T3 cells, allowing for individual analysis of the promoters. The p2178 promoter A and p1981 promoter B cell lines were treated with 5 ng/mL of TNFalpha for 6 and 12 hrs and luciferase activity determined. Results show that at 6 hr there was no significant increase in promoter A activity, whereas a significant increase of approximately 1.46-fold in promoter B activity was measured. At 12 hrs post TNFalpha treatment, promoter A activity increased 1.2-fold and promoter B activity 2-fold. To determine the involvement of the transcription factor NFkappaB and various effector kinases in the response of the promoters to TNFalpha, NIH3T3 promoter A and B reporter cells stimulated for 6 and 12 hrs with TNFalpha were treated with a NFkappaB inhibitor (JSH-23, 30 μM), ERK inhibitor (U0126, 10 μM), p38 inhibitor (SB203850, 10 μM), or JNK inhibitor (SP600125, 20 μM). At 6 hours for promoter B, the NFkappaB and ERK inhibitors caused a reduction in TNFalpha stimulated activity. At 12 hours for both promoters A and B, only the ERK and p38 inhibitors significantly reduced activity relative to the TNFalpha treated control cells. We designed Taqman primer/probe pairs for selective qRT-PCR analysis of promoter A and B transcripts derived from the endogenous Wnt5a gene. An increase in both promoter A and B relative transcripts levels was detected at 6 hr post TNFalpha treatment. The NFkappaB, ERK, and p38 inhibitors reduced the promoter B transcript levels in the TNFalpha treated cells but promoter A transcript levels were unaffected. Together these data indicate that promoter A and B are differentially affected by TNFalpha. The effect on promoter B involves NFkappaB, ERK, and p38, whereas promoter A is less affected by TNFalpha and the response involves ERK and p38. These results suggest a model for how the alternative promoters could provide a more complex pattern of regulation for the Wnt5a gene.

510

Structure and function analysis of TEF and NFκB interaction in regulation of HIF-1α.

J. Ma[1], A. Tipton[1], L. Zhang[2], J. Wu[1], A. Messmer-Blust[1], H. Liu[2], J. Li[1]; [1]Cardiovascular Institute, BIDMC, Harvard Medical School, Boston, MA, [2]College of Life Sciences,Liaoning University, China

Background: The transcriptional enhancer factor (TEF) family is responsible for the regulation of many genes expressed in cardiac, smooth muscle, and endothelial cells. Our lab previously demonstrated that Related Transcription Enhancer Factor-1 (RTEF-1) can increase angiogenesis via transcriptional regulation of HIF-1a and VEGF in endothelial cells. However, whether RTEF-1 utilizes a cofactor to aid in transcriptional regulation is still unclear. Methods and Results: TEF-1 (TEAD1) or RTEF-1 increased HIF-1a promoter activity by 1.88 ±0.12 and 3.73 ±0.23 fold, respectively, demonstrated by luciferase assay. Introduction of NFκB subunit p50 does not affect TEF-induced HIF-1a promoter activity, however, the introduction of subunit p65 or both p50 and p65 together significantly blocked the activity. Additionally, the physical interaction between TEF-1/RTEF-1 and NFκB were confirmed by co-immunoprecipitation with both p50 and p65-specific antibody. Crystal structure of human TEF-1 and RTEF-1 revealed a

conserved surface interaction with the helix domain of p65 but no interaction with p50 by Rosettadock software, in which the specific NFκB binding domain on TEF sequences were also determined. Moreover, GST pull-down assays indicated that the specific interaction area of NFκB was homologous between TEF-1 and RTEF-1. Conclusion: Both RTEF-1 and NFκB transcriptionally regulate the HIF-1 gene and NFκB may be a possible cofactor for RTEF-1. The structure of the NFκB-binding domain was found in human TEF sequences, and the competitive and negative regulation of the TEF family and NFκB requires HIF-1a transcriptional regulation. This finding may have therapeutic potential for hypoxia-/ischemia disorders.

511

Interaction of human Sin3B with Transcription Factor KLF11.

L. Vig[1], H. Batra[1], D. Saluja[1]; [1]DR. B. R. Ambedkar Center for Biomedical Research, University of Delhi, Delhi, India

Sin3 is a global corepressor protein essential for a diverse array of cellular functions. It has established roles in transcription, cell cycle regulation, embryonic development and differentiation. Sin3 is known to regulate transcription of important genes. Well conserved from yeast to human, Sin3 exists as two isoforms in humans namely, hSin3A and hSin3B. The modular nature of Sin3 characterized by the presence of four Paired Amphipathic Helices or PAH domains allow it to serve as a scaffolding protein for the assembly of chromatin remodeling proteins and other proteins. Sin3 proteins do not have a DNA binding domain and access the promoter regions of various genes by binding to suitable transcription factors. While a lot of work has been done to understand protein-protein interactions involving Sin3A in the cell, human Sin3B has not been as well characterized. Our study focused on investigating interacting proteins for hSin3B. KLF11 (Kruppel like factor 11) is one such protein that was already known to interact with Sin3A. Using co-immunoprecipitation experiments in HEK293 cell line, we have found that it also associates with hSin3B. In addition, our yeast two hybrid experiments have shown that the N-terminal region of hSin3B from amino acids 1 to 397, harbouring the three PAH domains, interacts very strongly with KLF11. We also studied the contribution to the interaction by the individual PAH domains by yeast two hybrid experiments and found that it is the first PAH domain of hSin3B (PAH1) that largely contributes to the interaction. In comparison, the hSin3B C-terminal region (from amino acids 448 to 1177) had weak interaction with KLF11. In addition, we found that not only is hSin3B recruited onto the KLF11 binding site on the promoter of Manganese Superoxide Dismutase 2 (MnSOD2), a well-established target gene of KLF11, it also modulated the mRNA expression level of MnSOD2 in mammalian cells. Thus, interaction of the corepressor hSin3B with KLF11 transcription factor is likely to have important implications in control of cell growth.

512

The Role of Human Spt6 in Transcription Regulation by RNA Polymerase II.

B. Fusby[1], D. Bentley[1]; [1]Biochemistry and Molecular Genetics, Univ Colorado-Denver Anschutz Med Campus, Aurora, CO

Spt6 is a conserved histone chaperone that functions in control of transcription elongation and mRNA metabolism. Spt6 has been previously shown to have interactions with RNA polymerase II, Ref1/Aly, Iws1, and subunits of the exosome. These interactions of Spt6 suggest that all the functions for this protein have not yet been determined. Most of the current characterization of Spt6 has been done in yeast and Drosophila. The purpose of our study is to characterize the role of human Spt6 (huSpt6. We have made a specific antibody for huSpt6 that we will use to perform chromatin immunoprecipitation (ChIP) analysis to map huSpt6 across human genes. To further elucidate the function and importance of huSpt6, we have developed a panel of inducible

Spt6 shRNA lentiviruses. We will use these shRNA to analyze how huSpt6 knockdown affects RNA polymerase II distribution on human genes. This study will provide further insight into the function of Spt6 in relation to regulation of transcription initiation, elongation, and termination.

513

Identification of AtWRKY46, a novel microgravity-specific transcription factor, by in silico and gene expression analysis.

E-J. Kil[1], H. Soh[1], Y. Choi[2], T-K. Lee[3], W-Y. Soh[2], U-D. Yeo[2], K. Han[4], Y. Rhee[1], J. Park[1], Y. Jung[1], S. Cho[1], J. Chae[1], J-D. Kim[1], S. Lee[1]; [1]Sungkyunkwan University, Suwon, Korea, [2]Chonbuk National University, [3]Korea Ocean Research and Development Institute, [4]Woosuk University

Agilent 43 K *Arabidopsis thaliana* DNA chips were used to detect genes specifically expressed under simulated microgravity stress (SMS). Ten SMS-inducible genes were selected from the DNA chip data and these 10 genes were found to be abundantly expressed in both 6-day-old seedlings and 3-week-old plants. Nine out of the 10 SMS-inducible genes were also expressed in response to the three abiotic stresses of drought, touch, and wounding in 3-week-old *Arabidopsis* plants; WRKY46, however, was elevated only in response to SMS. Six other WRKY genes did not respond to SMS. To clarify the characteristics of the genes expressed at high levels in response to SMS, 20 *cis*-elements in the promoters of the 40 selected genes including the 10 SMS-inducible genes, the 6 WRKY genes, and abiotic stress-inducible genes were analyzed and their spatial positions on each promoter determined. Four *cis*-elements (MYB1AT or TATABOX5, GT1CONSENSUS, TATABOX5, and POLASIG1) showed a unique spatial arrangement in most SMS-inducible genes including WRKY46. In addition, another sequence of six *cis*-elements (SORLIP2AT, ELRECOREPCRP1, two GT1CONSENSUSs, ANAERO1CONSENSUS, and IBOX) were identified only in WRKY46 and CML38, which are both SMS-responsive genes. Taken together, our data indicate that WRKY46 is a novel microgravity-specific transcription factor and the unique spatial arrangement of *cis*-elements in the WRKY46 promoter appears to be important for its response to SMS.

514

Insights into Nuclear Reprogramming via Heterokaryon RNA Sequencing.

J. Brady[1], M. Li[1], R. Tran-Bussat[1], H. Jiang[1], W. Wong[1], H. Blau[1]; [1]Stanford University, Stanford, CA

Induced pluripotent stem cells (iPS) can be produced from virtually any somatic cell by the overexpression of a few transcription factors, a process termed “nuclear reprogramming”. At present, the molecular mechanisms underlying reprogramming are not well understood, in large part due to an inability to analyze early stages of reprogramming at the molecular level in iPS.
We hypothesized that there are as yet unidentified molecular regulators critical to the early onset of reprogramming. To identify key regulators of reprogramming we developed a synchronous, high efficiency, rapid reprogramming approach consisting of heterokaryons (interspecies multinucleate fused cells) in which activation of human pluripotency genes occurs rapidly (24hrs) and efficiently (70% of single heterokaryons), enabling early mechanistic studies.
We conducted a transcriptome-wide investigation of heterokaryon reprogramming using high throughput RNA sequencing. Heterokaryons were isolated over a three day time-course and subject to RNA sequencing to characterize the early gene expression dynamics of the mouse and human transcriptome during the early stages of nuclear reprogramming. Our results show significant changes in transcriptional output of both the mouse and human nucleus, including the induction of key human pluripotency genes and chromatin remodelers. Our results also validate using heterokaryon RNA sequencing as a discovery tool via the identification of

previously published molecules known to have a role in reprogramming towards pluripotency. In conclusion, the speed and efficiency of reprogramming in the heterokaryon system provides a means to identify critical transcription factors and epigenetic regulators via RNAseq, providing temporal information and transcriptional insights into mechanisms of reprogramming and cell fate.

Cytokinesis I

515

Orc6 interacts directly with the Chromosomal Passenger Proteins.

S. P. Wheatley[1], J. R. Webster[1], H. Belsham[1]; [1]School of Biomedical Sciences, University of Nottingham, Nottingham, United Kingdom

The origin of replication complex (ORC) is best known for its essential role in replication where it binds directly to DNA to initiate its replication at specific start sites. The ORC is comprised of six subunits, Orcs1-6, which are essential, conserved and constitutively expressed. While in yeast the ORC remains bound to DNA throughout the cell cycle, it is beginning to emerge that the individual ORC subunits have additional roles outwith S-phase in higher eukaryotes. Of particular note, in Drosophila and vertebrate cells Orc6 associates only transiently with the core ORC proteins, and is found on the centromeres in mitotic cells, and in the midbody during cell cleavage. Work from the Stillman lab has shown that siRNA mediated depletion of Orc6 leads to defects in chromosome movements and cytokinesis, a phenotype similar to that exhibited when activity of the mitotic chromosomal passenger complex (CPC) is compromised. In this project we ask whether Orc6 contributes to mitotic events by interacting with the CPC proteins, aurora-B, borealin, INCENP and survivin. We report that Orc6 can bind directly to all CPC proteins in vitro, map their interactions and begin to investigate how Orc6 contributes to late mitotic events in cultured human cells.

516

Identification and characterization of novel proteins involved in cytokinesis in C. elegans embryos.

Y. Tse[1], M. Glotzer[1]; [1]University of Chicago, Chicago, IL

Cytokinesis is a highly regulated, robust process that involves a large number of proteins. Genome-wide screening in *C. elegans* has probably enabled the identification of the majority of proteins that are essential for cytokinesis. However, due to the redundant mechanisms for cleavage furrow establishment, we postulate that some proteins involved in cytokinesis remain to be identified and studied. To identify some of these proteins, we used an existing allele, *nop-1(it142),* that is defective in pseudocleavage (nop-1: no pseudocleavage), to generate a sensitized background for genome-wide RNAi screening. By high-throughput RNAi screening, we identified thirty candidate genes which, upon depletion, showed embryonic lethality in *nop-1* but not in wild type worms. Seven of these candidate genes, show obvious cytokinesis defects by a secondary screen using time lapse DIC microscopy. These defects include shallow furrow ingression and regression, symmetric division, polar body extrusion, and mixed phenotypes. Here, we report that one of the candidate proteins that shows a synthetic cytokinetic phenotype with NOP-1 regulates microtubules during cytokinesis. Embryos lacking this gene product have several phenotypes that are consistent with depletion of microtubule regulators including a pronuclei rotation defect, chromosome congression and segregation defects, and loss of central spindle integrity. In addition, the extent of pseudocleavage ingression is reduced when this gene

product is depleted. Furthermore, depletion of this gene product results in smaller centrosomes, loss of centrosome integrity, and a slower rate of microtubule nucleation. Thus, we provisionally conclude that this gene product may contribute to the formation and maintenance of the microtubule organizing center (MTOC) during cytokinesis. We conclude that either this gene product independently controls cortical contractility and MTOC organization or even subtle changes in organization of microtubules can affect cortical contractility during pseudocleavage and cytokinesis.

517

Structural Transitions in the Centralspindlin Complex Required for Microtubule Bundling During Cytokinesis.

E. A. White[1], H. Raghuraman[2], E. Perozo[2,3], M. Glotzer[1]; [1]Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, [2]Biochemistry and Molecular Biology, University of Chicago, Chicago, IL, [3]Institute for Biophysical Dynamics, University of Chicago

At anaphase onset, a set of overlapping, antiparallel, non-kinetochore microtubules become bundled to give rise to the central spindle. This structure is essential for the completion of cytokinesis and can dictate the position of the division plane. Central spindle assembly is controlled by the concerted actions of microtubule associated proteins and kinesin family motor proteins, most notably centralspindlin. The centralspindlin heterotetramer is comprised of two molecules each of a kinesin-6 family motor protein, ZEN-4, and a Rho GTPase activating protein CYK-4. Through its targeted localization to a narrow region of antiparallel microtubule overlap immediately following chromosome segregation, centralspindlin initiates central spindle assembly. Although it is known that microtubule bundling by centralspindlin requires the presence of both ZEN-4 and CYK-4, and their ability to interact, the mechanism of action of CYK-4 in microtubule bundling is not clear. Intriguingly, CYK-4 binds ZEN-4 in the linker region between the motor domain and the coiled coil, a key region for motility of other kinesins. This raises the possibility that CYK-4 binding allosterically modifies the structural and/or biochemical properties of ZEN-4. Consistent with this model, CYK-4 binding decreases the rate of motility of ZEN-4 in microtubule gliding assays. To directly address whether CYK-4 binding induces conformational changes in ZEN-4, we used EPR spectroscopy. ZEN-4 molecules comprised of the minimal CYK-4 binding region and the coiled-coil were spin-labeled at specific positions and the distances between sites determined in the presence and absence of CYK-4. We found that CYK-4 binding induces a global structural rearrangement in ZEN-4 that results in a dramatic stabilization of the relative positions of the two linker regions. Additionally, our structural studies indicate that the linker region of ZEN-4 is likely to be folded in both the bound and unbound states. We are currently investigating whether CYK-4 binding alters the positions of the motor domains of ZEN-4 in the presence and absence of microtubules, which could greatly impact the mechanism of motility of ZEN-4 in vivo. Combining these data with other structural considerations, we have developed a working model for the architecture of the centralspindlin complex and are examining the functional implications of these structural changes in ZEN-4 at the single-molecule level.

518

Localization of cytokinesis factors to the future cell division site by microtubule-dependent transport.

E. Atilgan[1], F. Chang[1]; [1]Microbiology, Columbia University, New York, NY

The mechanism by which spindle microtubules (MTs) determine the site of cell division in animal cells is still highly controversial. Putative cytokinetic “signals” have been proposed to be positioned by spindle MTs at equatorial cortical regions to increase contractility, and/or at polar

regions to decrease contractility. How factors are localized to the equatorial regions of the cortex is not understood. Here, we test cytokinesis models using computational modeling. We present a simple lattice-based model in which signal-kinesin complexes move by transient plus-end directed movements on MTs interspersed with occasions of uniform diffusion in the cytoplasm. In simulations, we find that these complexes distribute themselves initially at the spindle midzone and then move on astral MTs to accumulate with time at the equatorial cortex, much like central spindilin and chromosome passenger complexes. Simulations accurately predict cleavage patterns of cells with different geometries and MT arrangements and elucidate several experimental observations that have defied easy explanation by previous models. The organization of MTs, rather than differences in MT density, may be a critical determinant of cleavage furrow placement. Thus, our modeling suggests a simple mechanism for how spindle MTs localize signals that stimulate contractility to the future equatorial division site.

519

Fission yeast UCS protein Rng3p stabilizes the activity of myosin-II motors during contractile ring assembly.

B. Stark[1], M. Lord[1]; [1]Molecular Physiology & Biophysics, University of Vermont, Burlington, VT

UCS (Unc-45-/Cro1-/She4-related) domain proteins constitute a family of myosin regulators conserved from yeast to humans. Yeast UCS proteins are made up of the conserved central and UCS (myosin-binding) domains. Unlike fungal UCS proteins, higher eukaryotes have adapted to associate with Hsp90 through the inclusion of an N-terminal TPR domain. In muscle, UCS proteins have been shown to operate as co-chaperones that function with Hsp90 during the *de novo* folding of myosin-II motors. The fission yeast UCS protein (Rng3p) localizes to actomyosin contractile rings and is essential for cytokinesis and cell growth. Through careful analysis of actomyosin ring dynamics we show that the primary role of Rng3p lies in promoting the activity of the myosin-II (Myo2p) motor during actomyosin ring assembly. Isolation of Myo2p in the absence of Rng3p showed that the UCS protein is not required for its actin binding, but is essential for the motility and actin-activated ATPase activity of Myo2p. Similarly, a mutant form of Myo2p previously shown to be hypersensitive to loss of Rng3p function (Myo2-E1p) binds actin filaments effectively yet lacks motility and ATPase activity. Compared with wild-type Myo2p motors, mutant Myo2-E1p motors were more sensitive to limited proteolysis with trypsin, indicating defects in structural conformation. Rng3p has been proposed to function in the *de novo* folding of Myo2p and all other fission yeast myosin heavy chains. In contrast, our *in vivo* and *in vitro* analysis of fission yeast myosin-I (Myo1p) and myosin-V (Myo52p) indicates Rng3p is not required for the function of these unconventional myosins. Our work suggests Rng3p specifically activates Myo2p motors during contractile ring assembly. We propose a second role for UCS proteins in establishing and promoting myosin motor activity at appropriate actomyosin structures. This role involves maintenance of conformational stability, but is independent of a general role in myosin motor folding involving the TPR domain and Hsp90.

520

A transglutaminase-like protein participates in cytokinesis and cell morphogenesis in fission yeast.

L. Pollard[1], M. Lord[1]; [1]Molecular Physiology and Biophysics, University of Vermont, Burlington, VT

The transglutaminase family, with notable members such as factor XIII, represents a conserved class of enzymes responsible for covalent cross-linking between amines (i.e. lysine side chain) and glutamine residues. Here, we report the identification of a transglutaminase-like protein (Cyk3p) that functions in morphogenesis in fission yeast. The phenotype of a cyk3 knockout

strain indicated a primary role for Cyk3p in cytokinesis. Correspondingly, Cyk3p localizes both to the actomyosin contractile ring and the division septum, promoting ring constriction and subsequent cell separation following ring disassembly. In addition, Cyk3p also appears to play a role in cell shape and integrity, reflected by its localization to polarized growth sites and the stationary phase cell cortex. Furthermore, over-expression of Cyk3p results in a loss of cell polarity and obvious defects in cell shape. Intriguingly, while Cyk3p possesses a transglutaminase domain, it lacks the active site. However, mutagenesis at conserved sites within the transglutaminase catalytic core indicated that this enzymatically inactive domain was essential for Cyk3p function. Collectively, our results and the conservation of Cyk3p across fungi points to a role in cell wall remodeling. In a broader sense, our work illustrates the physiological importance of inactive members of the transglutaminase family which are found throughout eukaryotes. We predict that the proposed evolution of animal transglutaminase cross-linking activity from ancestral bacterial thiol proteases was accompanied by the emergence of a subclass of transglutaminases whose cellular function does not depend on enzymatic activity.

521

Cortical Ect2 is recruited by RhoA to potentiate its activity for successful cytokinesis.

A. J. Piekny[1], P. Frenette[1], M. Kinal[1], M. Loloyan[2]; [1]Biology, Concordia University, Montreal, QC, Canada

Cytokinesis occurs by the ingression of an actin-myosin ring to divide a cell into two daughter cells. This process requires RhoA activation by the GEF Ect2, which forms a phospho-dependent complex with MgcRacGAP/Cyk-4. This interaction recruits Ect2 to the central spindle, and potentiates its activation, possibly by altering its conformation to relieve autoinhibition of its GEF domain. Since the central spindle forms in anaphase, Ect2's recruitment to the central spindle coordinates RhoA activation with chromosome segregation. However, active RhoA forms a tight zone of localization around the cortex, and it is not clear how this zone is established when the bulk of Ect2 is on the central spindle. Ect2's GEF domain is comprised of conserved DH and PH regions. Although the DH region exchanges nucleotide on RhoA, the PH region has no known function. We found that a subset of human Ect2 is enriched at the equatorial cortex during furrow ingression. Its PH region mediates its cortical localization and is required for RhoA activation. Furthermore, Ect2's cortical recruitment is RhoA-dependent, suggesting a feed-forward pathway promotes Ect2 activation during cytokinesis. We propose that full Ect2 activation requires several steps. First, Ect2 binds to Cyk-4, which alters its conformation to make its GEF domain more accessible to interaction with other proteins and/or lipids, including its substrate, RhoA. Second, active RhoA recruits Ect2 to the cortex where it becomes fully active to generate more active RhoA. At the cortex, Ect2 also interacts with the contractile ring protein anillin, an effector for RhoA and a crosslinker for actin and myosin. In anillin-depleted cells there are fewer microtubules at the equatorial cortex and in Drosophila, an anillin-RacGAP50C/Cyk-4 complex was hypothesized to stabilize central spindle-cortical interactions to maintain the division plane. Drosophila anillin does not interact with the Ect2 homologue, Pebble, while human anillin does not interact with Cyk-4. We hypothesize that the human anillin-Ect2 interaction is functionally analogous to the Drosophila anillin-Cyk-4 interaction.

522

p27Kip1 Regulates Cytokinesis via the Control of Citron-Kinase Activation.

M. P. Serres[1], U. Kossatz[2], Y. Chi[3], J. M. Roberts[3], N. P. Malek[2], A. Besson[1]; [1]CRCT UMR1037, Cancer Research Center of Toulouse, France, [2]Hannover Medical School, Germany, [3]Fred Hutchinson Cancer Research Center

The cell cycle inhibitor p27Kip1 (p27) also has cyclin-CDK independent functions. For instance, p27 binds to and prevents the activation of the GTPase RhoA, thereby regulating cell migration and actin cytoskeleton dynamics. Genetic evidence for these functions was provided by p27CK- knockin mice in which p27 cannot bind or inhibit cyclin-CDK complexes. The p27CK- mutation dominantly causes hyperplastic lesions and tumors in multiple organs compared to wild-type and p27-/- mice, revealing an oncogenic role for p27.

We identified a phenotype of multinucleation and polyploidy in p27CK- mice not present in p27-/- animals, suggesting an important role for p27 in G2/M that is independent of cyclin-CDK regulation. Further analysis revealed that p27CK- caused a cytokinesis and abscission defect. We identified the Rho effector Citron-Kinase as a p27-interacting protein in a mass spectrometry screen. The interaction of p27 and Citron-Kinase was confirmed in vitro and in vivo and both proteins colocalized at the contractile ring and midbody during telophase and cytokinesis. Moreover, overexpression of the minimal p27-binding domain of Citron-Kinase was sufficient to rescue the phenotype caused by p27CK-. Finally, we find that by binding to Citron-Kinase, p27 prevented the interaction of Citron-Kinase with its activator RhoA. Altogether, we propose a novel role for p27 during cytokinesis via the regulation of Citron-Kinase activity.

523

Citron kinase is an abscission regulator that controls the localization of anillin and of active RhoA at the midbody.

M. Gai[1], P. Camera[1], F. Bianchi[1], A. Dema[1], E. Scarpa[1], G. Germena[1], F. Di Cunto[1];
[1]Department of Genetics, Biology and Biochemistry, Molecular Biotechnology Center - University of Turin, Turin, Italy

Citron kinase (CIT-K) is a conserved protein required for cytokinesis. It has been previously proposed that this protein may function in cleavage furrow ingression downstream of active RhoA. However, it is still not well understood by which mechanisms this protein deploys its function.

In contrast with previous hypothesis, we report here that CIT-K is not required for cleavage furrow ingression, but for abscission. HeLa cells depleted of CIT-K show midbody instability and abscission failure. On the contrary, the CIT-K overexpression leads to midbody stabilization and abscission delay. Studies in CIT-K knockout mice indicate that, in vivo, the protein is required for cytokinesis only in specific cell types, such as the cerebellar granule precursor cells (GPCs). Importantly, we observed the same abscission failure phenotype in primary cultures of GPCs from CIT-K knockout mice.

We show that these defects can be explained mechanistically by the functional interaction of CIT-K with two key players of cytokinesis: RhoA and Anillin.

CIT-K forms a physical complex with Anillin and is required for the localization of this protein at the midbody. Quite surprisingly, we also found that, in late cytokinesis, CIT-K functions upstream of RhoA: it positively regulates RhoA activation state and retains active RhoA at the midbody; in contrast, late CIT-K localization is independent of active RhoA. Finally, RhoA inactivation rescues the abscission delay produced by CIT-K overexpression.

In conclusion, we propose that CIT-K is a crucial abscission regulator that promotes midbody stability through Anillin and active RhoA.

524

Mitochondria in Cytokinesis.

E. J. Lawrence[1], C. A. Mandato[2]; [1]Anatomy & Cell Biology, McGill University, Montreal, QC, Canada

Cytokinesis is the final challenge faced by the dividing cell. In animal cells, cytokinesis begins in anaphase shortly after chromosome separation with the appearance of a cleavage furrow at the equator of the cell. Progressive advancement of the furrow causes the cell equator to become increasingly constricted and eventually leads to division. Mitochondria are organelles that function in energy production and calcium homeostasis. Whether mitochondria function at the cleavage furrow to provide local ATP supply and/or calcium signalling and thereby drive cytokinesis is completely unknown. In order to address this question, we performed live imaging of mammalian cells to determine the localization of mitochondria during cytokinesis. We observe that mitochondria localize to the cleavage furrow after anaphase onset and remain enriched at the cell equator until abscission. Using pharmacological inhibitors of cytoskeleton dynamics, we show that the equatorial localization of mitochondria is dependent on microtubules but not on actin. We also demonstrate that mitochondrial recruitment to the cell equator requires RhoA activity. This project will establish novel roles for mitochondria in cytokinesis and will provide critical insights into the molecular basis of cytokinesis. Such work is of dual importance for cell division research and for the development of improved cancer therapies.

525

Role of Survivin in cytokinesis revealed by a separation-of-function allele.

E. Szafer-Glusman[1], M. Fuller[1], M. G. Giansanti[2]; [1]Departments of Developmental Biology and Genetics, Stanford University School of Medicine, Stanford, CA, [2]IBPM, Dip. Biologia e Biotecnologie Università Sapienza Roma, CNR, Rome, Italy

The Chromosomal Passenger Complex (CPC), containing Aurora B kinase, INCENP, Survivin, and Borealin, regulates chromosome condensation and interaction between kinetochores and microtubules at metaphase, then relocalizes to midzone microtubules at anaphase and regulates central spindle organization and cytokinesis However, the precise role played by the CPC in anaphase have been obscured by its prior functions in metaphase. We have identified a missense allele of *Drosophila* Survivin that allows CPC localization and function during metaphase, but not cytokinesis. Analysis of mutant cells showed that Survivin is essential to target the CPC and the MKLP1 ortholog Pavarotti to the central spindle and equatorial cell cortex during anaphase in both larval neuroblasts and spermatocytes. Survivin also enabled localization of Polo kinase and Rho at the equatorial cortex in spermatocytes, critical for contractile ring assembly. In neuroblasts, in contrast, Survivin function was not required for localization of Rho, Polo, or Myosin II to a broad equatorial cortical band, but was required for Myosin II to transition to a compact, fully constricted ring. Analysis of this “separation-of-function” allele demonstrates the direct role of Survivin and the Chromosomal Passenger Complex in cytokinesis and highlights striking differences in regulation of cytokinesis in different cell systems.

526

Anillin acts as a bifunctional linker coordinating midbody ring biogenesis and stable anchoring of the plasma membrane during cytokinesis.

A. Kechad[1,2], S. Jananji[1], Y. Ruella[1,2], G. R. Hickson[1,2]; [1]Sainte-Justine Hospital Research Center, Montréal, Québec, Canada, [2]Pathology & Cell Biology, Université de Montréal, Montréal, Québec, Canada

During cytokinesis, an actomyosin contractile ring drives furrow ingression before transforming itself into a stable midbody ring. How this transformation occurs and how plasma membrane anchoring is maintained throughout cytokinesis is unknown. We have tested the potential contributions from the multidomain scaffolding protein, Anillin.
Coupling timelapse fluorescence microscopy with RNAi-mediated depletions in *Drosophila* S2 cells, we show that Anillin is required for complete closure of the contractile ring and the formation of the midbody ring. Cells depleted of Anillin failed cytokinesis in two distinct ways: some were characterized by oscillating cleavage furrows that failed to stabilize and regressed, as previously described in *Drosophila* (Hickson and O'Farrell, 2008 JCB 180:285-94) and human cells (Straight et al., 2005, MBoC, 16:193-201; Zhao and Fang, 2005, JBC, 280:33516-24; Piekny and Glotzer, 2008, Curr Biol 18:30-6); but the majority formed semi-stable furrows that ingressed almost to completion but still failed to form a midbody ring. Expression of Anillin truncations revealed that Anillin N- and C-termini are independently targeted to the equatorial cortex and perform distinct functions. Anillin N-termini (lacking their C-terminal Anillin homology and PH domains) connected with the actomyosin contractile ring and supported formation of stable midbody ring-like structures, but could not maintain anchoring of the plasma membrane. Conversely, Anillin C-termini (comprising the Anillin homology and PH domains) failed to connect with ring structures but recruited the septin, Peanut, to form ectopic membrane-anchored structures at the equatorial cortex. Anillin and septins were dispensable for membrane anchoring at the contractile ring stage, but essential at the midbody ring stage.
These data demonstrate that Anillin coordinates the transition from contractile ring to midbody ring, and that it does so by controlling and linking two distinct cortical cytoskeletal elements and by promoting stable anchoring of the plasma membrane.

527

Anillin mediates feedback between the cortex and microtubules to define the division plane.

H. Haji Bik[1], A. Piekny[1]; Biology, Concordia University, Montreal, QC, Canada

During cytokinesis, communication between the mitotic spindle and the cortex ensures that the division plane bisects segregated chromosomes. Previous studies showed that changing the position of the mitotic spindle causes the formation of a new division plane, even after the onset of furrowing. However, the molecular mechanism(s) that mediates spindle-cortical communication is not fully understood, as there are cues associated with both the astral and central spindle microtubules. Furthermore, it is not clear if there is feedback from the cortex to the mitotic spindle to regulate microtubule stability. Anillin is a scaffold protein that helps maintain the division plane by crosslinking several components of the cell, including the actin-myosin cytoskeleton, septins and RhoA. Recent studies using *C. elegans* embryos showed that anillin also interacts with astral microtubules, which removes it from the cortex to form cortical domains. Furthermore, anillin depletion in combination with central spindle disruption blocks furrowing, even though depletion of each alone does not block furrowing. These results imply that anillin is a key communicator between the mitotic spindle and cortex. We found that although human anillin is highly cortical during cytokinesis, it also localizes to microtubules, and this localization is enhanced after perturbations that disrupt RhoA activity or stabilize

microtubules. Depletion of anillin in combination with central spindle disruption blocks furrowing in human cells. These results suggest that human anillin may function similar to *C. elegans* anillin to model cortical domains via microtubule interactions. However, anillin may also regulate feedback from the cortex to the mitotic spindle. In anillin-depleted cells, there is an overall decrease in microtubule staining in comparison to control cells, which is not phenocopied by depletion of the Rho GEF Ect2. This result suggests that anillin may influence microtubule stability independent of active RhoA. Furthermore, anillin depletion blocks polarization of monopolar cells (where cortical feedback may be more pronounced vs. bipolar cells), and central spindle proteins fail to localize. This data suggests that anillin acts as a communicator between the cortex and mitotic spindle to influence microtubule stability, a key step in promoting symmetry break.

528

Regulation of syncytium formation and cell ploidy by a short anillin isoform.

R. Amini[1], N. chartier[1], A. S. Maddox[1,2], J-C. Labbé[1,2]; Institute for Research in Immunology and Cancer, University of Montreal, Montreal, QC, Canada, [2]Department of Pathology and Cell Biology, University of Montreal, Montreal, QC, Canada

Cytokinesis is the last step of cell division, in which the two daughter cells physically separate. During certain developmental stages such as germline development, complete partitioning of the cytoplasm and plasma membrane do not occur. Instead, cells undergo incomplete divisions and form a syncytium, wherein multiple nuclei share a common cytoplasm. The molecular basis of syncytium formation is not well known. The *C. elegans* adult germline is a syncytium whose cortex is highly enriched in components of the actomyosin cytoskeleton. Among these is ANI-2, one of the three *C. elegans* homologs of anillin, a conserved multidomain scaffolding protein that plays a fundamental role in cytokinesis. ANI-2 is required in the germline for proper oocyte individualization. Its activity in the embryo is negatively regulated by the polarity kinase PAR-4/LKB1. We hypothesize that ANI-2 promotes germline syncytium formation in *C. elegans* by inhibiting cytokinesis and that PAR-4 functions upstream of ANI-2 in this process. To test this idea, we first analyzed the structure of the oogenic gonad in homozygous *ani-2* mutants and observed germ cell multinucleation, defects in oocyte differentiation and an increase of germ cell apoptosis. Analysis of heterozygous *ani-2* mutants, which have half the normal levels of ANI-2 protein, revealed that the openings between germ cells and the syncytium are significantly larger and that oocytes are individualized precociously. We found that in wild-type gonads, PAR-4 localizes to the nuclei of germ cells progressing through meiotic prophase, but, interestingly to the cortex of mitotic germ cells and of cellularized oocytes. This cortical localization correlates with stages of oogenesis during which cortical dynamics occur and suggests a causative role. Loss of PAR-4 function by mutation reduces the size of syncytial openings and reverts the precocious oocyte individualization defect observed in *ani-2* heterozygous mutants. Together, our results suggest that ANI-2 and PAR-4 have opposite contributions to germline syncytium formation in *C. elegans*.

529

Truncation proteins allow dissection of the roles of Anillin in C. elegans zygote cytokinesis.

L. Zhang[1], J. Dorn[1], C. Patino[1], T-H. Nguyen[1], A. S. Maddox[1]; [1]IRIC, University of Montreal, Montreal, QC, Canada

Anillin is a conserved multi-domain protein that enriches in the contractile ring during cytokinesis and is implicated in crosslinking multiple regulatory and structural elements including the septins, non-muscle myosin II and actin filaments. When Anillin is depleted by RNA-mediated

interference from the C. elegans early embryo, the contractile ring displays several abnormalities, including abnormal circumferential symmetry. Our in silico model of cytokinesis proposes that feedback among cytoskeletal filament alignment, contractility and membrane curvature drive non-concentric (asymmetric) furrow ingression, thus promoting energy efficiency. The model predicts that Anillin contributes to furrow asymmetry by bundling actin, aligning actin with other cytoskeletal elements, or by coupling the cytoskeleton to the plasma membrane (directly or indirectly). To test what domains of Anillin are responsible for its contributions to cytokinesis, we generated C. elegans strains stably expressing GFP-tagged Anillin truncations. Because these transgenes are not expressed at levels equal to endogenous Anillin, nor do their expression levels respond consistently to depletion of endogenous Anillin, it was necessary to first generate a standard curve of a quantitative phenotype as a function of Anillin protein level. The severity and frequency of the abnormal furrow symmetry phenotype scaled linearly with protein levels. Using our Anillin level standard curve, we found that the predicted myosin-binding domain is not required for furrow asymmetry. In contrast, the C-terminal Anillin and Pleckstrin homology (AH and PH) domains, predicted to associate with Rho, a RhoGAP, the septins and lipids, are required for asymmetry. Truncations encoding the actin bundling domain (ABD) alone or a nearly full-length protein lacking half the ABD are expressed at levels too low to compare with the performance of endogenous Anillin. However, the latter truncation, and one lacking the AH and PH domains, perturb furrow asymmetry even in the presence of endogenous Anillin. The common feature of these constructs is that they are predicted to uncouple actin from the membrane. Together, these results support the idea that by bundling actin and linking the actomyosin cytoskeleton to the membrane, Anillin helps ensure proper furrow geometry and therefore energy efficiency.

Mechanistic model for ESCRT mediated cytokinetic abscission.

N. Elia[1], G. Fabrikant[2], J. Lippincoot-Schwartz[1], M. M. Kozlov[2]; [1]National Institues of Child Health and development (NICHD), National Institues of Health (NIH), Bethesda, MD, [2]Department of Physiology and Pharmacology, Tel Aviv University School of Medicine, Israel

The ESCRT machinery have recently been shown to be directly involved in the late events of cytokinetic abscission leading to final separation between two daughter cells. Specifically, components of the ESCRT-III complex has been localized to both the midbody dark zone, found at the center of the intercellular bridge connecting the daughter cells, and the narrow constriction site, where abscission occurs. Moreover, the arrival of the ESCRT-III complex to the abscission site correlated temporally with the abscission event itself. This spatio-temporal characterization of the ESCRT machinery in cytokinesis provides for the first time a platform to understand the mechanistic basis of ESCRT mediated cytokinesis. In this work, we integrated biophysical modeling with experimental data to generate a detailed mechanism of action for ESCRTs in cytokinetic abscission. Based on our computational and experimental data we propose that polymerization of the ESCRT-III helix initiate at the edge of the midbody dark zone. VPS4 mediated breakage of the growing ESCRT-III helix enables formation of a separate helix whose diameter relaxes to the ESCRT-III spontaneous diameter of 50 nm. The latter drives constriction of the intercellular bridge membrane that is attached to the surface of the separate ESCRT-III helix, via electrostatic interactions, and in parallel the movement of the separate ESCRT-III helix away from the midbody dark zone. Interestingly, our computational analysis shows that there is an equilibrium distance from the midbody dark zone that is energetically favorable for constriction of the ESCRT-III separate helix. Our experimental measurements of that distance fits very well with the computed distance therefore supporting and validating our model. These finding further suggest that the conserved distance between the midbody dark zone and the abscission site, observed in cytokinesis, is directly determined by the ESCRT-III

complex. This work provides the first mechanistic model for cytokinetic abscission as well as for any specific ESCRT-III mediated process. Its significance to other ESCRT-III mediated events is yet to be discovered.

531

Temporal regulation of cytokinetic abscission by mechanical clues.

J. Janvore[1], M. Piel[1]; [1]Institut Curie, Paris Cedex 05, France

The very last step of cytokinesis in animal cells consists in the cleavage of an intercellular bridge containing stable microtubule bundles connecting the two daughter cells. Recently, several studies have described the microtubules organization and the implication of ESCRT components in membrane fission, but neither the triggering signal of the abscission nor the function of the bridge are known yet.
We have been asking whether the abscission process is regulated in time by extrinsic factors of the cell micro-environment. We analyzed the time from anaphase to abscission (abscission timing) in cells plated on different adhesive substrates (glass, fibronectin-coated glass or micro-patterned surfaces). We observed that abscission timing was shorter when cells were more confined. When cells were not confined, we found that motility of the daughter cells inversely correlated with abscission timing: the faster cells migrated, the longer abscission was delayed. Therefore, we hypothesized that tension in the intercellular bridge negatively regulated abscission. To directly demonstrate the inhibitory role of tension on abscission, we performed laser ablation experiments. Stereotyped abscission occurs by severing of microtubules on one side of the central piece (midbody), followed by severing on the other side. We cut microtubules on one side with the laser and found that this induced severing on the other side with the same average time delay observed between severing of both sides in control abscission. Importantly, this induced severing was inhibited by Spastin depletion. Experiments aimed at studying dynamic localization of ESCRT components in the process are underway. Finally we will present data showing that daughter cells have a correlated migration path as long as the intercellular bridge is present, suggesting an interesting function for the bridge in allowing relative positioning of daughter cells following division.
In conclusion, we propose that forces exerted on each other by daughter cells inhibit abscission probably by affecting ESCRT and Spastin localization and/or activity. This would allow daughter cells to remain connected until they reach independent mechanical equilibrium and, in some particular situation, this would allow them to move in a coordinated way until they reach their final position.

532

The novel MIT-domain-containing protein MITD1 interacts with ESCRT-III proteins and functions in cytokinesis.

S. LEE[1], A. Tipirneni[1], S. Yang[1], C. Blackstone[1]; [1]NINDS, National Institutes of Health, Bethesda, MD

Endosomal sorting complex required for transport (ESCRT) proteins are required for terminal membrane scission events in several important biological processes, including endosomal intraluminal vesicle formation, viral budding and cytokinesis. Unlike ESCRT-I and –II that are stable heteropolymeric complexes, ESCRT-III proteins assemble into large complexes at membrane target sites. Midbody recruitment of the ESCRT-III proteins are regulated by interactions with a series of microtubule interacting and transport (MIT)-domain-containing proteins including VPS4, spastin and AMSH. Even though many MIT-domain-containing proteins have been identified, it is still not fully understood whether they also function in the ESCRT-III recruitment to the midbody. Here we describe the ESCRT-III interactions of MIT-

domain containing protein 1 (MITD1), a 28-kDa protein that contains an N-terminal MIT domain. MITD1 localizes to the peripheral midbody during cytokinesis, and the MIT domain is critical for its midbody localization. Yeast-two hybrid analyses and co-immunoprecipitation assays demonstrated that MITD1 can self-assemble through its C-terminus, and gel-exclusion chromatography and chemical cross-linking studies showed that MITD1 exists as an oligomer in vivo. Interactions of MITD1 with all the ESCRT-III proteins were examined by yeast-two hybrid assay. Among them, only CHMP1B, CHMP2A and IST1 show strong interactions. Interestingly, sequence analysis revealed that the MIT domain of MITD1 is very similar to that of VPS4 proteins. The VPS4 residues identified by structure studies as required for interaction with ESCRT-III proteins are highly conserved in MITD1. Mutations in these residues of MITD1 inhibit both the interactions with ESCRT-III subunits and its localization to the midbody. We also investigated a role of MITD1 in cytokinesis in HeLa cells using siRNA transfection. We found that depletion of MITD1 increases the number of multinucleated cells, reflecting impaired cytokinesis. The recruitment of CHMP1B and IST1 to the midbody is also inhibited by MITD1 depletion. Taken together, our findings will provide a better understanding of the functional interactions of MIT-domain-containing proteins and ESCRT complexes as well as new insights into their roles in cell division.

Mitosis and Meiosis I

533

Purification of CPC from Mitotic Chromosomes.

L. Liu[1], A. Sarkeshik[2], J. R. Yates III[2], T. Stukenberg[1]; [1]Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA, [2]Chemical Physiology, The Scripps Research Institute, La Jolla, CA

Mitosis is regulated at both global levels and local level. While global regulation drives mitotic progression, the localized regulation fine tunes mitosis by turning on and off various activities at specific times and locations. The chromosome passenger complex (CPC) is the best characterized mitotic regulator that operates at the local level. The localization of the CPC is dynamic throughout mitosis, which corresponds to its various mitotic activities. During premetaphase and metaphase the CPC localizes at inner centromere where it corrects misattachment of microtubule and kinetochore and generates spindle checkpoint signals. Little is known about how and where the CPC is targeted to the inner centromere. To address this question, we have established 3 stable lines expressing LAP-Aurora-B, LAP-Borealin and LAP-Survivin respectively. Using immunofluorescence microscopy, we confirmed these LAP-tagged proteins localize properly in cells. The expression level of each tagged protein is about 0.5-1 fold of each endogenous protein. Using these lines we have successfully purified CPC from mitotic chromosomes digested with MNase. By MudPit analysis, we identified 122 proteins as CPC associated proteins at the inner centromere. Among these 122 proteins, only ten have known mitotic functions. Surprisingly, nine of the 122 proteins are involved in DNA repair and sixteen are implicated in apoptosis. The biochemical and biological significance of these interactions are under investigation.

534

WNK1 is required for mitosis and abscission.

S. TU[1], A. Budge[2,3], K. Luby-Phelps[2,3], M. Cobb[1]; [1]Department of Pharmacology, UTSouthwestern, Dallas, TX, [2]Department of Cell Biology, UTSouthwestern, [3]Live cell imaging core facility

WNK (with no lysine (K)) protein kinases are found in all sequenced multicellular and many unicellular organisms. WNKs influence ion balance. Two WNK family members are associated with a single gene form of hypertension. RNA interference screens have implicated WNKs in survival and growth, and WNK1 is essential for viability of mice. We found that in resting cells the majority of WNK1 is localized on cytoplasmic puncta. During cell division, WNK1 localizes to mitotic spindles. Therefore, we analyzed mitotic phenotypes in WNK1 knockdown cells. A large percentage of WNK1 knockdown cells fail to complete cell division, displaying defects in mitotic spindles and also in abscission and cell survival. One of the best characterized WNK1 targets is the protein kinase OSR1 (oxidative stress responsive 1). OSR1 regulates ion cotransporters, is activated in response to osmotic stress by WNK family members, and is largely associated with WNK1. In resting cells, the majority of OSR1, like WNK1, is on cytoplasmic puncta. OSR1 is also in nuclei. In contrast to WNK1, however, OSR1 does not concentrate around spindles during mitosis and does not show a WNK1-like localization pattern in mitotic cells. Knockdown of OSR1 has only a modest effect on cell survival and does not lead to spindle defects. As we are seeking the potential mechanism by which WNK1 may regulate spindle formation and abscission, one of our yeast two hybrid- indentified interacting proteins with WNK1 is dynein light chain- LC8. Though LC8 is associated with several different complexes in addition to dynein motor complexes, we are able to co-immunoprecipitate endogenous dynein motor complexes with WNK1. One of the most important regulatory proteins for dynein motor complexes is dynactin. Loss of dynactin could phenocopy loss of WNK1 in the spindle defects and abscission. Furthermore, loss of dynactin also affects the formation of several dynein motor complexes-dependent organells- including Golgi and lysosomes. When we examined loss of WNK1 cells, we do observe defects of Golgi and lysosomes as well. Currently, we are investigating the mechanism by which WNK1 may affect dynactin and dynein motor complexes through its catalytic or non-catalytic activity.

535

Mitotic kinases and the Set1 methyl transferase complex act in concert to regulate mitosis and cell growth.

M. Govindaraghavan[1], S. McGuire[2], S. A. Osmani[1]; [1]The Ohio State University, Columbus, OH, [2]Millsaps College

In *Aspergillus nidulans*, the mitotic kinases Cdk1 and NIMA are required for the G2-M transition. To gain insight into the mechanism of NIMA function, a synthetic lethal screen was carried out utilizing the deletion of the non-essential *nimA* orthologue, *KIN3*, in *Saccharomyces cerevisiae*. Using the *nimA7* temperature-sensitive allele, four of the synthetic genetic interactions were found to be conserved in *A. nidulans*, including synthetic lethality between *nimA7* and deletion of the ortholog of a subunit of the Set1 methyl transferase complex (*An-swd1*). Importantly a similar synthetic lethality was subsequently found to exist between partial loss of Cdk1 activity (*nimT23*^{ts} allele) and *ΔAn-swd1*. Moreover, since the deletion of *An-set1*, which encodes the catalytic protein, also causes synthetic lethality with partial loss of mitotic kinase phosphorylation, these genetic interactions are caused by the absence of Set1 complex mediated methyl transferase activity.

Analysis of the *ΔAn-swd1* + *nimT23*^{ts} double mutant indicates a role for Set1 complex mediated methylation in the G2-M transition. Cells with partially active Cdk1 exhibit a mild delay in the G2-

M transition but no marked mitotic defects consistent with Cdk1 activation being a biphasic switch. Importantly, in the *ΔAn-swd1 + nimT23^ts* double mutant an enhanced defect in mitotic initiation was observed. This indicates that both Set1 complex mediated methylation and Cdk1 phosphorylation act in conjunction to regulate the G2-M transition.
Unlike cells with partially active Cdk1 activity, cells with partially active NIMA do not exhibit a G2-M delay but instead show lack of coordination between mitotic events. For instance, low NIMA function prevents the normal process of partial nuclear pore complex disassembly while allowing other mitotic events like spindle formation to occur (although often defectively), suggesting that NIMA activation is not a biphasic switch. Furthermore, lack of Set1 complex methylation modifies the phenotype of cells that lack NIMA function resulting in growth defects and a lack of coordination between septation and mitosis. Our results indicate that the synthetic lethality in cells lacking Set1 complex function combined with partial NIMA function is due to a combination of defects in mitosis and septation causing growth defects.
Taken together, these results indicate that Set1 complex methylation and mitotic kinase phosphorylation act in concert in the regulation of mitosis and septation.

536

Regulation of the Chromosomal Passenger Complex.

B. Banerjee[1], P. Stukenberg[1]; [1]Univ of Virginia, Charlottesville, VA

The *Xenopus* chromosome passenger complex (CPC), composed of Aurora B and its regulatory subunits INCENP, Survivin and Dasra, ensures correct chromosome alignment and segregation during mitosis. The CPC regulates each chromosome autonomously, however, the mechanism is not well understood. Positive feedback can explain how a checkpoint signal generated from a single misaligned chromosome can be amplified to cause mitotic arrest. Our aim is to develop an understanding of the regulation of AuroraB kinase activity and the role of co-factors involved in this process. We have investigated the kinetics of recombinant CPC in vitro. In this study we have also included a few known activators of Aurora B kinase such as microtubules, DNA and Monopolar spindle 1(MPS1). Microtubules have been shown to stimulate AuroraB kinase activity. MPS1, a mitotic dual-specificity kinase has been shown to phosphorylate Dasra to regulate AuroraB activity. Lambda-phosphatase treated CPC lacks critical activation marks such as phosphorylation of the Aurora B T-loop and lacks kinase activity. When a small amount of active CPC is added, the phosphatase-treated CPC is activated, indicating requirement of intermolecular phosphorylation. The kinetics of activation suggests positive feedback. Additionally, we have seen that the catalytic domain of CPC has higher affinity for microtubules under low activity state. Kinase activity of the whole complex is higher than the catalytic domain (AI+TSS) alone, although when AI+TSS is pre-incubated with microtubules it shows comparably high activity as CPC. This suggests that microtubules might act as a platform for inactive CPC to concentrate, where it is activated by auto-phosphorylation and is then released. MPS1 immuno-precipitated from *Xenopus* egg extracts can also activate lambda-phosphatase treated CPC in vitro. In conclusion, our study so far reveals that the activation of the CPC involves a 'trans' phosphorylation event and generates a positive feedback loop, which could be greatly amplified by cofactors like microtubules and MPS1 to generate a robust checkpoint signal from a single unaligned chromosome.

Inhibitory phosphorylation of CDC2A is required to release CSF arrest in mouse oocytes.

J. Oh[1], A. Susor[1], K. Schindler[2], R. Schultz[2], M. Conti[1]; [1]University of California, San Francisco (UCSF), San Francisco, CA, [2]University of Pennsylvania

Entry into and exit from the M-phase in the cell cycle require activation and inactivation of maturation-promoting factor (MPF), a complex of CDC2A and cyclin B. The activity of MPF is regulated by phosphorylation of two highly conserved residues of CDC2A, T14 and Y15. In mouse oocytes, the inhibitory phosphorylations are catalyzed by the WEE kinases, whereas dephosphorylation of these residues is catalyzed by the CDC25 phosphatases. Although regulation of MPF activity by CDC2A phosphorylation is well established during entry into meiosis or mitosis, it remains unclear whether this regulation functions later during the exit from M-phase. Here, we show that MPF activity is regulated by the state of CDC2A phosphorylation as well as cyclin B degradation during meiotic exit. When WEE1B was down-regulated, oocytes were not able to exit from cytostatic factor (CSF)-mediated arrest in response to Ca2+ signals. Conversely, knockdown of CDC25 phosphatases induced release from CSF arrest. Surprisingly, MPF inactivation, mainly regulated by cyclin B degradation during anaphase onset, was associated with an increase in the inhibitory phosphorylation of CDC2A in CDC25 knockdown oocytes. Conversely, this phosphorylation was significantly decreased after WEE1B down-regulation. Furthermore, WEE1B kinase and CDC25 phosphatases were regulated by CaMKII and CDC14 phosphatase during the release from the CSF arrest, respectively. These findings suggest that MPF activity during CSF arrest is maintained not only by cyclin dynamics but also by CDC2A phosphorylation, which is regulated by the balance between CDC2A inhibitory kinases, WEE1, and the counteracting phosphatases, CDC25. Therefore, the concerted action of phosphorylation and dephosphorylation of CDC2A and synthesis and degradation of cyclin B cooperates in fine-tuning the activity of MPF during CSF arrest and MII release in mouse oocytes.

Casein Kinase 1 Dependent Control of Wee1 Degradation Regulates Mitotic Entry and Cerebellar Granule Cell Proliferation.

N. Ayad[1], M. Hatten[2], W. Roush[3]; [1]Psychiatry and Behavioral Sciences, University of Miami, Miami, FL, [2]Laboratory of Developmental Neurobiology, The Rockefeller University, [3]Chemistry, Scripps Florida

Eukaryotic mitotic entry is controlled by Cdk1, which is activated by the Cdc25 phosphatase and inhibited by Wee1 tyrosine kinase, a target of the ubiquitin proteasome pathway. Here we use a reporter of Wee1 degradation, K328M-Wee1-luciferase, and a kinase directed chemical library to demonstrate that CK1d/e kinase activities are essential for Wee1 degradation and mitotic entry in cerebellar granule cell progenitors (GCPs). Novel small molecule CK1d/e inhibitors (FKL135 and RJR159) specifically disrupted Wee1 destruction and arrested GCP proliferation and development in vitro and ex-vivo (Figure 1 below). Pharmacological inhibition or siRNA knockdown of CK1d/e also reduced Wee1 turnover and mitotic entry of GCPs, underscoring the importance of Wee1 regulation in controlling proliferation during brain development. Since defects in GCP proliferation are associated with medulloblastoma, these findings suggest that small molecule inhibitors of CK1d/e kinase may provide novel cancer therapy.

Pin1 acts as a negative regulator in G2/M transition.

L. Yu-Cheng[1]; [1]The insitute of Basic medical sciences of NCKU, Tainan City, Taiwan

Pin1 is the first identified and essential prolyl isomerase (PPIase) for cell division in both yeasts and mammalian cells. Structurally and functionally, Pin1 can be divided into N-terminus WW domain and C-terminus PPIase domain. The WW domain works as a phosphoserine/threonine-proline (pSer/Thr-Pro) binding module that helps Pin1 to target phosphoproteins. The PPIase domain has shown to specifically isomerize pSer/Thr-Pro peptide bond in a defined subset of phosphoproteins including transcription factors and cell cycle regulator. Pin1 therefore provides a novel post-phosphorylation regulatory mechanism that induces conformational changes following phosphorylation to control protein functions. This post-phosphorylation regulatory mechanism is pivotal for controlling many physiological processes and normal cell cycle progression. Deregulation of Pin1 can lead to some human diseases such as Alzheimer's disease and cancer. However, the functional regulation of Pin1 in cells remains unclear. In previous studies, the phenotype of Pin1 depletion is characterized by premature entry into mitosis, followed by mitotic arrest, while overexpression Pin1 inhibits the G2 to M progression, these results indicate that Pin1 is essential for regulation of mitosis at G2 to M transition and may act as a negative regulator for mitotic activity in G2 to prevent lethal premature entry into mitosis. However, very little is known about the mechanism. In this study, we demonstrated that Pin1 can be negatively regulated by Aurora A and involved in controlling G2 to M transition whereas during mitosis, Pin1 will feedback to regulate Aurora A function by promoting the degradation of hBora and the formation of Aurora A/TPX2 complex. Our results showed that Aurora A phosphorylates Pin1 at Ser16 and Ser16 phsophorylation levels consist with Aurora A activity during the cell cycle; Aurora A colocalizes and coimmunuoprecipitates with Pin1; overexpress Aurora A can increase Pin1-S16 phsophorylation and silence Aurora A expression or inhibit its activity can reduce Pin1-S16 phsophorylation. Moreover, we also find that Pin1 interacts with Aurora A cofactor-hBora in a phosphorylation-dependent manner; in Pin1-/- MEF cells, hBora steady-state expression is elevated compare to Pin1 wt MEF cells and re-express Pin1 in Pin1-/- MEF cells, hBora expression is reduced. Pin1 overexpression in cells overrides the effect of Aurora A-mediated Pin1 inactivation and thereby delays mitotic entry through reducing hBora steady-state level by β-TrCP-mediated proteasomal degradation pathway.

Proper ER morphology and partitioning during mitosis require phosphorylation-driven dissociation of STIM1 from EB1.

J. T. Smyth[1], A. M. Beg[1], J. W. Putney[2], N. M. Rusan[1]; [1]NHLBI, NIH, Bethesda, MD, [2]NIEHS, NIH

STIM1 is a trans-endoplasmic reticulum (ER) membrane protein that functions as an ER Ca^{2+} sensor in the process of store-operated Ca^{2+} entry (SOCE). In addition, STIM1 functions in ER morphogenesis through its interaction with the microtubule plus-end tracking protein EB1. Via this interaction, STIM1 mediates the extension of ER tubules along growing microtubules. How these distinct STIM1 functions are regulated under physiological conditions is a topic of intense investigation. To this end, we previously showed that STIM1 is phosphorylated during mitosis at sites recognized by the phospho-specific MPM-2 antibody, resulting in suppression of SOCE during cell division. We now test the hypothesis that STIM1 phosphorylation also regulates its interaction with EB1 during mitosis. In fixed interphase cells, eYFP-tagged STIM1 (eYFP-S1) colocalized with the ER and with endogenous EB1. However, during metaphase eYFP-S1 was found in concentric ER sheets surrounding the spindle but was nearly completely segregated from EB1, which localized to spindle microtubules. This suggests that the interaction of STIM1

with EB1 is disrupted during mitosis. To determine whether phosphorylation is responsible, we expressed eYFP-S1 with all 10 putative MPM-2 phosphorylation sites mutated to alanine (eYFP-10A). Remarkably, eYFP-10A exhibited extensive co-localization with EB1 in the metaphase spindle, strongly supporting the hypothesis that phosphorylation negatively regulates the interaction of STIM1 with EB1 during mitosis. Further, concomitant mutation of the EB1 interaction site reversed the colocalization of eYFP-10A with EB1, verifying that EB1 interaction is responsible for this striking effect of mutation of STIM1 phosphorylation sites. In live-cell imaging, eYFP-10A exhibited microtubule tip tracking behavior within the metaphase spindle, similar to that seen with a tagged EB1 construct, whereas tip tracking was not evident with eYFP-S1. Further, when eYFP-10A was co-expressed with ER-targeted dsRed (ER-dsRed), the ER was seen to extend extensively within the spindle. This was in stark contrast to cells co-expressing eYFP-S1 and ER-dsRed or ER-dsRed alone, in which the bulk of the spindle was completely devoid of ER-dsRed with only a small amount localized at the spindle poles. Abnormal localization of ER-dsRed in cells expressing eYFP-10A remained through telophase and abscission, during which ER-dsRed associated with mid-body microtubules. Thus, STIM1 phosphorylation is critical for maintenance of proper ER morphology and partitioning during mitosis.

Cracking the Eggshell: Protective Barrier Assembly Following Fertilization of the *C. elegans* Embryo.

S. K. Olson[1], K. Sniegowski[1], G. Greenan[2], T. Müller-Reichert[2], K. Oegema[1]; [1]University of California, San Diego, La Jolla, CA, [2]Medical Theoretical Center (MTZ), TU Dresden, Dresden, Germany

Metazoan oocytes have an extracellular coating that governs fertilization. Following fertilization, this covering is altered to prevent polyspermy and protect the developing embryo. In *C. elegans*, a vitelline layer covers oocytes prior to fertilization. Fertilization initiates conversion of the vitelline layer into a trilaminar eggshell consisting of an outer vitelline layer, a middle chitin-containing layer, and an inner layer proposed to serve as a permeability barrier. Here, we characterize CPG-1 and CPG-2, functionally redundant chondroitin proteoglycans that are the first described protein eggshell components. We show that CPG-1 and CPG-2 are delivered to the extracellular space after formation of the chitin layer by cortical granule exocytosis during meiosis I. Although they contain multiple chitin binding domains, CPG-1 and CPG-2 localize to the inner eggshell layer, whereas chitin is confined to the middle layer. We show that the inner eggshell layer is not the permeability barrier for small molecular weight solutes. Instead, this function resides in a previously undescribed layer that assembles between the eggshell and the plasma membrane following meiosis II. Disruption of the permeability barrier leads to solute permeability and osmotic stress. Disruption of the inner CPG-1/2 eggshell layer causes these phenotypes, as well as adhesion of the embryonic plasma membrane to the eggshell and cytokinesis failure. Interfering with chitin layer assembly results in the inner layer phenotypes, plus polyspermy and catastrophic eggshell rupture. We conclude that the eggshell layers and permeability barrier are laid down in a step-wise and cell cycle-dependent fashion, with later assembly events requiring successful completion of previous ones. To build on this work, we conducted an RNAi screen to identify additional genes that regulate eggshell and permeability barrier assembly. Several screen hits rendered the eggshell permeable, with minimal deleterious effects on early embryonic development. We therefore developed a reliable method to permeabilize and immobilize embryos to allow acute drug/inhibitor treatment to study early embryonic processes with live imaging.

Polar body size is minimized by the centralspindlin complex.

A. S. Fabritius[1], F. McNally[1]; [1]Molecular and Cellular Biology, University of California Davis, Davis, CA

Polar body formation involves completion of a highly asymmetric cytokinesis that results in a large egg and 2 small polar bodies. Unlike mitotic contractile rings, polar body contractile rings assemble over one spindle pole so that the spindle must move through the contractile ring before cytokinesis. During time-lapse imaging of *C. elegans* meiosis, the contractile ring moved downward along the length of the spindle and completed scission at the midpoint of the spindle, even when spindle length or rate of ring movement was increased. Patches of myosin heavy chain and dynamic furrowing of the plasma membrane over the entire embryo suggested that global cortical contraction forces the meiotic spindle and overlying membrane out through the contractile ring center. Consistent with this model, depletion of myosin phosphatase increased the velocity of ring movement along the length of the spindle. Global dynamic furrowing, which was restricted to anaphase I and II, was dependent on myosin II, the anaphase promoting complex and separase, but did not require cortical contact by the spindle. Large cortical patches of myosin during metaphase I and II indicated that myosin was already in the active form before activation of separase. To identify the signal at the midpoint of the anaphase spindle that induces scission, we depleted two proteins that mark the exact midpoint of the spindle during late anaphase, CYK-4 and ZEN-4. Depletion of either protein resulted in the unexpected phenotype of initial ingression of a polar body ring with twice the diameter of wild type. This phenotype revealed a novel mechanism for minimizing polar body size. Proteins at the spindle midpoint are required for initial ring ingression to occur close to the membrane-proximal spindle pole.

Regulation of cell wall separation and osmotic stability by the *Saccharomyces cerevisiae* nuclear membrane proteins Brl1 and Brr6.

H. E. Loehr[1], N. J. Thomas[1], M. J. Wolyniak[1]; [1]Biology, Hampden-Sydney College, Hampden-Sydney, VA

The ability of yeast to replicate and divide properly through mitosis is crucial for the maintenance of species stability. Previous work in the budding yeast *Saccharomyces cerevisiae* has suggested that the peripheral nuclear membrane proteins Brr6 and Brl1 may play a role in the regulation of membrane fluidity in response to both environmental change and cell cycle progression (Hodge *et al.*, 2010). To assess the influence of Brl1 and Brr6 on the cell division process, we explored the cell growth and division properties of the temperature-sensitive conditional mutants *brl1-1* and *brl1-2*, as well as the cold-sensitive mutant *brr6-1*. When grown at their restrictive temperatures, all conditional mutant strains exhibited cell separation failures, with several yeast cells chained together or in clusters. In addition, the *brl1* strains showed an increased tendency to grow hypha-like structures and other abnormal shapes, indicating a failure to properly regulate daughter cell development during cell division. Zymolyase digestion analysis was performed to see if such treatment would be sufficient to break up cell chains and clusters. Treatment of the *brr6-1* strain grown at the restrictive temperature resulted in only single and budded cells, suggesting that the previously observed chains and clusters of cells were the result of a failure in cell wall remodeling following mitosis. The *brl1* strains showed a similar tendency following zymolyase treatment but more significantly became mostly desiccated in this same process, suggesting that Brl1 may play a significant role in osmotic regulation. This connection was further established in growth experiments with the osmotic stabilizer sorbitol. Use of 1M sorbitol completely rescued the growth defect of *brl1* mutant cells

grown at the restrictive temperature. Together, these findings strongly link Brl1 and Brr6 to the cell wall remodeling necessary to permit cell separation following mitosis and further implicate Brl1 in osmotic regulation and cell shape determination during the cell division process.

The Greatwall Substrate Arpp19 Controls Mitotic Entry By Inhibiting PP2A.

A. Gharbi Ayachi[1], J-C. Labbé[1], A. Burgess[1], S. Vigneron[1], A. Castro[1], T. Lorca[1]; [1]CNRS, CRBM, Montpellier, France, Montpellier, France

Initiation and maintenance of mitosis requires the activation of protein kinase cyclin B-Cdk1 and the inhibition of protein phosphatase 2A (PP2A), which respectively phosphorylate and dephosphorylate mitotic substrates. The protein kinase Greatwall (Gwl) is required to maintain mitosis through PP2A inhibition however this inhibition appears to be indirect. The objective of this work was the identification of the Gwl substrates that mediate PP2A inhibition and mitotic entry. To that Xenopus egg extracts were biochemically fractionated and submitted to *in vitro* phosphorylation with an ectopic Gwl kinase. The identity of the phosphorylated proteins was subsequently determined by mass spectrometry. We identified cyclic adenosine monophosphate-regulated phosphoprotein 19 (Arpp19) and α-Endosulfine as two substrates of Gwl that, when phosphorylated by this kinase, associate with and inhibit PP2A, thus promoting mitotic entry. Conversely, in the absence of Gwl activity, Arpp19 and α-Endosulfine are dephosphorylated and loose their capacity to bind and inhibit PP2A. Although both proteins can inhibit PP2A, endogenous Arpp19, but not α-Endosulfine, is responsible for PP2A inhibition at mitotic entry in Xenopus egg extracts. These results describe how Gwl activation results in PP2A inhibition. Thus, at mitotic entry Arpp19 phosphorylation by Gwl promotes the binding of Arpp19 to PP2A and the inhibition of this phosphatase allowing the phosphorylation of cyclin B-Cdk1 substrates and promoting mitotic entry.

545

APC/C-mediated multiple monoubiquitination provides an alternative degradation signal for cyclin B1.

N. Dimova[1], N. Hathaway[1], B-H. Lee[1], D. Kirkpatrick[1], M. Berkowitz[1], S. Gygi[1], D. Finley[1], R. King[1]; [1]Department of Cell Biology, Harvard Medical School, Boston, MA

The Anaphase-Promoting Complex/Cyclosome (APC/C) regulates progression through mitosis by orchestrating the ubiquitination of cell-cycle regulators such as cyclin B1 and securin. Although Lys48-linked ubiquitin chains represent a canonical signal targeting proteins for degradation by the proteasome, they are not required for the degradation of cyclin B1 in a reconstituted system. Recently, Lys11-linked ubiquitin chains have been implicated in degradation of APC/C substrates, but the Lys11-chain forming E2 UBE2S is not essential for mitotic exit. Together these findings raise important questions about the nature of the ubiquitin signal that targets APC/C substrates for degradation. Here, using a reconstituted system and Xenopus egg extracts, we demonstrate that multiple monoubiquitination of cyclin B1, catalyzed by UBCH10 or UBC4/5, is sufficient to target cyclin B1 for destruction by the proteasome. However, Lys11-linked ubiquitin polymers elaborated by UBE2S become increasingly important when the number of ubiquitinatable lysines in cyclin B1 is restricted. We therefore define a novel proteolytic signal in the ubiquitin-proteasome pathway that confers flexibility in the requirement for particular E2 enzymes in modulating the rate of ubiquitin-dependent proteolysis.

546

The Budding Yeast Kinesin Kar3/Cik1 Corrals Interpolar Microtubule Plus Ends During Mitosis.

E. Davidson[1], T. Davis[1]; [1]Biochemistry, University of Washington, Seattle, WA

During mitosis, spindle pole separation is maintained by interpolar microtubules (ipMTs) that emanate from each pole and that are bundled in the spindle midzone in antiparallel fashion. The budding yeast kinesin-14 Kar3/Cik1, a minus-end directed microtubule motor, is involved in microtubule bundling and localizes to ipMTs' plus ends. However, its exact role in organizing these microtubules is unclear.
To better understand the regulation and organization of spindle microtubules during mitosis, we performed a synthetic lethal screen against a mutant whose spindle microtubules adopt a random length. This screen produced mutant alleles of Kar3 and Cik1, among other genes. Analysis of the spindle localization of these proteins in various backgrounds using still and time-lapse fluorescence microscopy has shed light on how and when this motor is important for proper spindle function. Unlike many spindle components, Kar3/Cik1 foci do not concentrate at a particular point along the spindle axis; instead they are highly mobile, possibly tracking with polymerizing ipMT plus ends. Mutating Cik1 results in poorly bundled ipMTs in anaphase, while mutating the Kar3 motor domain results in a doubling of Cik1 fluorescence intensity, suggesting that motility is required for proper clearance of Kar3/Cik1. In addition, this Kar3 mutant displays defects in metaphase pole separation that appear to be a result of failure to properly create and maintain ipMT bundles. These results confirm that Kar3/Cik1 is necessary for proper ipMT organization and suggest that its role may be to track with polymerizing ipMT plus ends to keep them in the vicinity of the ipMT bundle.

547

Dual role of separase during the metaphase-to-anaphase transition ensures chromosome segregation in mammalian cells.

N. Shindo[1], T. Hirota[1]; [1]Cancer Inst JFCR, Tokyo, Japan

Separation of sister chromatids has long been recognized as a dynamic and irreversible event in the cell cycle. A fascinate feature of this process in mammalian cells is that the separation occurs abruptly in a highly synchronous manner at the onset of anaphase. Dissociation of sister chromatid cohesion is triggered by the cleavage of cohesin complexes, which is mediated by a cysteine endopeptidase separase. Activation of separase depends on proteolysis of separase inhibitors such as securin and cyclin B1 in metaphase, but the exact timing of activation and the relative importance of these inhibitors are not well understood. Here we developed a fluorescence-based sensor for separase activity, and found that separase is tightly regulated until the end of metaphase when the activity was abruptly detected on entire chromosome lengths. This switch-like activation is achieved by the relative abundance of securin over separase that prevents precocious activation and by securin's ability to target separase to chromosomes, whose function can be largely if not completely substituted by cyclin B1. Significantly, we found that the binding of separase to cyclin B1 is facilitated in anaphase and this binding is required to silence cdk1 activity and to promote sister chromatid separation. We propose that the switch-like activation of separase protease activity and subsequent inhibition of cdk1 is an ideal mechanism to ensure synchronous removal of sister chromatid cohesion and poleward movement of unpaired chromatids in mammalian cells.

548

The anaphase B switch: the role of kinesin-13.

H. Wang[1], I. Brust-Mascher[1], J. M. Scholey[1]; [1]Molecular & Cellular Biology, Univ California-Davis, Davis, CA

Accurate chromosome segregation in mitosis involves chromosome-to-pole movement in anaphase A and spindle elongation in anaphase B. Several studies suggest that anaphase B spindle elongation is driven by a “sliding filament” mechanism that depends on the action of kinesin-5, a bipolar, MT crosslinking motor which slides apart interpolar (ip) MTs. During metaphase and anaphase A (referred to as pre-anaphase B) in Drosophila embryonic mitosis, MT minus-end depolymerization at the poles balances the outward ipMT sliding, producing MT “poleward flux”, the movement of tubulin subunits from the equator to the poles and maintaining the spindle length constant. We propose that this depolymerization is due to KLP10A, a Drosophila kinesin-13, which is concentrated at spindles poles throughout embryonic mitosis. At anaphase B onset, cyclin B degradation induces suppression of MT depolymerization at the poles, and thus outward ipMT sliding drives spindle elongation.

To test if suppression of KLP10A activity leads to anaphase B spindle elongation, we experimentally reduced KLP10A activity in pre-anaphase B arrested spindles that had reached their steady spindle length. Specifically, we first injected embryos with non-degradable GST-cyclin B (cyc B) to arrest mitosis before anaphase B. Then an anti-KLP10A antibody was injected into embryos that had started anaphase A chromosome segregation, but had no anaphase B spindle elongation. While embryos injected with only cyc B reproducibly showed no evident spindle elongation from metaphase on and arrested in pre-anaphase B for 10-30 min, a subsequent anti-KLP10A injection into the cyc B treated embryos caused abrupt spindle elongation of those pre-anaphase B arrested spindles, at rates similar to wild-type anaphase B elongation rates. Fluorescent speckle microscopy further showed that cyc B injection perturbed the anaphase B switch by allowing MT poleward flux to persist, however, the subsequent KLP10A inhibition converted MT poleward flux to spindle elongation, which mimicked the anaphase B switch. These findings strongly support the hypothesis that inhibition of KLP10A-mediated ipMT depolymerization at the poles allows kinesin-5 ipMT sliding to drive anaphase B spindle elongation in wild type Drosophila embryos.

549

Molecular analysis and mathematical modeling of the ‘switch’-like behavior of the metaphase-to-anaphase transition.

J. Kamenz[1], T. Mihaljev[2], S. Legewie[2], S. Hauf[1]; [1]Friedrich Miescher Laboratory of the Max Planck Society, Tuebingen, Germany, [2]Institute of Molecular Biology, Mainz

The transition from metaphase to anaphase is one of the crucial steps in the cell cycle, at which the events of sister chromatid separation and mitotic exit need to be precisely coordinated. Central to the transition is the anaphase promoting complex/cyclosome (APC/C), which targets cyclin B and securin for proteasomal destruction. Cyclin B degradation inactivates the cyclin-dependent kinase CDK1 and hence promotes mitotic exit. Securin degradation releases its binding partner separase from the inhibitory association. Subsequently, free separase proteolytically cleaves a cohesin subunit and thereby promotes the loss of chromosomal cohesion and the irreversible separation of sister chromatids.
Surprisingly, sister chromatid separation is highly synchronous and about 20 times faster than the underlying securin degradation. We want to understand how slow securin degradation translates into abrupt sister chromatid separation and how this contributes to the robust

coordination of the events during mitotic exit. To this end, we employ a combination of live cell imaging, quantitative proteomics and computational modeling.
We have established two imaging assays with which we follow securin degradation and sister chromatid separation at high temporal resolution in *Schizosacharomyces pombe*. Consistent with findings in other organisms, we show that in *S. pombe* securin degradation is about a magnitude slower than sister chromatid separation. Furthermore, sister chromatid separation occurs invariantly when 25 % of securin have been degraded. In order to approach the underlying mechanism of this 'switch'-like behavior, we systematically changed abundances or activities of key proteins at the transition and observed the system's response to the alterations. First results suggest that APC/C but not CDK1 activity influences the threshold level at which sister chromatid separation takes place as well as the 'sharpness' of sister chromatid separation. We have subsequently tested several models of the transition, e.g. inhibitor-sequestration or positive feedback models, *in silico* for their ability to reconcile with our experimental data. Currently, we are in the process of testing experimentally the predictive power of the different models by further system changes.

550

Mechanism of inhibition of the Anaphase-Promoting Complex by a small molecule antagonist of the IR tail of Cdc20.

X. Zeng[1], R. W. King[1]; [1]Cell Biology, Harvard medical school, Boston, MA

The Anaphase-Promoting Complex/Cyclosome (APC) is a multi-subunit ubiquitin E3 ligase that drives anaphase onset by targeting securin and cyclin B1 for proteolysis by the 26S proteasome. APC activity in mitosis requires the activator Cdc20. Because of the APC¡¯s essential function in mitosis, it is important to understand its catalytic mechanism and how its activity is regulated by the mitotic machinery. Pharmacologically, the APC is a potential target for anti-mitotic cancer drugs.
We previously identified Tosyl Arginine Methyl Ester (TAME) as the first small molecule inhibitor of APC-dependent proteolysis and developed a cell permeable prodrug (proTAME) that induces mitotic arrest in cells. We then showed that TAME inhibits APC activation by competing with the C-terminal IR tail of Cdc20 for APC binding. Here we show that in the absence of APC substrates, TAME ejects Cdc20 from the APC by promoting Cdc20 auto-ubiquitination in its N-terminal region. Ubiquitination in N-terminal region reduces the binding affinity of Cdc20 for the APC. Cyclin B1 antagonizes TAME¡¯s effect by promoting the binding of free Cdc20 to the APC and suppressing Cdc20 auto-ubiquitination. However, TAME causes cyclin B1 ubiquitination to terminate before reaching the threshold necessary for proteolysis, because partially ubiquitinated cyclin B1 has reduced binding affinity for Cdc20 and loses its ability to promote Cdc20 binding to the APC in the presence of TAME. Furthermore, TAME reduces the kcat of the APC/Cdc20/substrate complex without affecting the Km, suggesting that docking of the IR tail of Cdc20 is critical for APC activity beyond recruiting Cdc20. Together these results provide a definitive answer to TAME¡¯s mechanism of action and shed light on the catalytic mechanism of the APC.

551

Is Cdk1 phosphorylation of the APC essential?

L. Williams[1], E. Redmond[1], A. Rudner[1]; [1]Biochemistry, Microbiology & Immunology, University of Ottawa, Ottawa, ON, Canada

Cdk1 promotes the metaphase to anaphase transition by phosphorylating the anaphase promoting complex (APC), a multisubunit ubiquitin ligase that targets specific mitotic regulators

for degradation by the proteasome. The degradation of these proteins is critical for accurate sister chromatid segregation and mitotic exit.
Here we show that overexpression of the kinase Swe1 (the budding yeast homolog of Wee1), which inhibits Cdk1, stabilizes mitotic cyclins and Pds1 (securin), and impairs sister chromatid segregation. These effects are not due to activation of the DNA damage or spindle checkpoint, which both act to inhibit the metaphase to anaphase transition. Furthermore, if Swe1 is overexpressed in anaphase, after degradation of Pds1, we see that Pds1 is re-stabilized, showing that Swe1 can block APC-mediated proteolysis throughout mitosis. Swe1 overexpression also reduces APC phosphorylation in vivo, which results in a drop in the in vitro ubiquitination activity of the APC. In vitro Cdk1 kinase treatment causes an increase in APC phosphorylation, which reactivates the activity of APC isolated under conditions of Swe1 overexpression. We believe the effects of Swe1 are therefore caused by inhibition of Cdk1-dependent phosphorylation of APC subunits, and suggest that Cdk1-dependent phosphorylation of the APC may be essential for mitotic APC activity.
Despite the results of the Swe1 overexpression studies, blocking phosphorylation of Cdk1 consensus sites on two different subunits of the APC (Cdc16 and Cdc27) does not lead to reduced activity of the APC in an in vitro ubiquitination assay. Preliminary genetic analysis, however, suggests that the presence of these phosphorylation sites is essential for viability when a number of the non-essential subunits of the APC have been deleted. In vitro Cdk1/Clb2 kinase treatment of the APC also shows that one of the non-essential subunits, Cdc26, is phosphorylated, indicating the presence of additional Cdk1 phosphorylation sites on the APC. We are currently furthering our investigation of the role of the non-essential subunits of the APC.

552

New Roles For The Budding Yeast Wee1 Kinase and PP2A Phosphatase In Regulating Anaphase Onset.

N. Lianga[1], E. Redmond[1], L. Williams[1], A. Rudner[1]; [1]Department of BMI, Ottawa Institute of Systems Biology, Ottawa, ON, Canada

Wee1 kinase plays a critical role in linking cell growth to cell division. Wee1 phosphorylates and inhibits Cdk1. This inhibition is relieved by the phosphatase Cdc25. Deletion of Wee1 causes cells to divide at a reduced cell size and deletion of Cdc25 promotes increased cell growth and is lethal. Cdk1 inhibition by Wee1 has been shown to delay mitotic onset. The budding yeast Wee1, Swe1, is also important in regulating mitotic onset in response to cues regarding cell morphogenesis. Mutations and drug treatments that inhibit bud growth cause a Swe1-dependent cell cycle delay. This delay is also dependent on Cdc55, a regulatory subunit of the PP2A phosphatase, however the target of PP2A in this response is unknown.

Interestingly, overexpression of Swe1 or treatment with the actin depolymerizing drug Latrunculin A delays cell cycle progression with separated spindle pole bodies, suggesting a role for Swe1 inhibiting anaphase onset. The metaphase to anaphase transition is triggered by Cdk1-dependent phosphorylation and activation of the Anaphase Promoting Complex (APC) associated with its activating subunit Cdc20. Here we show that Swe1 inhibition blocks Cdk1-dependent activation of the APC and that this inhibition plays a role in the timing of anaphase in every cell cycle. Additionally, our preliminary results suggest that PP2A-Cdc55 delays anaphase onset by dephosphorylating Cdk1 sites on the APC.

Although Swe1-dependent inhibition of Cdk1 blocks APC activity, stabilization of the APC substrate Pds1 (securin) does not fully explain the block to anaphase initiation caused by Swe1 activity. We therefore believe the effects of Swe1 are caused by inhibition of both Cdk1-

dependent phosphorylation of APC subunits, as well as Cdk1-dependent inhibition of a second substrate that promotes anaphase in concert with the APC. We are currently trying to identify this critical second Cdk1 substrate (or substrates) whose activation is needed to promote anaphase.

553

Dynamics of kinesin-5 and kinesin-14 throughout the anaphase B switch in *Drosophila* syncytial embryos.

I. Brust-Mascher[1], G. Civelekoglu-Scholey[1], D. Cheerambathur[2], P. Sommi[3], J. M. Scholey[1]; [1]Molecular and Cellular Biology, University of California-Davis, Davis, CA, [2]Cellular and Molecular Medicine, University of California-San Diego, [3]Physiology, University of Pavia, Italy

The mitotic spindle is a dynamic protein machine. In *Drosophila* syncytial embryos, Fluorescence Recovery after Photobleaching (FRAP) experiments have shown that tubulin exhibits turnover on the order of a few seconds during all stages of mitosis. However, the extent of recovery changes at anaphase B onset: before anaphase B, recovery is complete all along the spindle, whereas during anaphase B, recovery near the poles is lower. The bipolar kinesin-5 is required during mitosis. Kinesin-14, although not required, acts antagonistic to kinesin-5. What are the dynamics of these two kinesins? We performed FRAP experiments in *Drosophila* embryos expressing either KLP61F-GFP in a *klp61f* mutant background, or GFP-Ncd in an *ncd* mutant background, in each case the transgene rescued the corresponding mutant phenotype. Both motor proteins have turnover rates of 3-4 seconds and recover 80 to 90% of fluorescence intensity. KLP61F-GFP exhibits a decrease in recovery near the poles during anaphase B similar to that seen in tubulin FRAP. Fluorescence Speckle Microscopy (FSM) of these proteins shows that a fraction of KLP61F-GFP motors are stationary on the spindle, while interpolar microtubules (MTs) are slid apart. The other fraction of KLP61F-GFP and most of GFP-Ncd appears to move in both directions. We have developed a computational model that describes the dynamics of the MTs, and the two mitotic kinesins' binding and detachment from the MTs. We are varying the biochemical properties of the motors in *in silico* FSM and FRAP and comparing simulation results with our experimental observations to further study the motors' mode of function and interdependence. KLP61F data conform to a reaction-diffusion model in which most KLP61F is bound to spindle MTs, with the remainder diffusing freely. KLP61F appears to transiently bind MTs, moving short distances along them before detaching.

554

Optical traps can stop movements of Mesostoma spermatocyte kinetochores.

J. Ferraro-Gideon[1], Q. Zhu[2], M. W. Berns[2], A. Forer[1]; [1]York University, Toronto, ON, Canada, [2]University of California, San Diego

Mesostoma spermatocytes have 3 bivalents, each bipolarly oriented. Each bivalent's kinetochore moves to and away from its spindle pole at speeds of 6-12µm/m in excursions of 6-7µm, reversing its direction at 1-2 minute intervals. Kinetochore oscillations in *Mesostoma* spermatocytes continue for approximately 2 hours prior to the onset of anaphase, making *Mesostoma* spermatocytes ideal for determining the force required for chromosome movement. To study the force required for chromosome movement, we focused a Nd:YVO4 continuous wave 1064 nm wavelength laser using a 63x oil immersion objective (na 1.4) to a single point [Shi *et al Microsc Res Tech* **69** (2006) 894] in order to trap kinetochores that moved to or away from their poles. We were able to stop movement as the kinetochore moved in either direction using laser power of 300mW or greater in the focused spot but kinetochore movement did not recover when the trap was released. Consequently we lowered the laser power and were able to stop chromosome movements with powers as little as 26mW in the focused spot. Movements

recovered when the kinetochores were released from traps with these lower powers. When individual kinetochores were stopped by the traps the oscillatory movements of their partner kinetochores were not affected. From the power in the trap we calculated that the minimum force required to stop chromosomes moving to the pole or away from the pole is of the order of 10^{-6}dynes (10^{-11}Newtons).

Investigating the role of SPD-3 in homolog pairing and synapsis of meiotic chromosomes in *C. elegans.*

R. Rillo[1], A. Dernburg[1,2]; [1]Molecular and Cellular Biology, University of California, Berkeley, Berkeley, CA, [2]Howard Hughes Medical Institute

Faithful segregation of chromosomes at the first meiotic division is dependent on proper homologous pairing and synapsis. In *C. elegans*, specific regions on each chromosome called Pairing Centers are essential for linking chromosomes to the microtubule cytoskeleton, thereby facilitating chromosome motion required for the proper coordination of pairing and synapsis. Previous work from our lab has shown that specific nuclear envelope proteins aggregate at sites of Pairing Centers and are important for the establishment of chromosome-MT bridges across the nuclear envelope. In the absence of the inner nuclear membrane protein SUN-1 and KASH-domain bearing protein ZYG-12, chromosomes fail to pair and undergo inappropriate synapsis with random, nonhomologous partners. How these components execute their function to facilitate proper pairing and synapsis remains to be determined.

A candidate screen for new factors involved in meiotic chromosome dynamics revealed a potential role for SPD-3 in pairing and synapsis. A temperature-sensitive allele, *oj35*, results in variable meiotic defects when shifted to the restrictive temperature (25°C) at the L4 stage. To deplete SPD-3 more completely, I performed RNAi in *spd-3(oj35)* mutants at the restrictive temperature. *spd-3(oj35, RNAi)* mutants undergo extensive nonhomologous synapsis in pachytene, similar to that seen in *sun-1* loss of function mutants, indicating that SPD-3 may play a similar role in coordinating pairing and synapsis.

Using SPD-3 as bait in a yeast two-hybrid screen revealed potential interactions with a putative ubiquitin ligase RFP-1 and a small, uncharacterized protein, K12H4.2, among other candidates. Both *rfp-1* and *K12H4.2* exhibit a synthetic genetic interaction with *spd-3*. Knockdown of either RFP-1 or K12H4.2 by RNAi shows no meiotic defects. However, knockdown of either protein in the *spd-3(oj35)* background results in nonhomologous synapsis even at the permissive temperature. These observations suggest that SPD-3 is a bona fide interactor of both RFP-1 and K12H4.2. I am continuing to investigate the function and relationship of these proteins and how they contribute to early events of meiosis in C. elegans.

556

CDK16/PCTAIRE kinase 1 is activated by Cyclin Y and is essential for spermatogenesis.

P. Mikolcevic[1], R. Sigl[1], V. Rauch[1], M. Hess[2], K. Phaller[2], L. J. Pelliniemi[3], M. Boesl[4], S. Geley[1]; [1]Medical University Innsbruck, Biocenter, Innsbruck, Austria, [2]Division of Histology and Embryology, Medical University Innsbruck, Innsbruck, Austria, [3]Institute of Pathology and Microbiology, Turku, Finland, [4]Max-Planck-Institute of Biochemistry, Martinsried, Germany

Cyclin dependent kinase 16 (CDK16, PCTK1) is a poorly characterised protein kinase highly expressed in the brain and in the testis. We found that membrane-associated cyclin Y (CCNY) binds to and activates CDK16. The PKA activator forskolin blocked, while kinase inhibition promoted, CCNY-dependent targeting of CDK16-GFP to the cell membrane, implying a kinase-

controlled mode of cyclin-CDK interaction. CCNY binding to CDK16 required a region upstream of the kinase domain and was found to be inhibited by phosphorylation of serine 153, a potential PKA phosphorylation site. Thus, unlike other CDKs, CDK16 is regulated by phosphorylation controlled cyclin binding. In human cell lines, endogenous CDK16 was phosphorylated at S153 and inactive. In contrast, CDK16 isolated from murine testis was less phosphorylated, interacted with CCNY and exhibited kinase activity. Mice lacking CDK16 developed normally but male mice were infertile. Spermatozoa isolated from the epididymis of *Cdk16* knockout mice displayed thinning and elongation of the annulus region, adopted a bent shape and showed impaired motility. Moreover, CDK16-deficient spermatozoa had malformed heads and excess residual cytoplasm suggesting a role of CDK16 in spermiation. Thus, CDK16 is a membrane-targeted CDK essential for spermatogenesis.

557

Protein Phosphatase 1 is Required Downstream from Cdk1 Inactivation in Exit from Mitosis but Cdc14 Phosphatase is not.

J. M. Keaton[1], B. Workman[1], L. Xie[1], M. Stark[2], J. R. Paulson[1]; [1]Chemistry, Univ Wisconsin-Oshkosh, Oshkosh, WI, [2]Wellcome Trust Centre for Gene Regulation and Expression, University of Dundee, Dundee, United Kingdom

We show that inactivation of Cdk1/Cyclin B (Cdc28/Clb2 in the budding yeast, Saccharomyces cerevisiae) induces cells to leave mitosis and return to interphase. S. cerevisiae strains carrying the mutation cdc28-as1, which makes Cdc28 (Cdk1) uniquely sensitive to inhibition by a specific ATP analog, were arrested at metaphase and then treated with the analog. These cells did not undergo cytokinesis but did exit mitosis based on the following observations: Rebudding was initiated, MAT a cells underwent “shmooing” when treated with alpha-factor, Sic1-GFP was stabilized in the nuclei, and the mitotic cyclin Clb2 and the securin Pds1 were degraded. These results show that specific inhibition of Cdk1 (Cdc28) in mitotic cells is sufficient to induce mitotic exit. They also provide a chemical genetic system in which to test whether particular gene products are required downstream from Cdk1 inactivation in the transition from mitosis to G1-phase. Using this approach and various conditional mutations in protein phosphatase genes, we demonstrate that Protein Phosphatase 1 (Glc7 in S. cerevisiae) is required downstream from Cdk1 inactivation during exit from mitosis, but the Cdc14 Phosphatase is not.

558

Dynamic mobility of Chk2/Mnk is required for DNA damage responses in early Drosophila embryos.

S. Takada[1], B. J. Cha[2], E. R. Collins[3], M. Hara[1]; [1]Dept. BMBB, Univ Minnesota, Minneapolis, MN, [2]Lisa Muma Weitz Advanced Microscopy Laboratory, College of Medicine, Univ South Florida, [3]College of Biological Sciences, Univ Minnesota, Minneapolis, MN

DNA damage that persists in cells can cause severe problems including cancer and genetic diseases. A tumor-suppressor Chk2 (CHeckpoint Kinase 2) is one of the major signal transducers that receive the DNA damage signal from upstream kinases such as ATM (Ataxia Telangiectasia-Mutated) or ATR (AT and Rad3-related), amplify the signal, and target cellular effectors to cause a wide variety of DNA damage responses. The *Drosophila* homolog of Chk2, which is known as Mnk or Loki, is essential for DNA damage responses in early embryos. The responses include a block of mitotic progression (centrosome/sindle disruption and spindle checkpoint activation), nuclear dropping from the embryo cortex during the syncytial blastoderm stage, and blocks of transcriptional activation of zygotic genes and termination of a rapid cleavage cell cycle at the midblastula transition. We have shown that Chk2/Mnk dynamically changes its localization to the nucleus and the centrosomes during interphase, and to the

centrosomes (spindle poles), kinetochores, midbody, and pseudo-cleavage furrows during mitosis, by observing transgenic embryos that express EGFP-Mnk under the control of UAS/GAL4. To understand the mechanisms of embryonic DNA damage responses, we have further created a variety of transgenic strains that are designed to express deletions or point mutants of Mnk conjugated with EGFP. We have shown that the FHA (Fork-Head Associated) domain of Mnk plays essential role to recruit the Mnk to the key sub-cellular locations such as the centrosomes and kinetochores, by means of its phosphopeptide binding property. The DNA damage responses described above do not occur in *mnk* null mutant embryos. We investigated functional competency of the each Mnk mutant construct (conjugated with EGFP) to rescue *mnk* null mutant phenotype. We found that the SQ/TQ motif, function of the FHA domain, and the kinase activity were all required for the Mnk function to cause the mitotic disruption and the nuclear dropping in response to DNA damage. We also disrupted interphase nuclear localization of Mnk by deleting a putative NLS motif, and the Mnk mobility that was required for targeting the Mnk to the sub-cellular locations other than the nucleus by tethering the Mnk onto chromatin. We found that both the nuclear recruitment and the mobility of the Mnk were essential to the embryonic DNA damage responses.

559

The role of mRNA export factor RAE1 in leukemogenesis.

T. Funasaka[1], C. Hashizume[1], A. Kobayashi[1], T. Nakamura[2], R. W. Wong[1]; [1]Frontier Science Organization, Kanazawa University, Kanazawa, Japan, [2]Department of Carcinogenesis, The Cancer Institute

Chromosomal translocations involving chimeric fusions of the nucleoporin NUP98 protein have often been described in acute myelogenous leukemia (AML). All the fusion proteins have an identical NUP98 N-terminus, which contains the GLEBS motif for interaction with the mRNA export factor RAE1, and FG repeats that associate with the transcription factors HDAC1 and p300. It is virtually unknown whether these interactions affect leukemogenesis. Many human cancers have irregular chromosome content, a condition known as aneuploidy, and we previously showed that RAE1 depletion caused aneuploidy. Therefore we speculated that RAE1 may also be directly involved in NUP98 fusion-mediated leukemogenesis. We show here that knockdown of NUP98 by RNA interference method caused severe chromosome segregation defects and disrupted RAE1 but not HDAC1 expression and localization. Next, we performed rescue experiments to confirm that the RAE1-NUP98 complex orchestrates proper chromosome segregation. Interestingly, we found diverse behaviors of NUP98 and the leukemogenic fusion protein NUP98-HOXA9 throughout the cell cycle. Strikingly, in NUP98-HOXA9-transfected cells, RAE1 protein were reduced and mislocalized. Our cellular interpretations were further confirmed by NUP98-HOXA9 transgenic mice and the NUP98-HOXA9 AML patient. These data suggest that RAE1 orchestrates NUP98-mediated leukemogenesis and raise the possibility that targeting this system may provide a new strategy for the therapy of aggressive leukemias.

560

SPIM imaging of live cell division dynamics in 3D in large spheroid tumor models.

C. Lorenzo[1], C. Frongia[1], R. Jorand[1], J. Fehrenbach[2], P. Weiss[2], A. Maandhui[1], G. Gay[1], B. Ducommun[1], V. Lobjois[1]; [1]UMS3039 ITAV, CNRS, Toulouse, France, [2]UMR5219-IMT, CNRS

Multicellular tumor spheroids are models of increasing interest for cancer biology studies; however, 3D imaging in living spheroids is difficult and has never been reported with large spheroids. Here, we have engineered spheroids expressing a fluorescent reporter protein, and specifically designed sample holders to image cell division dynamics in large spheroids in 3D

with single-plane illumination microscopy, paving the way for studies of tumor cell proliferation in this model.

G1, G1-S, and S Phase Regulation

561

Regulation of DNA Polymerase ζ by Cdc7/Dbf4 kinase.

C. L. Punt[1], R. Sclafani[1]; [1]University of Colorado, Aurora, CO

Translesion DNA synthesis (TLS) is a tolerance mechanism in response to DNA damage. In *Saccharomyces cerevisiae* there are three TLS polymerases; Rev1, polymerase eta (Polη/Rad 30), and polymerase zeta (Polζ), composed of the Rev3 and Rev7 proteins. These specialized low-fidelity polymerases, through a polymerase-switching mechanism, allow the DNA replication machinery to replicate past DNA lesions which escape repair prior to replication. It is known that Cdc7, the catalytic subunit of Dbf4-dependent kinase (DDK), is required for UV-induced mutagenesis and our lab has previously shown that *CDC7* and *REV3* are epistatic in response to UV exposure, suggesting that Cdc7 has a direct role in Polζ-mediated TLS (Pessoa-Brandão and Sclafani, 2004). Here, we identify Rev7 as a potential substrate of Cdc7 and have shown that the putative DDK phosphorylation sites of Rev7 are required for UV-induced mutagenesis. These findings are the first demonstration of Rev7 regulation by direct phosphorylation and provide a new model for Polζ function in TLS.

562

Chk1 Phosphorylation by p90 Ribosomal S6 Kinase (p90 RSK).

H. Goto[1], P. Li[1], T. Kiyono[2], M. Matsuyama[1], K. Kasahara[1], Y. Murakami[3], Y. Yatabe[3], M. Inagaki[1]; [1]Div Biochem, Aichi Cancer Ctr Res Inst, Nagoya, Japan, [2]Div Virol, Natl Cancer Ctr Res Inst, [3]Dept Pathol & Mol Diag, Aichi Cancer Ctr Hosp

In response to DNA damage, ATR phosphorylates Chk1 at Ser317 and Ser345, which then induces Chk1-Ser296 autophosphorylation. These Chk1 phosphorylation events are required for the transmission of checkpoint signals to arrest cell cycle until the repair of damaged DNA. However, less is known about Chk1 phosphorylation in other cellular events. In this study, we found that Chk1 was phosphorylated specifically at Ser280 and translocated from cytoplasm to nucleus in response to serum (growth factor) stimulation. Chk1 mutation at Ser280 to Ala attenuated nuclear Chk1 accumulation although the mutation to Glu had a reverse effect. The treatment with p90 RSK inhibitor impaired not only Chk1-Ser280 phosphorylation but also nuclear Chk1 accumulation. The *in vitro* analysis supported that p90 RSK directly phosphorylated Chk1 at Ser280. These results suggest that p90 RSK controls nuclear Chk1 accumulation through Chk1 phosphorylation. We consider that this signaling pathway may play an important role in the preparation to monitor genetic stability during cell proliferation.

563

Chk1-S is a ubiquitously expressed splice variant and endogenous inhibitor of Chk1 that regulates cell cycle and DNA damage checkpoints.

N. S. Pabla[1,2], K. Bhatt[1], Z. Dong[1]; [1]Georgia Health Science University, Augusta, GA, [2]Division of Biology, California Institute of Technology, Pasadena, CA

Checkpoint Kinase 1 (Chk1) is essential for normal cell cycle progression and a critical regulator of cellular DNA damage response. Chk1 activation during the unperturbed S-phase and during

DNA damage response prevents mitotic entry till DNA is properly replicated or repaired. Presently, it is unclear how Chk1 activity is controlled during normal cell cycle progression. After DNA damage, Chk1 is activated by ATR-mediated phosphorylation; however it is not entirely clear how the phosphorylation results in Chk1 activation. Here we report an N-terminally truncated alternative splice variant of Chk1, Chk1-S that is ubiquitously expressed in most mammalian cells and tissues. Importantly, we show that Chk1-S is an endogenous repressor and regulator of Chk1. In unperturbed cell cycle, Chk1-S interacts with and antagonizes Chk1 to promote S to G2/M phase transition. During DNA damage, Chk1 is phosphorylated and the phosphorylation disrupts the Chk1/Chk1-S interaction, resulting in activation of Chk1 and cell cycle arrest. We propose that Chk1-S temporally regulates Chk1 activity and is thus essential for cellular proliferation.Chk1-S is mainly expressed during the G2/M phase and its expression is high in proliferating normal human fetal and cancer tissues. Interestingly, Chk1-S over-expression results in untimely inhibition of Chk1 activity resulting in premature mitotic entry and mitotic catastrophe. In tumor xenografts, overexpression of Chk1-S induces mitotic catastrophe and reduces tumor growth. Identification of the widely expressed Chk1-S as a novel splice variant and key regulator of Chk1 provides new insights into cell cycle regulation, DNA damage response, and cancer therapy.

564

Determining Functional Conservation of β-Finger Hairpin Structures Between Archaeal MCM Proteins and MCM Proteins of Saccharomyces cerevisiae.

C. J. Ramey[1], J. Diller[1], R. Sclafani[1]; [1]Biochemistry and Molecular Genetics, University of Colorado at Denver, Aurora, CO

Objective: The objective of our research is to characterize the in vivo function of conserved beta–finger structures identified in the archaeal MCM atomic structures. Mini-chromosome maintenance (MCM) proteins form complexes that are required for DNA replication and are highly conserved throughout evolution. The replicative helicase of eukaryotic organisms is composed of the six paralogs MCM2-7, which form a heterohexameric ring structure. In contrast, the structure of the archaean replicative MCM helicase is a single MCM protein that forms a homohexameric complex. Atomic structures of archaeal MCMs have identified multiple beta-finger structures in MCM proteins whose in-vivo function is unknown[1,2].

Methods and Results: In vitro assays using archaeal MCM complexes have demonstrated the importance of the N-terminal beta-finger for DNA binding and the PS1H beta-finger for helicase activity[3]. Utilizing structural information from the archaeal MCM atomic structure, our lab has previously shown that the eukaryotic Mcm5 N-terminal beta-finger is important for replication initiation because it promotes the binding of the Mcm2-7 complex to origins of DNA replication in *Saccharomyces cerevisiae*[4]. In the present study, we have investigated the in vivo role of the PS1H beta-finger of Saccharomyces cerevisiae Mcm4 and Mcm5 in replication initiation and elongation. The PS1H beta-finger mutant of Mcm5 (mcm5 K506A) has a growth defect at 22˚ C and 37˚C by serial dilution analysis. Mutation of the MCM4 PS1H beta-finger (mcm4 K658A) does not have a growth defect by serial dilution analysis, indicating a differential importance of the PS1H beta-finger structures of different MCM helicase subunits. PS1H beta-finger mutants form hexameric MCM helicase complexes by co-immunoprecipitation experiments. PS1H beta-finger mutants have a plasmid loss phenotype that is suppressible by origin dosage, which indicates a defect in replication initiation. ChIP analysis will be used to determine the binding of PS1H-beta finger mutants to origins of DNA replication and BrdU incorporation analysis of replication will be presented.

Conclusions: Characterization of highly conserved beta-finger hairpin structures of MCM proteins in vivo indicates the importance of the PS1H beta-finger function in DNA replication. (Supported by PHS grant GM35078 to R. Sclafani).

Pds5 Viability is Rescued by Deletion of Elg1 and Exhibit Cell Cycle Progression Defect.

K. Tong[1], R. V. Skibbens[2]; [1]Lehigh University, Bethlehem, PA, [2]Lehigh University

Cells that progress through the cell cycle must properly replicate each chromosome to produce sister chromatids, tether together chromatids to identify sisters through mitosis, and finally segregate each sister pair into resulting daughter cells. To maintain that identity from early S phase until anaphase onset, sister chromatids are tethered together by cohesin complexes. In budding yeast, cohesins are loaded onto chromatin in G1/early S phase, but sister chromatid pairing requires that chromatid-bound cohesins become activated (“established”) during S phase by an establishment factor termed Ctf7/Eco1 (Skibbens et al. 1999; Toth et al. 1999). Pds5 is an essential cohesion regulatory protein that binds Ctf7 and functions in concert with Ctf7 to establish sister chromatid pairing and then maintain that pairing into M phase (Hartman et al. 2000; Panizza et al. 2000; Noble et al. 2006). Numerous studies reveal that Pds5 also exhibits anti-establishment activity which antagonizes Ctf7 function(Tanaka et al. 2001; Sutani et al. 2009; Rowland et al. 2009). Several models suggest that Ctf7-establishment function and the process of replication are linked, yet it is not known whether Pds5 also functions in concert with the replication fork (Kenna et al. 2003; Terret et al. 2009). Evidence from this lab identified an alternative replication factor C large subunit, Elg1, as an anti-establishment factor that rescues viability in both *ctf7* and *pds5* mutant cells(Maradeo and Skibbens 2009; Maradeo and Skibbens 2010). Here, we explore the link between Pds5 and Elg1. Our results reveal that *pds5-1 elg1* double mutant strains exhibit both increased viability as well as decreased cohesion defects, compared to *pds5-1* mutant strains. We also show that the double mutant strain has a unique G1/early S phase delay phenotype that is DNA damage independent, suggesting that S phase progression is dependent on the function of Pds5. Here, we discuss possible roles of Pds5 outside of cohesion establishment and maintenance.

566

Tau-Dependent Cell Cycle Re-Entry of Post-Mitotic Neurons Induced by β-amyloid Oligomers.

M. E. Seward[1], E. Swanson[1], G. S. Bloom[1]; [1]Department of Biology, University of Virginia, Charlottesville, VA

One of the most enigmatic features of Alzheimer’s disease (AD) neurons is their tendency to express markers of cell cycle re-entry. For example, compared to healthy age-matched brains AD brains contain a pronounced increase in hyperploid neurons and the levels of multiple cell cycle regulatory proteins, including PCNA, and cyclins D, E and A. In mouse models of AD the presence of such cell cycle markers can precede the onset of behavioral symptoms by 3-6 months and propagate through brain in a pattern that mimics the spread of AD in human brain. Moreover, studies of cultured primary neurons have indicated that this putative, ectopic cell cycle re-entry can be induced by extracellular exposure to oligomers of β-amyloid (Aβ). To investigate the molecular mechanisms that underlie this process, we compared the responses

of primary neurons derived from wild type (WT) versus tau knockout (KO) mice to Aβ42 oligomers using incorporation of BrdU into nuclear DNA as an indicator of apparent cell cycle re-entry. Neurons derived from WT, but not tau KO mice frequently contained BrdU-positive nuclei within 24 hours of exposure to Aβ42 oligomers. BrdU uptake was accompanied by tau phosphorylation at Y18, S409 and S416, which are catalyzed respectively by the src-family kinase, fyn, the cyclic-AMP dependent protein kinase A (PKA) and calcium/calmodulin dependent kinase-II (CaMKII). Pharmacologic inhibition of fyn, PKA or CamKII individually prevented BrdU incorporation by WT neurons exposed to the Aβ42 oligomers, but did not block activation of the other two kinases in either WT or tau KO neurons. In addition, CaMKII-catalyzed phosphorylation of tau at S416 potentiated PKA-catalyzed phosphorylation of tau at S409 in both primary neurons and *in vitro* reconstituted sytems using purified tau and kinases. Collectively, these data indicate that Aβ42 oligomers induce activation of neuronal fyn, PKA and CamKII independently of tau expression, and that in the presence of tau the three kinases function in parallel pathways, without cross-activating each other, to induce cell cycle re-entry.

567

Rad53 protein kinase regulates DNA replication by interacting with histones.

R. Sclafani[1], T. Holzen[1]; [1]Biochemistry and Molecular Genetics, University of Colorado, Aurora, CO

Objective: The objective of our research is to further characterize the novel function of Rad53 in replication initiation in budding yeast *S. cerevisiae*. Protein kinase Rad53/Chk2 is central to activation of DNA checkpoints. The *rad53Δ* allele is synthetically lethal with *cdc7* mutations and suppresses *mcm5-bob1* bypass of DDK function (Cdc7/Dbf4 kinase)[1]. Rad53 also maintains cellular histone levels[2], and the functions of Rad53 in DNA replication and in histone regulation are independent of Rad53-mediated regulation of DNA checkpoints[1,2]. We hypothesized that Rad53 plays a role in DNA replication initiation independently of its roles in checkpoints and that Rad53's role in replication initiation is related to its role in regulating cellular histone levels.

Methods and Results: We isolated the *rad53-rep* separation of function allele[3], which is checkpoint proficient but is synthetically lethal with *cdc7*. The H426R mutation in the Rad53 kinase domain confers the *rad53-rep* phenotype, but the mutant protein has kinase activity similar to wild-type Rad53 during the DNA checkpoint response. In contrast, the checkpoint defective *rad53 fha1 fha2* mutant is normal in replication functions. Unlike wild-type or kinase dead Rad53, Rad53-rep protein cannot interact with origins of replication in the ARS-lacZ one-hybrid assay and the *rad53-rep* mutant displays a chromosome loss phenotype suppressible by origin dosage. The *rad53-rep* mutant is also sensitive to overexpression of histone H3/H4 similar to rad53Δ[2]. In contrast, a *rad53 fha1 fha2* checkpoint mutant is normal in these assays. Thus, loss of checkpoint function is not needed for histone sensitivity. *rad53-rep-cdc7* synthetic lethality is suppressed by deletion of the major H3/H4 gene pair. Furthermore, the *rad53-rep* mutant accumulates excess soluble histones, suggesting Rad53's functions in replication initiation and in histone homeostasis are related.

Conclusions: Identification and characterization of *rad53-rep* supports our hypothesis that Rad53 functions in DNA replication initiation independently of its checkpoint role. We propose that during DNA replication initiation, Rad53 acts as a "nucleosome buffer" to prevent histones from associating with replication origins and interfering in the origin activation process that is regulated by CDK and DDK (Supported by PHS grant GM35078 to R. Sclafani).

Lipid droplets buffer histone availability during early Drosophila embryogenesis.

Z. Li[1], K. Thiel[2], M. Beller[2,3], M. A. Welte[1]; [1]Dept. Biology, Univ Rochester, Rochester, NY, [2]Dept. of Mol. Devel. Biology, Max Planck Inst. for Biophysical Chemistry, Goettingen, Germany, [3]Institute for Math. Modeling Biol. Systems, Heinrich-Heine University, Duesseldorf, Germany

Histones are essential for proper chromatin packing and gene expression, but cells face a tremendous challenge to manage their overall supply: sufficient histones need to be available to package newly replicated DNA, yet free histones not incorporated into chromatin are toxic. In most cells, multiple regulatory mechanisms ensure that new histone synthesis is tightly coupled with DNA replication. Here we report that Drosophila embryos transiently sequester histones on lipid droplets to buffer histone availability; without such sequestration, these embryos are very sensitive to altered histone expression, leading to abnormal cell cycles, mitotic defects and lethality. A buffering role for lipid droplets may be very general since transient droplet association of proteins from other cellular compartments, including but not limited to histones, has been reported from yeast to mammals.

We had previously found that early Drosophila embryos contain a thousand-fold excess of certain histones relative to DNA content and that these extra histones are bound to lipid droplets. Transplantation and photo-activation experiments demonstrate that droplet-bound histones can be transferred to nuclei. We now report that the novel droplet protein Jabba acts as a histone receptor: Jabba co-immunoprecipitates with histones; histone levels on droplets are decreased in parallel with Jabba levels; and without Jabba, histones are entirely absent from droplets. In cultured cells that do not usually exhibit histone recruitment to droplets, Jabba expression is sufficient to induce droplet association.

In *Jabba* mutants, overall embryonic histone levels are greatly reduced; extra histones not bound to lipid droplets apparently cannot be stably maintained. These embryos are also hypersensitive to changes in histone expression: both reduced dosage of classical histones and overexpression of the variant H2Av cause a dramatic increase in defective mitoses and disruption of early development. We propose that in wild-type embryos lipid droplets help maintain a balanced pool of extra histones that supports the rapid cell cycles of early development.

γ-tubulin plays an important role in inactivating APC/C^{Cdh1} in interphase.

H. D. Edgerton-Morgan[1,2], B. R. Oakley[1]; [1]Molecular Biosciences, University of Kansas, Lawrence, KS, [2]Molecular Genetics, The Ohio State University, Columbus, OH

A cold-sensitive γ-tubulin mutation of *Aspergillus nidulans*, *mipA*D159, causes a nuclear-autonomous failure of inactivation of the anaphase promoting complex/cyclosome (APC/C) in interphase at restrictive temperatures, resulting in constitutive destruction of cyclin B and removal of nuclei from the cell cycle (Nayak et al., 2010, J. Cell Biol., 190, 317-30). γ-tubulin, thus, has an important role in regulating the APC/C in interphase. The APC/C is activated by two proteins, Cdc20 in metaphase and Cdh1 in anaphase through G_1. Inactivation of APC/C^{Cdh1} at the end of G_1 is normally required for accumulation of S-phase cyclins. In *A. nidulans*, cyclin B is both the S-phase cyclin and M-phase cyclin. We identified, GFP-tagged, and deleted the *A. nidulans* homologs of *cdc20* and *cdh1. Ancdc20* is essential but *Ancdh1* is not. GFP-AnCdc20 is excluded from interphase nuclei, but enters the nucleoplasm when the nuclear pore complex disassembles at mitotic entry. It moves back into the cytoplasm in late mitosis. APC/C activity in the nucleoplasm is, thus, regulated in part by the localization of AnCdc20. AnCdh1-GFP

localizes to the nucleoplasm and spindle pole body in late G_2, disappears in mitosis, returns at the beginning of G_1 and disappears again a few minutes later. Deletion of *Ancdh1* significantly shortens the period of time in which cyclin B is absent from interphase nuclei, consistent with APC/C^{Cdh1} targeting cyclin B for destruction in G_1. Deletion of *Ancdh1* also eliminates the constitutive destruction of cyclin B caused by *mipA*D159. Since inactivation of APC/C^{Cdh1} is required for S-phase cyclin accumulation, these data indicate that *mipA*D159 causes a failure of inactivation of APC/C^{AnCdh1} in interphase and, thus, that γ-tubulin is important for APC/C^{Cdh1} regulation. Additional data indicate that constitutively active APC/C^{AnCdh1} causes destruction of BubR1, resulting in abrogation of the spindle assembly checkpoint. Supported by NIH grant GM031837.

Nitrilase 1, a New Player in Plant Cell Cycle and Programmed Cell Death.

A. Doskocilova[1], H. Kourova[1], J. Volc[1], L. Kohoutova[1], J. Chumova[1], P. Halada[1], O. Benada[1], O. Plihal[1], B. Petrovska[2], P. Binarova[1]; [1]Institute of Microbiology, AS CR, Prague, Czech Republic, [2]Institute of Experimental Botany, AS CR, Prague, Czech Republic

Nitrilase-1 (Nit1), member of C-N hydrolases superfamily, was previously described as an enzyme involved in glucosinolate catabolism in Brassicaceae family. We identified Nit1 among proteins copurified with γ-tubulin from Arabidopsis extracts. Both endogenous Nit1 and Nit1-GFP protein expressed from native promoter localized in Arabidopsis cells in cytoplasm and a weaker signal was observed in the nuclei. The protein was enriched at the nuclear periphery, and on microtubular arrays throughout the cell division. Nit1 protein was present in plant extracts in high molecular forms; that when examined by EM were shown to be linear polymers. Arabidopsis cell culture overexpressing Nit1 showed lower mitotic index and slower growth rate compared to the wild type cells. In vertebrates, homologue of plant and bacterial Nit1 was demonstrated as a possible tumor suppressor gene involved in induction of apoptosis. Correspondingly, we found that level of programmed cell death was higher in cells overexpressing Nit1 in comparison to the controls. Severe defects of shoot apical meristem development were observed in plants with Nit1 downregulated by RNAi. Differentiation of the first true leaves was remarkably impaired and instead, ectopic cell division occurred. Furthermore, disruption of final symmetric division of guard cells in the stomata complex indicated cell division defects. Our data showed that plant Nit1 belongs to the growing number of metabolic enzymes with ability to assemble polymers and suggested for Nit1 function in cell division and programmed cell death.

Mck1p, a yeast homologue of GSK-3 kinase, targets Cdc6p at C-terminus for its degradation to inhibit DNA re-replication.

A. Ikui[1]; [1]Brooklyn College, The City University of New York, Brooklyn, NY

Orc6p is a part of the pre-replicative complex (pre-RC) which binds to origin of DNA replication to promote initiation of DNA replication. DNA replication takes place only once per cell cycle. After the initiation of DNA replication, pre-RC components are phosphorylated by Cyclin/CDK in order to inhibit DNA re-replication. In addition to this mechanism, S-phase cyclin (Clb5p) directly binds to Orc6p to inhibit Cdt1/Mcm2-7 loading to ORC. To better understand the DNA re-replication control in *S. cerevisiae*, synthetic genetic array (SGA analysis) was performed using *ORC6* mutant, *ORC6-rxl*. *ORC6* is an essential gene. The *ORC6-rxl* mutation eliminates Clb5-Orc6 binding, but these strains are viable. We looked for haploid gene deletion strains in which

ORC6-rxl was synthetically lethal; in other words, haploid deletion strains which require Clb5p-Orc6p protein binding for their survival. Interestingly, we found that *mck1* deletion cells showed synthetic lethality with the cells containing the *ORC6-rxl* mutation. The *mck1* deletion genetically interacted with *ORC6* or *ORC2* phosphorylation mutant as well. To study the genetic interaction between *MCK1* (a yeast homologue of GSK-3 kinase) and *ORC6* (origin binding protein), temperature sensitive mutant of *mck1* was generated by PCR mutagenesis. The temperature sensitive mutant, *mck1-16*, in the combination of *ORC6-rxl* induced moderate DNA re-replication followed by DNA damage checkpoint activation at 37 degree. Combination of *mck1-16* with *MCM7-NLS*, *ORC6-ps* and *ORC2-ps* induced extensive DNA re-replication suggesting that mechanism on DNA re-replication inhibition by Mck1p is additive. However *mck1* deletion did not genetically interact with *CDC6* mutant such as *CDC6ΔNT*. Therefore Mck1p and Cdc6p could act in the single pathway.

It has been shown that Cdc6p at N-terminus are phosphorylated by Cyclin Dependent Kinase (CDK) for its degradation. Here we show that Mck1p, a yeast homologue of Gsk-3 kinase, promotes Cdc6p degradation. Cdc6p was stabilized in the *mck1* deletion cells during late S phase and mitosis, and overexpression of Mck1p promoted rapid Cdc6p degradation. Mck1p interacted with Cdc6p through GSK-3 consensus site at C-terminus. The protein interaction between Mck1p and Cdc6p was abolished in the Cdc6 mutant which contains an amino acid substitution (from threonine to alanine) at GSK-3 consensus site. These results suggest that Mck1 kinase and CDK target Cdc6p for its degradation to inhibit DNA re-replication. We will discuss the molecular mechanism how Mck1p and CDK corporate to trigger complete degradation of Cdc6p.

Changes in intracellular signaling and cell growth rate accompany regulation of cell size at S-phase entry.

M. Ginzberg[1], R. Kafri[1], M. Kirschner[1]; [1]Systems Biology, Harvard Univ-Harvard Med Sch, Boston, MA

The mechanisms coordinating mammalian cell growth with cell cycle have not yet been elucidated. Here, we use quantitative fluorescence microscopy to simultaneously measure cell cycle position, cell size, and the level of cell growth regulators such as phosphorylated rpS6 in very large numbers (>10^6) of fixed HeLa cells. Cell cycle is monitored by expression of stage-specific fluorescent proteins, cell size is measured by staining all proteins with a dye-conjugated succinimidyl ester, and protein phosphorylation levels are measured by immunofluorescence. By combining these measures, we obtain profiles of cell growth and growth-related signaling over the course of the cell cycle. We find that cell growth slows significantly in late G1, concurrent with a transient decrease in cell-to-cell size variation prior to S-phase entry. This tightening of the cell size distribution is accompanied by several signaling events, most notably a shift to high levels of translation component phospho-rpS6 and a decrease in Akt phosphorylation. Interestingly, we also find that the inactivating phosphorylation of translational repressor 4EBP1 is cell-size dependent, with smaller cells maintaining higher phospho-4EBP1 concentrations than large cells. Increased homogeneity of phospho-S6 levels, an overall slowing of cell growth due to decreased phospho-Akt, and an increased growth rate in small cells due to differential 4EBP1 phosphorylation could all contribute to the observed decrease in cell size variance. To further explore these findings, we use growth-inhibiting drugs to perturb cell size regulation. We find that under low doses of rapamycin or cycloheximide, cells can proliferate normally, but shift to an average size 10% smaller than control cells. These cells display the same growth dynamics as undrugged cells throughout the cell cycle, including the late-G1-slowdown described above. With rapamycin treatment, the cell-cycle-dependent dynamics of both rpS6 and Akt phosphorylation are lost, and the variance in cell size increases

by 18%. These results implicate late-G1 rpS6 and Akt phosphorylation dynamics in cell size control. In contrast, with cycloheximide treatment, these dynamics are more closely conserved, and cell size variance does not increase. We are currently using the methods described here to extend these results and dissect the molecular mechanisms used to maintain cell size uniformity.

573

How do cells coordinate growth and division?

Q. A. Justman[1], A. W. Murray[1]; [1]FAS Center for Systems Biology, Harvard University, Cambridge, MA

Any process that requires sustained cellular proliferation over many generations relies on the coordination of cell growth and division. In the budding yeast *S. cerevisiae*, proliferation rates are limited by the rate of cell growth; growth rate, in turn, can be limited by the cells' nutrient environment. While it is well established that the cell cycle contains homeostatic mechanisms to abolish size differences between mother and daughter cells, it is unclear how it accommodates environmentally-driven depressions in growth rate. Here, we explore this question in the context of glucose withdrawal. We demonstrate that cell cycle progression is dependent on the presence of glucose: withdrawal induces immediate growth arrest, irrespective of cell cycle position. In the arrested state, cell size remains constant for hours; new budding and cytokinesis events are not observed.

Ongoing work aims to understand these observations in light of glucose's dual role as a hormone-like initiator of signal transduction and the preferred raw material for fermentative metabolism. Exchanging glucose for 2-deoxyglucose, a metabolically inert analog, produces an equivalent growth arrest, suggesting that active glycolytic metabolism is a pre-requisite for cell cycle progression in glucose-grown cells. Additionally, modulating glucose-responsive signal transduction can 1) bypass growth arrest upon glucose withdrawal, and 2) increase the probability that arrested cells will escape to resume the cell cycle at their present position. Together, these data suggest that glucose withdrawal elicits an unidentified, glycolysis-dependent intracellular signal that inhibits both growth and cell cycle progression.

Cell cycle checkpoint acquisition in early embryogenesis.

M. Zhang[1], M. A. Lampson[1,2]; [1]Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, [2]Dept of Biology, University of Pennsylvania, Philadelphia, PA

Cell cycle checkpoints are crucial for the maintenance of genomic integrity and the fidelity of cell divisions. Interestingly, many metazoan embryos undergo a brief developmental stage characterized by synchronous, rapid cell divisions that lack gap phases of the cell cycle and the mitotic and DNA damage response checkpoints. When cells reach a critical nuclear to cytoplasmic (N:C) ratio, the mid-blastula transition (MBT) is triggered, zygotic transcription is activated, and cell cycle remodeling occurs: cell cycles lengthen and acquire gap phases, and checkpoints become functional. It is unclear how checkpoint function is acquired at the MBT. In this work, we use zebrafish embryos to address this question, focusing specifically on the effects of transcriptional activation, cell cycle lengthening and the N:C ratio. By inhibiting RNA Polymerase II at the MBT, we show that checkpoint acquisition is independent of zygotic transcription. This result demonstrates that components of the checkpoint signaling pathway are present prior to the MBT. However, we find that pre-MBT embryos do not phosphorylate histone H2AX upon DNA damage, which indicates that DNA damage signaling is blocked at an early step. We also use a Cdc25a morpholino and Cdk inhibitor to determine the effect of longer cell

cycle lengths on checkpoint function in pre-MBT embryos. We are developing an integrated model of how the N:C ratio, cell cycle lengthening, zygotic transcriptional activation and checkpoints influence one another at the MBT.

The circadian factor Period2 modulates p53 stability in unstressed cells.

T. Gotoh[1], M. Vila-Caballer[1], C. S. Snatos[1], J. Yang[1], J. Liu[1], C. V. Finkielstein[1]; [1]Biological Sciences, Virginia Tech, Blacksburg, VA

Circadian rhythms are mechanisms that measure time on a scale of about 24 h and that adjusts our body to external environmental signals. Core circadian clock genes are defined as genes whose protein products are necessary components for the generation and regulation of circadian rhythms. Circadian proteins also regulate genes involved in either cell division or death; and a perturbation of the balance among these processes leads to cancer development and progression.
A key aspect of cancer research is identifying new regulatory pathways involved in proliferation and differentiation of cell. Disruption of circadian rhythm has recently emerged as a new potential risk factor in the development of cancer, pointing to the core gene period 2 (per2) as a tumor suppressor. However, it remains unclear how the circadian network regulates tumor suppression, nor which, if any, of its components is either the ultimate effector that influences the fate of the cell.
Initial experiments were devoted to identify new interacting partners for Per2 using a two-hybrid system. Interestingly, among the positive clones analyzed was the tumor suppressor protein p53. This result was validated by immunoprecipitation of recombinant and endogenous Per2/p53 complexes from unstressed cells. Pull-down assays using tagged-expressed proteins fragments and labeled proteins were later used to map the interacting regions between Per2 and p53. Our results show Per2 binds to the C-terminus of p53 in a region that includes the DNA binding and tetramerization domains and that includes the ubiquitination sites. Thus, we hypothesized that binding of Per2 to p53 might act by blocking Mdm2-mediated ubiquitination of p53 target residues in the C-terminus and therefore altering its stability. We next examined the formation of the Mdm2/p53/Per2 complex by immunoprecipitation. Our data show anti-p53 antibody is able to co-immunoprecipitate Per2 and Mdm2. Moreover, in vitro and in vivo ubiquitination assays show that binding of Per2 to p53 prevented ubiquitination of p53 by Mdm2 without altering their binding. Immunofluorescence studies using H1299 cells (p53-) confirmed Per2 role in p53 stabilization and for localization. Overall our results suggest that Per2 modulates the stability of p53 in unstressed cells, and might be responsible for the oscillatory levels of p53 observed in a 24 h cycle.

Polyploidizing cell cycles yield unstable genomes and aneuploidy in *Drosophila.*

D. Fox[1]; [1]Pharmacology and Cancer Biology, Duke University Medical Center, Durham, NC

Cell cycle checkpoints ensure alteration between complete DNA replication and mitosis, and evasion of these checkpoints promotes a host of pre-cancerous genome stability defects. Programmed endo-cell cycles represent a tolerated form of checkpoint evasion, as in these cell cycles mitosis is truncated, yielding polyploid cells. Understanding whether endo-cell cycles promote genome instability has proven challenging, as normal polyploid cells typically do not divide further, while in contrast polyploidy is one of numerous potential drivers of early stage cancer. My previous work[1] established a *Drosophila* model to elucidate connections between endo-cell cycles, polyploidy, and genome instability. During *Drosophila* hindgut development, endo-cell cycles generate polyploid cells that then re-enter mitotic cell cycles. In these wild-type

polyploid cells, chromosome segregation in mitosis is highly error-prone. In further characterization of these polyploid divisions, I have identified two principal causes of polyploid genome instability. By conducting time-lapse imaging of polyploid divisions, I observed polyploid hindgut cells to elaborate numbers of centrosomes. These cells frequently yield multipolar spindles and aneuploid daughter cells. Following progression of polyploid hindgut cells through development revealed a non-canonical origin of centriole elaboration involving *de novo* centriole synthesis. However, many polyploid cells with normal centrosome number also exhibit error-prone division, and prior to dividing polyploid chromosomes exhibit “fragile” sites indicative of defects in DNA replication. By taking advantage of a developmental sequence of polyploidization followed by error-prone mitotic divisions, I have uncovered *in vivo* roles for centriole and DNA replication as causes of genome stability in variant cell cycles. These same mechanisms are likely contributors to early cancer progression.

Cadherin regulation in fibroblast and fibrosarcoma cells: influence of culture density and MAPK activity.

V. Marchese[1], D. Emporelli[1], M. Gaballah[1], A. Pass[1], J. Juarez[1], D. Hutter Lobo[1]; [1]Biology, Monmouth University, West Long Branch, NJ

Cadherins are integral proteins that play an important role in cellular adhesion. If E-cadherin is cleaved, releasing an 80 kDa fragment, it is no longer active. Interestingly, this 80 kDa product has been found to be increased in several types of cancers. In this work, the presence of an 80 kDa protein reactive with E-cadherin antibody, consistent with the inactive cleavage product of E-cadherin, has been detected in normal fibroblasts (BJ cells) and fibrosarcoma cells (HT-1080), and is expressed at a slightly higher level in subconfluent cells than confluent cells. Similarly, matrix metalloproteinase-9 (MMP-9), which is capable of cleaving cadherins, is also expressed more in subconfluent cells. Levels of MMP-2 were found not to be altered with increased culture density. Therefore, obtaining a confluent state is correlated with decreased MMP-9 expression, and loss of the 80 kDa fragment. ERK is upregulated in proliferating cells, and may also upregulate expression of E-cadherin. To investigate the potential role in the regulation of the 80 kDa fragment, dexamethasone treatment was used. Dexamethasone treatment resulted in lower expression of the 80 kDa fragment, as well as decreased expression of phosphorylated ERK. These results suggest a relationship between increased culture density, ERK activity, and regulation of cadherins.

578

Modulation of STAT3 activation and prostate cancer proliferation by cyclin-dependent kinase 5.

F-N. Hsu[1], M-C. Chiang[1], E. Lin[1,2], H. Lin[1]; [1]Life Sciences, National Chung Hsing University, Taichung, Taiwan, [2]Chang Bing Show Chwan Memorial Hospital, Changhua, Taiwan

STAT3 (signal transducer and activator of transcription 3) is a major transcription factor in prostate cancer. Phosphorylation is an important translational modification for transactivation. Initially, the protein biochemical interaction between Cdk5 and STAT3 was identified and this

interaction relied on Cdk5 activity. Besides, Ser727 phosphorylation of STAT3 was positively regulated by Cdk5 in LNCaP cells and xenografted tumors. The S727A mutant declined the protein interaction between Cdk5 and STAT3. The distribution of phospho-Ser727-STAT3 proteins and the expression of STAT3-regulated gene are regulated by Cdk5 activity. By using a Cdk5 inhibitor roscovitine (Rv, also named Seliciclib or CYC202, a clinical trial drug on non-small cell lung cancer and leukemia), we subsequently found that STAT3 was a Cdk5-regulated survival factor through Ser727 phosphorylation in prostate cancer cells. Finally, our clinical evidence demonstrated the significant correlations of phospho-Ser727-STAT3 with Cdk5 and with Gleason score in prostate cancer patients. These clinical data also revealed that the protein level of phospho-Ser727-STAT3 was relatively higher in tumor tissue as compared to individual normal one. In conclusion, our data indicates that Cdk5 is a positive modulator of STAT3 activation and prostate cancer cell proliferation through Ser727 phosphorylation.

579

JNK-1 Promotes Survival or Programmed Death of Cardiac Myocytes by Differential/ATP-dependent Regulation of Akt and ERK Survival Pathways.

W. Wang[1], H. Li[1], K. Webster[1]; [1]Pharmacology, Miller School of Medicine, University of Miami, Miami, FL

INTRODUCTION The survival kinases PI3K-Akt and Raf-MEK1/2-Erk1/2 are required to protect the heart during ischemia/reperfusion and are key components of the protection afforded by ischemic preconditioning. Our group recently reported that JNK-1 activity is essential for the activation of Akt when reperfusion followed brief but not extended ischemia (Wei et al., J Biol Chem. 286:13995-4006, 2011). We show here that JNK-1 is also essential for the activation of ERK under the same conditions of simulated brief ischemia. HYPOTHESIS JNK-1 mediates differential regulation of both Akt and ERK in a manner that is dependent on the time of ischemia and [ATP] at the time of reoxygenation/reperfusion. METHODS Cardiac myocytes were cultured in physiological glucose ((PG) 5mM glucose) or low glucose ((LG), 0.5mM glucose) and subjected to 8hrs of hypoxia followed by reoxygenation in the presence or absence of constitutively active JNK-1 (caJNK) or JNK inhibitors (Ad-dnJNK or SP600125). Proteins were analyzed by western blots using phosphor antibodies. RESULTS When myocytes were subjected to hypoxia with LG, glucose was depleted within 4hrs and intracellular ATP decreased to 18±7% at 8hrs. Glucose and ATP remained high in the PG condition. Myocyte death after reoxygenation was greater in the LG condition (31± 5% vs. 12± 4%; $p<0.05$). JNK inhibition conferred massive cell death in the PG condition (38±12 vs. 12± 4%), but was protective in the LG condition (not shown). Death in the PG condition was paralleled by increased caspase 3 cleavage (7.5±2.9-fold), enhanced release of cytochrome c, and opening of the mPTP. As indicated in Fig 1, P-ERK was activated by ReOx but inclusion of dnJNK-1 reduced the levels of P-ERK2, P-MEK and P-Raf1 by >80% (n=3). Ad-dnJNK did not reduce the P-ERK cascade under the LG condition and caJNK significantly activated P-ERK only in the PG condition (not shown). CONCLUSIONS: JNK-1 is essential for activation of ERK as well as Akt during ReOx with sustained ATP.

580

Anti-allergic Effects of compounds isolated from wheat bran extract on mast cell-mediated allergic model.

J. Lee[1], H-J. Ko[2], E-K. Ahn[2], S. Hong[2], J. Oh[3]; [1]Drug Evaluation Team, Gyeonggi Natural Products Research Institute, Suwon, Korea, [2]Gyeonggi Institute of Science and Technology Promotion Natural Products Research Institute, Gyeonggi Bio Center, Suwon, Korea, Dem People's Rep, [3]College of Pharmacy, Dankook University, Cheonan, Korea, Dem People's Rep

In order to determine anti-allergic activity, this study investigated whether 5-*n*-nonadecylresorcinol and 5-*n*-heneicosylresorcinol isolated from wheat bran extract suppress immunoglobulin E (IgE)-mediated allergic response and expression of inflammatory cytokines in mast cells. We observed that two compounds significantly inhibited release of β-Hexosaminidase, as a marker of degranulation, and expression of proinflammatory cytokines such as TNF-α, IL-4, IL-10 and COX-2 a dose-dependent manner in antigen-stimulated RBL-2H3 mast cells. Moreover, two compounds blocked phosphorylation of AKT, p38MAPK, JNK and ERK1/2 and activity of nuclear factor- κB (NF-κB) in mast cells. We also showed two compounds exhibited 5-lipoxygenase inhibitory activity with EC_{50} values of 233.06 and 184.56 μM, respectively. Our findings suggest that 5-*n*-nonadecylresorcinol and 5-n-heneicosylresorcinol isolated from wheat bran extract suppress mast cell-derived allergic response and expression of inflammatory cytokines and that these effects were related by inhibition of AKT, p38MAPK, JNK and ERK1/2 phosphorylations and NF-κB.
This work was supported from Rural Development Administration, South Korea (PJ0081552011).

581

Lucidenic acids-rich extract from antlered form of *Ganoderma lucidum* enhances TNFα induction in THP-1 monocytic cells possibly via its modulation of MAP kinases p38 and JNK.

M. Sato[1,2], K. Watanabe[1,2], T. Shuto[1,2], S. Mizunoe[1,2], S. Suzuki[1,2], M. Ann Suico[1,2], T. Ikeda[3], H. Kai[1,2]; [1]Graduate School of Pharmaceutical Sciences, Kumamoto, Japan, [2]Global COE"Cell Fate Regulation Research and Education Unit", [3]Natural Medicine, Graduate School of Pharmaceutical Sciences

The *Ganoderma lucidum (G. lucidum)* is one of the oriental fungi that has been reported to have immunomodulatory properties. Although effect of β-glucans from *G. lucidum* has been well documented, little is known about how other major bioactive components, the triterpenes, contribute to the immunomodulatory function of *G. lucidum*. Here, we showed that triterpenes-rich extract of antlered form of *G. lucidum* (*G. lucidum* AF) induces TNFα production in monocytic THP-1 cells. Furthermore, the extract also synergized with lipopolysaccharide (LPS) to induce TNFα production in THP-1 cells, suggesting an immunostimulatory role of triterpenes-rich extract of *G. lucidum* AF. Notably, the extract enhanced LPS-induced phosphorylation of p38 mitogen-activated protein kinase (MAPK), while it suppressed LPS-induced phosphorylation of c-Jun N-terminal kinase (JNK) MAPK. p38 Inhibitor suppressed TNFα production, while JNK inhibitor enhanced TNFα production, implying that synergistic effect of the extract may work by modulating p38 and JNK MAPKs. Moreover, we found that the triterpenes-rich extract of *G. lucidum* AF contains high amounts of lucidenic acids. Lucidenic acid-A, -F and -D_2, which seem to dominantly exist in the extract, were purified from the triterpenes-rich extract. We also identified Lucidenic acid-A and -F as modulators of JNK and p38, respectively. Thus, our data demonstrate that lucidenic acids-rich extract from *G. lucidum* AF enhances LPS-induced immune responses in monocytic THP-1 cells possibly via the modulation of p38 and JNK MAPKs activation.

582

The role of the Akt substrate APE (Girdin, GIV) in insulin signaling.

A. Hartung[1], H-U. Häring[1], R. Lammers[1]; [1]Internal Medicine IV, University of Tuebingen, Tuebingen, Germany

Akt kinases are important mediators of the insulin signal. Several Akt substrates are directly involved in glucose homeostasis, e.g. Glycogen synthase kinase 3 (GSK3) and Akt substrate of 160 kDa (AS160). Recently, Akt phosphorylation enhancer (APE) has been described as a new Akt substrate. It is expressed ubiquitously in mammals and highly in a variety of cancer cell lines. Based on its actin and microtubule binding domains it is involved in remodelling of actin cytoskeleton and cell motility. In addition, APE is also a Gαi–interacting protein and controls the Gαi triggered cell migration. However, not much is known about its role in insulin signalling.
To investigate the function of APE we knocked down APE with siRNA and found a reduced Akt and Insulin receptor substrate 1 (IRS-1) phosphorylation. We then established C2C12 cell lines which permanently overexpress APE. With this approach we found that Akt was constitutively active, as determined by its phosphorylation at T308 and S473. Consequently, GSK3 phosphorylation was also increased after insulin stimulation. One possible reason for the activation are changes in the expression of several proteins. The insulin receptor was upregulated and tyrosine phosphorylation of IRS-1 enhanced even though the protein itself was down regulated. Additionally, the tyrosine kinase Abelson murine leukemia viral oncogene homolog 1 (c-ABL) and its substrates e.g. Avian sarcoma virus CT10 oncogene homolog (CrkII) and Src homology 2 domain containing transforming protein 1 (p66shc) were constitutively phosphorylated. To investigate medium-term insulin responses we measured the C14-glucose incorporation into glycogen. The APE overexpressing cells showed a higher basal glycogen synthesis without stimulation. In addition, the insulin sensitivity was increased with glycogen synthesis peaking at 1 nM of insulin compared to wild type cells (100 nM). Moreover, the internalisation of the insulin receptor is slowed down in the APE overexpressing cell line compared to C2C12 cells which permanently overexpress the insulin receptor to an equal extent. Of note, these effects were independent of APE phosphorylation by Akt. An Akt phosphorylation site mutant, in which serine and threonine (S1417/T1419) are mutated to alanine behaved similar to wild type APE.
We conclude that changes in the APE level have strong effects in C2C12 cells indicating that APE is an important mediator of the insulin signal in muscle cells.

583

PI3K and Akt play an essential role for quiescent myogenic cell activation.

K. Ohashi[1], Y. Nagata[1], R. Matsuda[1]; [1]Univ Tokyo, Meguro Tokyo, Japan

Muscle satellite cells (MSCs), which are stem cells in skeletal muscle, have a role in skeletal muscle growth and repair. MSCs are normally quiescent but are activated in response to various stimuli such as injury and overload. Activated MSCs enter the cell cycle to produce a large number of myogenic progenitor cells. In regenerating skeletal muscle fibers, the activation of MSCs must be tightly regulated by certain mechanisms. However, the molecular mechanisms of MSCs activation are not understood.
Reserve cells, a model of quiescent MSCs in vitro, are activated by fetal bovine serum in medium (FBS) but are not activated by serum free medium. We found that treatment with epidermal growth factor (EGF) alone in serum free medium was not sufficient to activate reserve cells. However, treatment with a combination of insulin and EGF (i+E) could activate the reserve cells almost as efficient as FBS. We also found that the reserve cell activation treated with i+E was dependent on extracellular signal-regulated kinase (ERK) and c-Jun-N-terminal kinase (JNK).

In this study, we focused on the involvement of PI3K/Akt pathway in the mechanism of quiescent myogenic cell activation. We also sought inducible factors of JNK phosphorylation.
We investigated the involvement of PI3K/Akt pathway during reserve cell activation with i+E by detecting incorporation of BrdU in the presence of an inhibitor for PI3K or Akt. PI3K inhibitors (LY294002 or wortmannin) or an Akt inhibitor (triciribine) prevented incorporation of BrdU into reserve cells. Furthermore, triciribine also prevented it into MSCs on single myofibers isolated from adult C57BL/10 mice.
To elucidate factors involving JNK induction, we analyzed the expression and phosphorylation of JNK in reserve cells treated with insulin, EGF or i+E by Western Blot. We found that JNK phosphorylation increased with EGF and i+E, but did not change with insulin. These results suggested that JNK phosphorylation during the reserve cells activation is induced with EGF.
We conclude that PI3K and Akt are involved in the reserve cell activation induced in i+E. In addition, JNK phosphorylation is induced with EGF. Therefore, we found that quiescent myogenic cell activation is induced with not only activation of ERK but also with activation of PI3K, Akt and JNK. We conclude these pathways play an essential role for quiescent myogenic cell activation.

584

DYRK3 couples mTORC1 signaling to mRNA granule turnover.

F. Wippich[1], B. Bodenmiller[2], S. Wanka[1], J. Mercer[3], R. Aebersold[2], L. Pelkmans[1]; [1]Institute of Molecular Life Sciences, University of Zurich, Zurich, Switzerland, [2]Institute of Molecular Systems Biology, ETH Zurich, [3]Institute of Biochemistry, ETH Zurich

Mammalian cells dynamically regulate the activation and repression of messenger ribonucleoprotein complexes by growth factor signaling and the formation of cytoplasmic stress granules. However, little is known about the molecular mechanisms that connect these activities. Using an unbiased phospho-proteomic and protein microarray approach, we here report that the dual- specificity tyrosine-phosphorylation regulated kinase DYRK3 is essential for basal as well as growth factor-induced mTORC1 activity by directly phosphorylating PRAS40, a negative regulator of mTORC1. We show that small compound inhibitors are able to induce a kinase-inactive state of DYRK3, and that kinase-active and -inactive DYRK3 have distinct cellular effects. In the kinase-active state, DYRK3 dynamically associates with P-bodies and activates mTORC1 signaling, while in the kinase-inactive state, DYRK3 is stably associated with stress granules to prevent stress granule disassembly and blocks mTORC1 signaling. Based on our findings, we propose that DYRK3 couples mRNA granule turnover to the regulation of protein translation during normal and stressful conditions.

Influence of the PI3K/Akt signaling pathway on the regulation of HIV-1 alternative RNA splicing.

F. Hillebrand[1], S. Erkelenz[2], H. Schaal[2], M-C. Dabauvalle[1]; [1]Electron Microscopy, Biocenter, University of Wuerzburg, Wuerzburg, Germany, [2]Institute of Virology, University of Duesseldorf, Wuerzburg, Germany

In contrast to constitutive splicing, alternative splicing describes the differential removal of specific exonic sequences from mature mRNA or inclusion of intronic ones and is therefore a major contributor to proteomic diversity and an important mechanism for the regulation of gene expression.
Beside the importance of alternative splicing for the cellular gene expression, the replication of many viruses (e.g. HIV-1) depends on alternative splicing to generate mRNAs encoding viral proteins essential for viral replication. More than 40 different alternatively spliced HIV-1 mRNAs

are produced through the differential combination of four 5` splice donor sites and eight 3`splice acceptor sites.
Like most biological processes the splicing process is tightly regulated. This regulation depends on the strength of splice sites and regulatory cis acting elements within the exons and introns, which function by recruitment of sequence specific trans- acting factors that either activate (like SR proteins) or repress (hnRNPs) the use of adjacent splice sites.
Until now, little is known about the influence of transduction pathways on the regulation of alternative splicing. Nevertheless, in the last years it has been shown that the PI3K/Akt pathway affects the activity of the SR proteins SRSF1, SRSF5 and SRSF7 in vitro and thereby influences the alternative splicing of the Protein kinase C and Fribonectin mRNA.
Using the PI3K/Akt signaling pathway inhibitor LY294002, we have analysed the importance of this pathway on the HIV-1 splicing pattern and the viral replication.
By performing RT- and real time- PCRs we first carried out experiments using HIV-1 based splicing reporter constructs. Here the inhibition of the PI3K/Akt signaling pathway resulted in a shift from spliced mRNA species to intron retaining RNA species indicating that the inhibition of the PI3K/Akt pathway interferes with the splicing process. Next we conducted experiments with cells infected with HIV-1. Beside the accumulation of intron containing mRNAs, we found that the PI3K/Akt inhibition resulted in the generation of alternative tat mRNAs and the use of a novel HIV-1 splice donor site. Further, the inhibition of the PI3K/Akt pathway interfered with the viral replication shown by diminished p24 detection in the presence of the inhibitor.
These results clearly demonstrate that there is an influence of PI3K/Akt on the HIV-1 splicing pattern and the viral replication and that the inhibition of this pathway could be a new approach for antiviral therapy.

PDK1 mediates rephosphorylation of the activation domain of atypical PKC during the keratin intermediate filament dependent rescue from degradation.

A. Mashukova[1,2], R. Forteza[2], F. Wald[2], P. J. Salas[2]; [1]College of Medical Sciences, Nova Southeastern University, Davie, FL, [2]Cell Biology and Anatomy, University of Miami, Miami, FL

Phosphorylation of the activation domain of PKC isoforms is essential to start a conformational change that results in an active catalytic domain. While there is consensus that PDK1 is the activating kinase that phosphorylates this domain in newly synthesized molecules, it is unclear what kinase performs that function in molecules that were previously de-phosphorylated and refolded by Hsp70 chaperones. The latter, considered a “rescue” mechanism is responsible for the maintenance of the steady-state levels of atypical PKC and other isoforms. Even in the presence of normal levels of transcription and translation, atypical PKC levels fall by one order of magnitude if the rescue from degradation is abrogated. To identify the activating kinase during the rescue mechanism, we inhibited protein synthesis and analyzed the stability of the remaining atypical PKC pool. Two different PDK1 inhibitors, BX-912 and a specific pseudosubstrate peptide, destabilized that pool. PDK1 was shown to co-immunoprecipitate with PKC iota in cells without protein synthesis. We confirmed that PDK1 rephosphorylates atypical PKC during the rescue mechanism by in vitro rephosphorylation assays, where rephosphorylation was abrogated by immunodepleation of PDK1 and rescued with recombinant PDK1. Importantly, we demonstrate that the keratin scaffold that sustains atypical PKC rescue contains all the components necessary for the mechanism except PDK1. We also found that in Caco-2 epithelial cells PDK1 distributes to an apical membrane compartment comprising plasma membrane and endosomes, which, in turn, colocalized with intermediate filaments. These results shed light on a novel function of keratin intermediate filaments sustaining normal intracellular signaling.

587

Identification of proteins that interact with tyrosine-phosphorylated catalytic subunits of cyclic-AMP-dependent protein kinase A.

G. B. Caldwell[1], P. B. Deming[1,2]; [1]Medical Laboratory and Radiation Science, University of Vermont, Burlington, VT, [2]Vermont Cancer Center, University of Vermont, Burlington, VT

Growth factors and their cognate receptor tyrosine kinases mediate a host of cellular behaviors including proliferation, differentiation and cellular migration. cAMP-dependent protein kinase A (PKA) is one protein that is activated downstream of growth factor receptors. Recent results from our laboratory demonstrated that 1) the catalytic subunit of PKA (PKA-C) is phosphorylated on tyrosine 330 (Y330) *in vitro* by growth factor receptor tyrosine kinases 2) PKA-C subunits isolated from growth factor-stimulated cells are phosphorylated on Y330 and 3) the kinetic activity of PKA-C is enhanced upon phosphorylation (Caldwell et al., J Cell Biochem. 2011 Aug 22. doi: 10.1002/jcb.23325. [Epub ahead of print]). Phosphorylation of tyrosine residues often induces a new protein interaction, therefore, we hypothesized that phosphorylation of PKA-C on Y330 also alters its binding properties. An SH2 domain array was employed to screen for candidate proteins that interact specifically with PKA-C phosphorylated on Y330. Positive interactions were observed for six Src family kinase members (c-Src, Fyn, Fgr, Yes, Hck and Lck), phospholipase C- γ, RasGap and the p85 regulatory subunit of PI3 kinase. Interestingly, c-Src was also found to phosphorylate PKA-C on Y330 *in vitro*. Since PKA-C is phosphorylated on Y330 in response to growth factors, our results identify several proteins that may interact with PKA to coordinate growth factor-mediated signaling events.

Regulation of Pigment Granule Aggregation by Protein Kinase A in Fish Retinal Pigment Epithelial (RPE) Cells.

N. E. Fischer[1], C. King-Smith[1]; [1]Department of Biology, Saint Joseph's University, Philadelphia, PA

In the eyes of fish and amphibians, light flux into the retina is controlled by the bidirectional movement of pigment granules within retinal pigment epithelial (RPE) cells. Pigment granules disperse from the cell body into apical projections in response to light and aggregate back into the cell body in the dark. Both aggregation and dispersion require actin filaments. RPE pigment granule aggregation *in vitro* is stimulated by cAMP, however, it has not been shown that cAMP, the canonical activator of protein kinase A (PKA), indeed activates PKA in the aggregation process. Using an *in vitro* kinase assay, PKA activity was demonstrated in RPE lysates. RPE cells isolated from sunfish, *Lepomis spp.*, were treated with the PKA inhibitors H89 and myristoylated PKI, a cell-permeable inhibitor of PKA. H89 blocked pigment granule aggregation, however, H89 is not specific to PKA, but is also known to inhibit rho kinase (ROCK). PKI concentrations of 10-100 µM had no effect on pigment granule aggregation. Efficacy of PKI was tested by treating rod inner and outer segments (RIS-ROS), which normally shorten myoids in response to PKA, with either H89 or PKI. H89 blocked myoid shortening in RIS-ROS, however PKI did not. It is possible that PKI cannot enter cells, despite myristoylation, which is expected to enhance membrane permeability. To directly assess whether cAMP stimulation of PKA activates aggregation, isolated RPE cells were microinjected with purified PKA catalytic subunit. Injected cells aggregated pigment granules, demonstrating that PKA elicits pigment granule aggregation in RPE cells.

589

Analyzing the role of a Golgi transport-vesicle coat protein in PKC-epsilon-dependent signaling.

T. A. Peterson[1], M. Stamnes[1]; [1]Molecular Physiology and Biophysics, University of Iowa, Iowa City, IA

Protein Kinase C (PKC) epsilon has been implicated in a variety of human diseases, including cell transformation and cardioprotective signal transduction associated with heart disease.
The localization and function of PKC-epsilon has been shown to involve the beta'-COP subunit of coatomer, a coat protein of intracellular transport vesicles. Our objective has been to use NIH3T3 fibroblast cell line, cultured cardiomyocytes, and cell-free Golgi-binding assays as model systems to understand the role of coatomer in PKC-epsilon-dependent signaling.
We confirm that activating PKC-epsilon with phorbol esters causes PKC-epsilon to translocate from the Golgi apparatus to the cell surface in fibroblasts. Disrupting the Golgi apparatus with the drug brefeldin A, disrupts the steady state localization of PKC-epsilon at the Golgi apparatus but does not interfere with PKC-epsilon translocation to the cell surface. Mutations that are known to affect the binding interaction between PKC-epsilon and beta'-COP have only subtle effects on the translocation of PKC-epsilon. The majority of beta'-COP does not appear to translocate with PKC-epsilon to the cell surface upon treatment with phorbol ester. We find that multiple coatomer subunits colocalize with PKC-epsilon at steady state suggesting that the entire coatomer complex could contribute to PKC-epsilon function. We have confirmed that phosphorylation of PKC-epsilon at residue 729 stimulates PKC-epsilon localization to the Golgi apparatus. The oncogenic constitutively active mutant, PKC-epsilon A159E, also localizes predominantly to the Golgi apparatus. The intact-cell experiments support a role for coatomer in both the steady-state localization of PKC-epsilon and the activation-induced translocation. We have used a cell-free Golgi-binding assay to begin defining the molecular basis for the regulated PKC-epsilon binding interaction with the Golgi apparatus. We confirm that the ARF1 GTPase increases the binding of both coatomer and PKC-epsilon to Golgi membranes and that binding of PKC-epsilon to isolated Golgi membranes is stimulated by phorbol esters. Our results indicate that protein phosphorylation and ARF1/coatomer recruitment play connected regulatory roles in PKC-epsilon binding to the membrane.
Both the intact-cell and cell-free binding studies support a model wherein the beta'-COP subunit of coatomer helps specify the steady-state localization of PKC-epsilon at the Golgi apparatus. In this way, coatomer would influence human-disease-related signaling by directing PKC-epsilon subcellular distribution.

Localization and Binding Partners of Obscurin Kinases in Striated Muscle Cells.

L-Y. R. Hu[1], J. Valenti[1], A. Kontrogianni-Konstantopoulos[1]; [1]Biochemistry and Molecular Biology, University of Maryland Baltimore, Baltimore, MD

Obscurins are giant muscle proteins that have been implicated in myofibrillogenesis and linked to hypertrophic cardiomyopathy. They are composed of tandem arrays of structural and signaling motifs, including an isoleucine-glutamine (IQ) repeat, a Src homology 3 (SH3) domain, a pleckstrin-homology (PH) domain, a Rho-guanine nucleotide exchange factor (Rho-GEF) motif, and two serine/threonine kinase domains, namely SK1 and SK2. To understand the cellular pathway(s) that the obscurin kinases are involved, we sought to identify their interacting partners using the yeast-two-hybrid system. Our screening demonstrated that the β-subunit of Na+/K+-ATPase (NKA) and N-cadherin are potential interacting partners of SK1 and SK2, respectively. Immunofluorescence and Duolink® immuno-histological staining demonstrated that the identified SK1/NKA and SK2/N-cadherin interacting pairs are localized in close

proximity (<40 nm) at the level of the sarcolemma and the intercalated disc, respectively. Detailed deletion analyses revealed that the extracellular domain of the β-subunit of NKA is sufficient to interact with the catalytic portion of SK1, whereas both the extracellular and intracellular regions of N-cadherin are required to interact with the catalytic portion of SK2. Immunostaining of non-permeabilized primary cultures of adult flexor digitorum brevis (FDB) muscle with antibodies recognizing the obscurin-kinase isoforms suggested that at least some parts are localized extracellularly. Consistent with this, select obscurin-kinase isoforms are efficiently and specifically retained by lectin columns, but not if pre-treated with Peptide: N-Glycosidase F (PNGase F). Thus, our results demonstrate that at least some portions of the obscurin-kinase isoform(s) are localized extracellularly, potentially functioning as ectokinases, where they may undergo glycosylation.

PP4 is required for NHEJ-mediated repair of DNA double strand breaks.

J. Liu[1], L. Xu[1], X. Xu[1]; [1]Beijing Key Lab of DNA Damage Responses, Capital Normal Univ-Coll Life Sci, Beijing, China

Reversible phosphorylation is an essential post-translational modification to turn on/off a protein function, regulating many cellular activities, including DNA repair. DNA double-strand break (DSB) is the most lethal form of DNA damage and is mainly fixed by the high-fidelity homology-directed repair and the error-prone non-homologous end joining (NHEJ) repair. In this report, we performed a genomewide serine/threonine phosphatase siRNA screen using a reporter system of NHEJ-mediated DSB repair and identified PP4c, when depleted by siRNA, compromised NHEJ-mediated DSB repair. Both PP4C and its regulatory subunit PP4R2 physcially interacted with the chromatin condensation factor KAP1 (KRAB-associated protein 1). Depletion of PP4c led to sustain phosphorylation of KAP1. Conversely, overexpression of PP4c resulted in a decrease of KAP1 phosphorylation. PP4 dephosphorylated pKAP1 in vitro. Depletion of both PP4c and KAP1 did not have any significant synergistic effect on NHEJ-mediated DSB repair. Taken together, our results suggest that PP4 is required for NHEJ-mediated DSB repair through, at least partially, regulating phosphorylation status of KAP1.

592

Receptor-type protein tyrosine phosphatase sigma a (ptprsa) expression in the central nervous system of adult zebrafish and brainstem-derived primary neuron cultures.

A. Tapanes-Castillo[1], M. Staudenmaier[1], A. Wood[1], F. Shabazz[1], K. Vajn[2], M. Oudega[2], J. A. Plunkett[1]; [1]School of Science, Technology and Engineering Management, St. Thomas University, Miami Gardens, FL, [2]Center for Neuroscience, University of Pittsburgh School of Medicine, Pittsburgh, PA

In the mammalian central nervous system (CNS), the transmembrane protein tyrosine phosphatase PTPsigma was recently identified as a receptor for chondroitin sulfate proteoglycans (CSPGs), such as neurocan, which inhibits axon regeneration following an injury. The goal of our project is to elucidate the role of PTPsigma in zebrafish axon regeneration following spinal cord injury (SCI). Unlike mammals, in adult zebrafish damaged axons regenerate across and beyond a SCI site. We hypothesize that the zebrafish homolog of PTPsigma, protein tyrosine phosphatase sigma a (ptprsa), like its mammalian counterpart, is a receptor for CSPGs. Furthermore, we suspect that axon regeneration in the zebrafish CNS is due in part to reduced PTPsigma activity following injury. To qualitatively investigate ptprsa expression following CNS injury in the zebrafish, we are currently using Reverse Transcriptase Polymerase Chain Reactions (RT-PCR). We are also investigating possible ptprsa interactions with CSPGs through the evaluation of ptprsa expression in adult zebrafish brainstem-derived

primary neuron cultures. We observed ptprsa mRNA expression in uninjured brain and spinal cord tissue as well as in injured brain tissues. We have also detected ptprsa mRNA expression in brainstem neuron cultures grown on a growth-permissive laminin substrate, as well as on a CSPG-containing/laminin substrate. Our qualitative RT-PCR data suggest that overall ptprsa gene expression may not be governed by injury (*in-vivo*) or substrate (*in-vitro*). We are currently determining whether ptprsa activity is differentially regulated in the presence versus absence of injury through a post-transcriptional mechanism. Using morpholino knockdown, *in-vitro* experiments are also underway to determine whether ptprsa functionally interacts with zebrafish specific neurocan. Funded by U.S. Dept. of Defense W81XWH-10-1-0617 to JP.

Dual function of the Bub1 kinase in the spindle checkpoint and the DNA damage response.

H. Wang[*1], C. Yang*[*1], Y. Xu[1], K. L. Brinkman[1]; [1]Department of Radiation and Oncology, The Methodist Hospital Research Institute, Houston, TX*

*These authors contributed equally.

The DNA damage response (DDR) and the spindle assembly checkpoint (SAC) are two critical mechanisms by which mammalian cells maintain genome stability. There is a growing body of evidence that DDR elements and SAC components crosstalk. Here we report that Bub1 (Budding Uninhibited by Benzimidazoles 1), one of the critical kinetochore proteins essential for SAC, is required for optimal DDRs. We found that knocking-down Bub1 resulted in prolonged H2AX foci and comet tail formation as well as hypersensitivity in response to ionizing radiation (IR). Further, we found that Bub1-mediated Histone H2A Threonine 121 phosphorylation was induced after IR in an ATM-dependent manner. We demonstrated in vitro and in vivo that the ATM kinase, being activated in mitosis and in response to DNA damage, phosphorylated Bub1 on Serine 314. We further showed that ATM-mediated Bub1 Serine 314 phosphorylation was required for Bub1 activation during mitosis, for initiation of SAC and for the optimal DDR. Together, we elucidate the molecular mechanism of Bub1 activation and highlight dual functions of the Bub1 kinase in DDR and SAC.
Key words: ATM, Bub1, DNA Damage Response, Spindle Assembly Checkpoint

594

The Nek8 protein kinase, mutated in the human cystic kidney disease nephronophthisis, is both activated and degraded during ciliogenesis.

D. Zalli[1], A. M. Fry[1], R. Bayliss[1]; [1]Biochemistry, University of Leicester, Leicester, United Kingdom

Mutations in the NIMA-related kinase, Nek8, are associated with cystic kidney disease in both humans and mice, with Nek8 being the NPHP9 gene in the human juvenile cystic kidney disease, nephronophthisis. Previous localisation studies have shown that Nek8 localises to centrosomes and cilia in dividing and ciliated cells, respectively, strengthening the ciliary hypothesis of cystic kidney disease. However, the role of Nek8 in ciliogenesis remains to be defined and no substrates for this kinase have yet been identified. Here, by establishing Nek8 kinase assays, we first confirmed that localization of Nek8 to centrosomes and cilia is dependent upon both its kinase activity and its C-terminal non-catalytic RCC1 domain. The kinase domain alone is active, but does not localize correctly, while the RCC1 domain does localize correctly and can be phosphorylated by Nek8. We propose that centrosome recruitment is mediated by the RCC1 domain, but requires a conformational change in the full-length protein that is promoted by autophosphorylation. Interestingly, three NPHP9-associated mutants retain

full kinase activity. However, only two of these, L330F and A497P, localize correctly, suggesting that the third mutant, H425Y, disrupts the centrosome-targeting motif in the RCC1 domain. Importantly, we also found that serum starvation induces proteasomal degradation of Nek8, specifically in cell lines in which serum starvation induces quiescence and ciliogenesis. Strikingly, serum starvation also induces activation of the Nek8 kinase, whilst overexpression of Nek8 leads to microtubule hyperacetylation and suppression of ciliogenesis. Taken together, these findings reveal important insights into the mechanisms through which Nek8 activity and localization are regulated, and suggest that Nek8 is an inhibitor of ciliogenesis.

595

A novel role for Ack1 in the regulation of CTP synthase.

T. Strochlic[1], S. Thomas[1], A. O'Reilly[1], J. Peterson[1]; [1]Department of Cancer Biology, Fox Chase Cancer Center, Philadelphia, PA

Ack1 (activated cdc42-associated kinase 1) is an evolutionarily conserved effector of the Rho GTPase Cdc42 although little is known regarding the biological functions of this non-receptor tyrosine kinase. To investigate the role of Ack1 in vivo, we studied the homologous protein DAck in the genetically tractable organism *Drosophila melanogaster*. *DACK* null female flies displayed reduced fertility and defects in oogenesis, suggesting a possible function for DAck in germ cell development. In female germ cells, DAck localized to unusual 20 μm long filamentous structures distinct from conventional cytoskeletal elements. Co-localization studies revealed that these filaments correspond to recently described novel filaments of the enzyme cytidine triphosphate synthase (CTPS). CTPS plays an essential role in CTP synthesis and in the production of phospholipids. The inactive form of CTPS forms filaments in bacteria and *Saccharomyces cerevisiae*, suggesting that filament formation controls CTPS activity and supporting the notion that these structures serve an important evolutionary function. We find that CTPS filament number, morphology, and distribution are altered in *DACK* null or *DACK* overexpressing flies, implicating DAck as a critical regulator of CTPS during oogenesis. Furthermore, in mammalian cells, chemical inhibition of CTPS results in the formation of morphologically identical filaments that contain both CTPS and activated Ack1. Our results identify Ack as a second component of CTPS filaments and implicate Ack in the regulation of CTPS activity in both flies and mammals.

596

Simple Informatics Approach to Correct Arginine-Proline Conversion in SILAC Data.

N. Inomata[1], H. Mutoh[1], N. Yabuki[1], K. Nagano[1], T. Shinkawa[1], M. Haramura[1]; [1]Discovery Science & Technology Dept, Chugai Pharmaceutical Co., Ltd., Kanagawa, Japan

Stable isotope labeling by amino acids in cell culture (SILAC) is widely used to monitor the change in the abundance of proteins in cells. In this method, a natural amino acid (most commonly arginine and/or lysine) in one of two cell cultures is replaced with heavy labeled amino acid, and the culture is treated with the biologically active sample. The other cell culture is cultured with light (natural) amino acid and treated with a control sample, and finally the findings are validated by swapping the labels. However, it has become known that heavy labeled arginine is catabolically converted to heavy labeled proline inside the cells, which could cause a miscalculation of the ratios of proline-containing light and heavy peptides. Accurate quantification of protein, especially phosphorylations is a key step to understanding many cellular events so we developed a correction method of calculating arginine–proline conversion easily.

To this end, we analyzed 1:1 mixtures of 4 lines of cultured cells grown in light or heavy media using an LTQ Orbitrap mass spectrometer. The histograms, light vs heavy and heavy vs light, showed a large shift in the distribution of peptide ratios. This shift became greater as the

number of prolines per peptide increased but did not occur with other amino acids. When we looked at the subset of peptides in which prolines increased, we found that the median of this subset increased linearly. By using this correlation, the large shift in the ratio distribution was completely overlapped and centered at zero. We tested 4 lines of cultured cells, and found that the shift in the ratio distribution varied according to the cell line and also to the culture condition (i.e. duration of labeling, treatment with a drug). We applied this method to see the effect of PD0325901 (a pure MEK inhibitor) on cellular phosphorylation of proteins in COLO205, DLD1, HCT15, and HCT116 cells.
In conclusion, we established a new simple calibration method for SILAC data which does not rely on special software to solve the arginine–proline conversion. We hope this finding will facilitate the quest to understand cell mechanism more precisely than before.

597

Signal transduction network mediated homeostatic photobiomodulation on high glucose induced dysfunctions of C2C12 myoblasts.

T. C-Y. Liu[1], F-H. Li[1], E-X. Wei[1], Y-Y. Liu[1]; [1]Laboratory of Laser Sports Medicine, South China Normal University, Guangzhou, Guangzhou, China

Background and Objective: Photobiomodulation promotes the wound healing of diabetes. Summer sunlight improves diabetes. These phenomena were simulated with the modulation of red light (640±15 nm) at 0. 35 W/m^2 from light emitting diode array for 15 min (RLED) once a day on high glucose induced dysfunctional C2C12 myoblasts and their signal transduction pathways were studied in this paper. **Study Design/Materials and Methods:** The C2C12 myoblasts were cultivated in 10% fetal bovine serum and the glucose at **22.5** (CON) and 90 (HG) **mmol/L**, respectively. The RLED irradiated HG groups were with or without LY294002 or SP600125, the inhibitor of phosphatidylinositol 3-kinase (*PI3K*) or Jun NH2-terminal kinase (JNK). All the parameters were routinely assessed. **Results: (1) There were no effects of RLED on the proliferation in the CON group or** HG +SP600125(10 μmol/L) group, of SP600125 at 1, 2 or 5 μmol/L on the HG+RLED proliferation, and of SP600125(10 μmol/L) on HG proliferation**. (2)** Compared with the CON group at the 72nd h from HG-cultivated C2C12 myoblasts on**, HG** induced apoptosis ($P < 0.05$), inhibited proliferation ($P < 0.01$) and ATP activity ($P < 0.01$), and increased caspase-3/7 activities ($P < 0.05$). According to Western blotting, HG reduced AKT Threonine 473 phosphorylation and increased JNK phosphorylation, respectively. **HG further** increased the mRNA level of forkhead transcription factor (FOXO) 3a ($P < 0.01$) and Bim ($P < 0.05$). HG increased the reactive oxygen species level ($P < 0.05$) at the 18th h, extracellular activities in lactate dehydrogenase ($P < 0.01$) at the 24th h, loss of mitochondrial membrane potential at the 48th h ($P <0.05$) and at the 72nd h ($P < 0.01$). **HG also increased** at the 4th h but decreased at the 72nd h $NAD^+/NADH$ ($P < 0.01$). RLED inhibited all those HG effects, but LY294002 inhibited all those RLED effects. **(3) At** the 72nd h**, HG decreased** manganese superoxide dismutase (MnSOD) mRNA level ($P <0.05$) and sirtuin 1 (SIRT1) protein level, but increased p27 mRNA level ($P < 0.05$). RLED inhibited all those HG effects, but there were no effects of LY294002 on all those RLED effects. (4) **At** the 72nd h**, HG increased** insulin-like growth factor (IGF) 1 mRNA level ($P < 0.05$) and decreased SIRT1 mRNA level ($P < 0.05$), but the mRNA level of the two genes was increased with RLED ($P < 0.05$) and further increased with LY294002 ($P < 0.01$). (5) **At** the 72nd h**,** HG proliferation was significantly promoted by SP600125 at 1, 2 or 5 μmol/L ($P<0.05$), which was further significantly promoted by RLED ($P < 0.01$). **Conclusions:** RLED might self-adaptively promote the establishment of proliferation-specific homeostasis of C2C12 myoblasts by inhibiting HG-induced apoptosis, which might be coordinatedly mediated by PI3K, JNK and IGF-1 signal transduction pathways.

Temporal evaluation of differential expressive proteins during the progression of balloon angioplasty-induced neointimal hyperplasia.

C-H. Wu[1], C-H. Pan[1]; [1]Pharmacy, China Med Univ, Taichung, Taiwan

Background: Restenosis is still a limiting factor for clinical applications of percutaneous transluminal coronary angioplasty (PTCA) with stent deposition. Elucidation of the molecular mechanisms involved in the progression of restenosis remains a pivotal issue.
Objectives: We attempted to explore the candidate proteins with temporal differential expression in the balloon-injured artery thus identifying the potential targeting molecules for preventing neointimal formation.
Methods: Neointimal hyperplasia was induced in rat model of balloon angioplasty, and the candidate proteins with temporal differential expression were screened by the method of two-dimensional gel electrophoresis (2-DE) coupling with liquid chromatography-tandem mass spectrometry (LC-MS/MS). Additionally, the small interfering RNA (siRNA) oligonucleotides were applied to clarify the possible effect of the candidate proteins in the cell growth and migration of vascular smooth muscle cells (VSMCs).
Results: Four candidate proteins, glutamate dehydrogenase 1 (GLUD1), glutathione S-transferase pi (GSTp), protein disulfide isomerase family A member 3 (PDIA3) and phosphoglycerate kinase 1 (PGK1), have been identified with temporal difference in protein expression after balloon angioplasty. Our current results showed that silencing PDIA3 or PGK1 reduced VSMCs proliferation, and PGK silence was found to be associated with activation of AMP-activated protein kinase (AMPK) and deactivation of extracellular signal-regulated kinase 1/2 (ERK1/2). Furthermore, migration of VSMCs can be suppressed by silencing GSTp, PDIA3 or PGK1. Of these, PDIA3 or PGK1 silence was resulted in a decreased expression in both matrix metalloproteinase (MMP)-2 and MMP-9 proteins.

Mild electrical stimulation with heat shock ameliorates diabetic nephropathy.

Y. Okamoto[1,2], S. Morino-Koga[1,2], T. Koga[1,2], K. Omachi[1,2], M. Suico[1,2], T. Shuto[1,2], H. Kai[1,2]; [1]Molecular Medicine, Graduate School of Pharmaceutical Sciences, Kumamoto University, Kumamoto, Japan, [2]Global COE "Cell Fate Regulation Research and Education Unit", Kumamoto University, Kumamoto, Japan

Diabetic nephropathy is a serious complication of diabetes with only limited treatment. Glomerular visceral epithelial cells (podocytes) play a critical role in maintaining the structure and function of the glomerular filtration barrier. It is known that podocyte foot process effacement in glomeruli is observed in early stage of diabetic nephropathy and is caused by apoptosis and disruption of cytoskeleton of podocytes, leading to progression of chronic renal injury. Previous studies have shown that specific deletion of the insulin receptor from podocytes in mice resulted in kidney diseases, implying that podocyte insulin signaling is important for normal kidney function. We previously showed that mild electrical stimulation and heat shock (MET) activated insulin signaling in various cell lines. Results of our investigation in healthy human subjects indicated that MET tended to improve serum creatinine level and blood urea nitrogen. These results suggested that MET could have protective effects against podocyte apoptosis and might induce reorganization of the cytoskeleton by activating the insulin signaling, leading to the improvement of diabetic nephropathy. Here, we investigated whether MET could affects podocyte insulin signaling. MET treatment for 10 min induced Akt phosphorylation in immortalized mouse podocytes (MPC5). We also assessed the effect of MET on high glucose (25mM)-induced apoptosis of MPC5. Pre-treatment of MET reduced high glucose-induced apoptosis of MPC5. To determine the effect of MET on podocyte cytoskeleton, we performed

phalloidin staining in MPC5. MET reorganized the cytoskeleton, similar to insulin. Finally, we investigated the effect of MET on in vivo model of diabetic nephropathy. It is known that db/db mice (leptin receptor-deficient mice, resulting in diabetes) have features of diabetic nephropathy. Db/db mice were treated with MET for 10 min twice a week for 5-20 weeks. MET prevented albuminuria and serum creatinine. To determine renal injury, we assessed mRNA in mice kidney. MET tended to decrease mRNA of renal injury markers and pro-inflammatory cytokines and pro-fibrotic cytokines. Our results indicated that MET could improve diabetic nephropathy by preventing apoptosis and cytoskeleton destruction of podocytes through activation of insulin signaling.

Zinc protoporphyrin up-regulates heme oxygenase-1 in PC-3 cells via the PI3-kinase-ERK-Nrf2 signaling pathway.

S. Kwok[1]; [1]ORTD, Albert Einstein Med Ctr, Philadelphia, PA

Objectives. Zinc protoporphyrin (ZnPP), a naturally occurring molecule formed in iron deficiency or lead poisoning, is a potent competitive inhibitor of heme oxygenase-1 (HO-1). It also regulates the expression of HO-1 at the transcriptional level. However, the effect of ZnPP on HO-1 expression is controversial. It was shown to induce HO-1 expression in some cells, but suppress it in the others. In fact, it even suppressed the induction of HO-1 by inducers, such as statins and lipopolysaccharide. The objective of this study is to investigate the mechanism of action of ZnPP on the induction of HO-1 in human prostate cancer PC-3 cells. Methods. PC-3 cell line was used as a model to study the mechanism of action of ZnPP. Cell proliferation was determined using CellTiter assay. Activation of HO-1 promoter by ZnPP was determined by enhancer-luciferase reporter assays. Induction of HO-1 protein was studied by Western blot analyses. Results. ZnPP induced significant cell proliferation in PC-3 cells at a concentration of 0.6-10 μM, but suppressed cell growth above 20 μM. Therefore, 10 μM ZnPP was used for all subsequent experiments. Basal level of HO-1 protein in PC-3 was undetectable. Incubation of the cells with 10 μM ZnPP for 4 h showed only a slight induction of HO-1 protein, but the induction was high after 16 h and was maintained through 48 h of incubation. Of all the known responsive elements in the HO-1 promoter, ZnPP activated mainly the stress response elements (StREs). StRE3 showed the highest (6.6-fold) induction level by ZnPP, although these elements had different levels of relative luciferase activities due to different copy number of the response elements present in the luciferase-reporter constructs. ZnPP did not activate the HSE, SREBP and SP1 elements. To investigate the effect of various protein kinase inhibitors and antioxidant on the activation of StRE by ZnPP, cells transfected with StRE3-pGL3 were pretreated with SB203580 (p38-MAPK inhibitor), LY294002 (PI3-kinase inhibitor), U0126 (MEK inhibitor), SP600125 (JNK inhibitor), IPA-3 (p21-activated Kinase Inhibitor III) or N-acetyl cysteine (NAC, antioxidant) prior to treatment with ZnPP. SP600125 had little effect. SB203580, IPA-3, and NAC reduced the activation by less than 50% of the control. However, LY294002 and U0126 suppressed the activation to 28.3 and 22.8%, respectively, of the control, suggesting the involvement of PI3-kinase and ERK. Conclusions. ZnPP up-regulated HO-1 expression in PC-3 cells via PI3-kinase-ERK-Nrf2 signaling pathway.

Signaling Scaffolds and Microdomains

Molecular characterization of a multiprotein complex that links membrane depolarization with gene expression in skeletal muscle.

S. Buvinic[1,2], G. Almarza[2], M. Arias[2], E. Jaimovich[2]; [1]Department of Basic and Community Sciences, Faculty of Dentistry, Universidad de Chile, Santiago, Chile, [2]Center for Molecular Studies of the Cell, ICBM, Faculty of Medicine, Universidad de Chile, Santiago, Chile

Electrical activity regulates the expression of skeletal muscle genes by a process known as “excitation-transcription” (E-T) coupling. We have previously demonstrated that release of ATP after depolarization activates membrane P2X/P2Y receptors, being a fundamental mediator between electrical stimulation, slow calcium transients and gene expression. We propose that this pathway would require the proper coordination between the voltage sensor (dihydropyridine receptor, DHPR), pannexin hemichanel (ATP release conduit), nucleotide receptors, and several signal molecules. The goal of this study was to assess protein-protein interactions within the E-T machinery in skeletal muscle, in order to unveil a putative signaling complex.

Co-immunoprecipitation of the selected proteins was achieved in extracts of newborn rat derived myotubes, and in rat and mouse adult muscle isolated triads. Components of multiprotein complexes were also resolved using blue-native SDS/PAGE, and selected proteins detected by immunoblot. Immunofluorescence assays were performed in isolated fibers from mice adult muscles. We constructed cDNA for fused $P2Y_2$- or PnX1-proteins with the One-STrEP-tag and transfected into L6-rat skeletal muscle cells to allow one-step purification of protein complexes on Strep-tactin Superflow.

DHPR, $P2Y_2$ receptor, Panexin 1, phospholipase Cγ1 and dystrophin, all co-immunoprecipitated in a crossed manner in the different preparations assessed. DHPR, pannexin-1, $P2Y_1$, $P2Y_2$ and $P2X_7$ did show a striated pattern of distribution by immunofluorescence, possibly representing location at the T-tubules in adult skeletal fibers. Blue-native SDS/PAGE for adult muscle triads showed that DHPR is an integral part of large multiprotein complexes of different sizes, some of them also containing $P2Y_2$ and Pannexin-1 protein. Novel interactors within these complexes using MALDI-TOF mass spectrometry are being explored. We have also expressed $P2Y_2$- and PnX1- proteins with the One-STrEP-tag into L6-rat skeletal muscle cell line in order to isolate and characterize the functional multiprotein complex in different physiological conditions.

Results strongly suggest that there is a multiprotein complex located in skeletal muscle T-tubules that is relevant to link membrane depolarization with gene expression. Unveiling general mechanisms that lead muscle plasticity could help to understand and treat a variety of skeletal muscle disorders associated with muscle homeostasis.

Stimulus-specific activation and actin dependency of distinct, spatially separated ERK1/2 fractions in A7r5 smooth muscle cells.

S. Vetterkind[1], R. Saphirstein[1], K. Morgan[1]; [1]Health Sciences, Boston University, Boston, MA

A proliferative response of smooth muscle cells to activation of extracellular signal regulated kinases 1 and 2 (ERK1/2) has been linked to cardiovascular disease. In fully differentiated smooth muscle, however, ERK1/2 activation can also regulate contraction. Here, we use A7r5 smooth muscle cells, stimulated with 12-deoxyphorbol 13-isobutylate 20-acetate (DPBA) to induce cytoskeletal remodeling or fetal calf serum (FCS) to induce proliferation, to identify factors that determine the outcomes of ERK1/2 activation in smooth muscle. Knock down experiments, immunoprecipitation and proximity ligation assays show that the ERK1/2 scaffold caveolin-1 mediates ERK1/2 activation in response to DPBA, but not FCS, and that ERK1/2 is released from caveolin-1 upon DPBA, but not FCS, stimulation. Conversely, ERK1/2 associated with the actin cytoskeleton is significantly reduced after FCS, but not DPBA stimulation, as determined by Triton X fractionation. Furthermore, treatment with the inhibitor of actin polymerization, cytochalasin D, inhibited DPBA, but not FCS induced ERK1/2 phosphorylation, indicating that the actin cytoskeleton is not only a target but also is required for ERK1/2 activation. Our results show that (1) at least two ERK1/2 fractions (caveolar and actin-associated) are regulated separately by specific stimuli, and that (2) the association of ERK1/2 with the actin cytoskeleton regulates the outcome of ERK1/2 signaling. Our findings help explain how in smooth muscle, ERK1/2 signaling can be directed either towards proliferation, as associated with atherosclerosis, or towards contractility associated with hypertension. Support: HL80003, HL86655.

Identification of a novel Bcl10 domain that contributes to NF-κB activation.

A. Shaloo[1], B. Schaefer[1]; [1]Microbiology and Immunology, Uniformed Services University, Bethesda, MD

The NF-κB transcription factor is a centrally important mediator of T cell functional responses. Activation of the NF-κB signaling pathway via T cell receptor (TCR) stimulation requires the adaptor protein Bcl10. How Bcl10 transmits NF-κB -activating signals remains incompletely understood. To better understand the function of the Bcl10 protein, we have performed deletion and site-directed mutagenesis of the 12-amino acid Bcl10 N-terminal peptide, a domain which has not yet been studied in-depth. Our results show the Bcl10 N-terminal peptide is functionally important for TCR-mediated activation of NF-κB. Deletion of this peptide or replacement of amino acids 2-12 with alanines abolishes Bcl10-mediated NF-κB activation, and mutation of residues 5 and 10-12 also substantially reduces Bcl10 signaling to NF-κB. Further analysis of these N-terminal peptide mutants by co-immunoprecipitation has shown that mutation at specific sites, such as 10-12, causes a pronounced decline in binding to partner proteins, including CARMA1. Imaging of these mutants in stimulated T cells shows absent or aberrant Bcl10 translocation to known cytoplasmic NF-κB signaling clusters called POLKADOTS. Altogether these results demonstrate that the Bcl10 N-terminal peptide is required for Bcl10 association with signaling partners, Bcl10 cellular translocation, and for signal transmission to NF-κB. These data establish the N-terminal peptide of Bcl10 as a novel determinant of Bcl10 function.

604

Co-recruitment with the GM-CSF Receptor Beta Chain to Intersectin/Clathrin-Coated Pit is Essential for JAK2V617F-mediated Autonomous Cell Growth.

P-H. Chen[1], I-H. Lin[2], C-S. Liu[1], F-J. Lee[3], H-F. Yang-Yen[4], J. J. Yen[5]; [1]Graduate Institute of Life Sciences, NDMC, Taipei, Taiwan, [2]Department of Microbiology, Soochow University, [3]Institute of Molecular Medicine, College of Medicine,NTU, [4]IMB, Academia Sinica, Taiwan, [5]IBMS, Academia Sinica, Taiwan

The V617F mutation of JAK2 has been frequently identified in neoplastic myeloproliferative disorders. JAK2V617F-mediated autonomous cell growth requires the interaction of JAK2V617F with un-liganded cytokine receptors. However, the underlying mechanism remains elusive. Here we demonstrate that the GM-CSF receptor β chain (GMR β) constantly undergo ligand-independent endocytosis, albeit such process can be enhanced by the presence of ligand and the GM-CSF receptor α chain. Recruitment of the GMR complex onto intersectin/clathrin-coated pit (CCP) is essential for GM-CSF signaling. A WxxxI motif in the membrane proximal region of GMRβ is required for the GMR complex to be recruited to intersectin/CCP where wild-type JAK2 is activated in a ligand-dependent manner. Interestingly, blocking GMRβ recruitment to intersectin/CCP via mutation of the WxxxI motif or knockdown the expression of intersectin or clathrin abolished ligand-independent activation of JAK2V617F. This study reveals that un-liganded GMR promotes JAK2V617F-mediated autonomous cell growth via co-recruitment of this oncoprotein to intersectin/CCP for activation.

605

Role of IQGAP1 in S6K-Akt1 Feedback.

Y. K. Tekletsadik[1], R. Sonn[2], M. A. Osman[3]; [1]Department of Biological and Environmental Engineering, Cornell University, Ithaca, NY, [2]SUNY, Stony Brook, Syony Brook, NY, [3]Brown Univ, Providence, RI

Defining the mechanisms that orchestrate cell growth and division to regulate cell proliferation is crucial to understanding tumorigenesis. The mTOR pathway, the center of cell growth control, is commonly activated in human cancers but proved ineffective as a clinical target due to incomplete understanding of its mechanisms in cell growth inhibition. IQGAP1, a widely conserved effector/regulator of CDC42GTPase is a putative oncogene that control cell proliferation, however, its mechanism in tumorigenesis is unknown. Using complementary studies in yeast and mammalian cells, here we report that IQGAP1 has a key role in regulating the negative feedback loop (NFL) of the target of rapamycin complex1 (mTORC1) that control cell growth. A Two-hybrid screen identified yeast TORC1-specific subunit, Tco89p, as an Iqg1p-binding partner sharing roles in rapamycin-sensitive growth, axial bud-site selection and cytokinesis, thus coupling cell growth and division. Mammalian IQGAP1 binds mTORC1 and Akt1 and in response to epidermal growth factor (EGF), cells expressing the mTORC1/Akt1-binding region, IQGAP1^{IR-WW}, contained attenuated *p*ERK1/2 activities and inactive glycogen synthase kinase 3α/β (*p*GSK3α/β), which control apoptosis. Interestingly, these cells displayed high *p*Akt1^{S473} activity but attenuated activity of the mTORC1-dependent kinase, *p*S6k1^{T389} and induced mTORC1/Akt1-depnedent transformed phenotypes. Moreover, IQGAP1 influences cell abscission and its activity is elevated in carcinoma cell lines. These findings support the model that IQGAP1 acts upstream on the mTORC1/S6K1→Akt1 NFL and downstream of it to couple cell growth and division and regulate cell homeostasis, dysregulation of which leads to tumorigenesis. These results could have implications on developing the next generation of anticancer therapeutics.

Oxidative stress enhances pro- inflammatory signal cascade by increasing association of TLR4 with it's adaptor TIRAP (MAL), enhancing of TIRAP-MyD88 signaling pathway.

M. Ailenberg[1], O. Rotstein[1]; [1]Surgery, St. Michael's Hospital, Li Ka Shing Knowledge Institute and the University of Toronto, Toronto, ON, Canada

Resuscitated hemorrhagic shock following trauma is known to contribute to the development of late organ dysfunction in patients who survive the initial trauma insult and thus contributes to morbidity and mortality in this patient population. There is ample evidence to suggest that hemorrhagic shock followed by resuscitation fluids causes excessive immune response via enhanced reactive oxygen species (ROS). TLR4 is a trans- membrane receptor on immune system cells that transduces Gram negative bacterial ligand's signal into the cell, culminating in synthesis of pro- inflammatory cytokines. Two sets of TLR4- related adaptor proteins exist: MyD88-TIRAP (MAL) and TRAM-TRIF that relay the signals into the cell. The mechanism of ROS stimulation of the innate immune response is incompletely understood. To gain insight into the mechanism by which ROS enhances the innate immune response, we created a murine macrophage cell line (RAW 264.7) that constitutively produce mouse TLR4 tagged with HA. This cells were transiently co- transfected with TIRAP (MAL) -flag. Using immunoprecipitation with HA antibody and immunobloting with flag antibody, we show that Hydrogen Peroxide (H2O2) treatment results in increased association of TLR4 with the adaptor protein TIRAP (MAL) in temporal and dose- related fashion. Furthermore, H2O2 enhanced signaling through the MyD88-TIRAP (MAL) pathway (p-p38); and decreased signaling through the TRAM-TRIF pathway (p-IRF3). These findings suggest that H2O2 disrupts the immune response homeostasis by increasing the MyD88-TIRAP (MAL) pathway that may culminate in production of pro- inflammatory cytokines; and decreasing the TRAM-TRIF pathway that may result in production of anti- viral agents like INFβ.

607

Phase Transitions of Multivalent Signaling Proteins Regulate Actin Assembly.

S. Banjade[1], H-C. Cheng[1], P. Li[1], S. Kim[1], M. K. Rosen[1]; [1]Department of Biochemistry and HHMI, UT Southwestern Medical Center, Dallas, TX

The actin cytoskeleton plays a key role in various biological processes such as endocytosis, differentiation and motility. However, how actin assembly is spatially and temporally controlled in cells remains elusive. In cells, the Arp2/3 complex plays a central role in controlling actin dynamics by catalyzing nucleation of new actin filaments. The Arp2/3 complex, in turn, is regulated by various members of the neuronal Wiskott Aldrich Syndrome Protein (N-WASP) family.

In podocytes, epithelial cells in the kidney, the cytosolic portion of the transmembrane protein Nephrin recruits Nck to the membrane, which in turn recruits N-WASP. Nck has three SH3 domains that interact with the six proline-rich motifs of N-WASP, and one SH2 domain that interacts with the three phosphotyrosine motifs of Nephrin. Cooperative interactions between Nephrin, Nck and N-WASP oligomerize N-WASP and enhance its activation of the Arp2/3 complex.

We have discovered that the multi-valent interactions between N-WASP, Nck and Nephrin lead to a sharp transition between small complexes and large polymer. This transition coincides with a macroscopic phase transition that produces micron-size droplets of a second liquid-like phase in equilibrium with bulk solution, which we term the "droplet phase." This phase transition occurs as a function of the number of phosphotyrosines in Nephrin, suggesting that this phenomenon

could be regulated by kinases in cells. The phase transition also corresponds to a sharp change in activity toward the Arp2/3 complex, indicating that a switch-like transition from small oligomers to large assemblies of N-WASP could be an important mechanism to spatially and temporally control actin assembly.

In cells, the interaction between Nephrin, Nck and N-WASP occurs at the membrane, and therefore the “droplet phase” will be the 2-dimensional corollary to the observed 3-dimensional droplets. To understand this behavior in the context of the membrane, we have reconstituted interactions between N-WASP, Nck and Nephrin on supported lipid bilayers. We have discovered that the multi-valent interactions between these players drive them to form micron-sized dynamic puncta, and now aim to study the physical properties of the puncta and the parameters that control their formation.

Multi-valent molecules are present everywhere in biology - both at the membrane and in the cytoplasm. This kind of phase transition, resulting from multi-valent interactions, could be a general phenomenon that nature uses to regulate biological functions.

608

Detergent-resistant membranes are essential along the signalling pathways of prostate-specific membrane antigen.

S. Schmidt[1], H. Y. Naim[1]; [1]Department of Physiological Chemistry, University of Veterinary Medicine Hannover, Hannover, Germany

Prostate-specific membrane antigen (PSMA) is a surface protein overexpressed in prostate cancer and neovasculature of further tumours. It is therefore one of the most promising biomarkers in diagnosis and treatment of prostate cancer.
PSMA is associated with detergent-resistant membranes (DRMs). The mature form of PSMA is mainly insoluble in Lubrol WX, but does not associate with Triton X-100 DRMs.
Recently we could demonstrate that cross-linking of cell surface PSMA with specific antibodies activates different signalling cascades like the MAPK-pathway. Here we show that internalization of PSMA is increased after antibody binding and this leads to redistribution of PSMA to Triton X-100 DRMs in a time-dependent manner and to alterations in the expression levels of several proteins in these DRMs. One of these proteins is laminin receptor-1 which directly interacts with PSMA in co-immunoprecipitation experiments.
Our results propose an essential role for different DRM types in the signalling pathways involving PSMA.

609

Hedgehog signaling is dependent on ciliary trafficking proteins in the sea urchin embryo.

J. F. Warner[1], D. R. McClay[1]; [1]Duke University, Durham, NC

A recent frontier in Hedgehog (Hh) signaling research is the requirement of the primary cilium and intra-flageller transport (IFT) proteins for signal transduction. Studies in vertebrates have shown that proper trafficking of Hh pathway components within the primary cilium is essential for Hh signaling. This machinery is not necessary, however, for Hh signal transduction in protostomes such as Drosophila. As a basal deuterostome, the sea urchin occupies a unique phylogenetic position and can provide crucial insight into the evolution of hedgehog signaling. Here we provide evidence that, as in vertebrates, Hh signaling in the sea urchin relies on the presence of cilia. It has been previously shown by Robert Morris and John Scholey that Kinesin II is essential for cilia assembly. Indeed, knockdown of Kinesin II using an antibody phenocopies Hh morphants. Likewise, knocking down the microtubule associated protein, Costal2, also

produces a phenotype consistent with inhibition of Hh signaling. These findings lead to a model of sea urchin Hh signaling that closely resembles the pathway as it functions in vertebrates. This indicates the necessity of cilia for Hh signal transduction is not vertebrate specific as previously speculated but is in fact deuterostome specific.

610

PSD-95 binding capacity of GPR30, an estrogen receptor that can be identified in CA1 dendritic spines in vivo.

K. T. Akama[1], L. I. Thompson[2], T. A. Milner[1,2], B. S. McEwen[1]; [1]Neuroendocrinology, The Rockefeller University, New York, NY, [2]Neurology and Neuroscience, Weill Cornell Medical College, New York, NY

Dendritic spines are often the sites for excitatory synapse formation, and the steroid hormone estrogen stimulates an increase in spine formation and subsequent synaptogenesis in the hippocampus. Recent studies have demonstrated that the estrogen receptor can be immunolocalized to non-nuclear sites in hippocampal neurons, and specifically, estrogen receptors have been identified at CA1 pyramidal neuron dendritic spines. Such spine-targeting of estrogen receptors potentially allows for local signaling from hormonal stimuli in order to modify dendritic spine structure or to downstream neuronal responses.
To determine how the estrogen receptor is localized to the dendritic spine, and to identify specific protein binding partners that might selectively direct a rapid, estrogen-stimulated non-genomic response, we are biochemically investigating the estrogen receptor interaction with dendritic spine proteins. One potential membrane-localized estrogen receptor that has described is GPR30. Our preliminary studies demonstrate that GPR30 is expressed in the stratum radiatum of the rat hippocampus in vivo, and can be immuno-detected in hipppocampal synaptosome lysates in vitro. Therefore, it is important to understand how receptors such as GPR30 might interact with spine-specific proteins. GPR30 target partners relevant to our studies include the spine scaffolding protein PSD-95, and GPR30 localization to the dendritic spine avails the receptor to interact with and potentially to modulate other post-synaptic receptors.

611

ErbB receptors exist in distinct signaling domains in primary cilia.

S. Jerman[1], H. H. Ward[1], E. Romero[1], A. Wandinger-Ness[1]; [1]Pathology, The University of New Mexico Health Sciences Center, Albuquerque, NM

The epidermal growth factor receptor (EGFR) signaling axis exacerbates autosomal dominant polycystic kidney disease (ADPKD) caused by the expression of mutant polycystin-1 (PC1) or polycystin-2 (PC2) proteins. PC1 and PC2 are localized to primary cilia where they are central to ciliary calcium signaling and tyrosine kinase cascades. Our objective was to elucidate the mechanism by which the ErbB signaling proteins interface with polycystins in the cilia by analyzing their localization to and organization within the primary cilium and how this is disrupted in ADPKD. Our results show that EGFR, ErbB2, and PC2 localize to the primary cilium of renal epithelial cells. Ciliary localization of all three proteins is perturbed in PKD cells. Based on co-immunoprecipitation experiments, EGFR is in a complex with PC1 and PC2. Our previous work demonstrated that the polycystins associate with specialized membrane domains organized by cholesterol binding flotillin proteins. Here we show that the flotillin-1 and -2 proteins also localize to cilia and interact with the polycystins and EGFR. The data suggest that the cholesterol binding flotillins may serve a major function in trafficking signaling proteins to the primary cilium and subsequent organization of ciliary signaling hubs. Furthermore, we have identified a conserved VxPx motif common to the polycystins, EGFR, and ErbB2 which serves as primary binding sites for a multimeric GTPase complex with known function in exocytosis.

The VxPx motif has been shown by our lab to be essential for Arf4 GTPase mediated ciliary trafficking of PC1. Purified, active Arf4 interacts with EGFR. In conclusion, we have shown for the first time that EGFR and ErbB2 localize to the primary cilium of renal epithelia and interact with domain organizing flotillins in addition to polycystins which, when mutant, cause ADPKD.

612

The Role of CD82 in Hematopoietic Stem Cell Niche Adhesion.

M. L. Cotter[1], J. M. Gillette[1]; [1]Pathology, University of New Mexico Health Sciences Center, Albuquerque, NM

The spatial organization and dynamics of proteins and lipids within the cell membrane is important for the regulation of cell signaling, adhesion, and cell communication. Within the bone marrow niche, communication between hematopoietic stem/progenitor cells (HSPCs) and niche cells is essential for regulating their proliferation, differentiation, and survival. Previous work from our laboratory has ascertained that HSPCs utilize a polarized domain on the plasma membrane that serves as the contact site with osteoblasts, which are important members of the bone marrow niche. Using primary CD34+ cells and the progenitor-like KG1a cell line, this domain was found to be enriched in the specific tetraspanin proteins, CD63, CD81, and CD82. Tetraspanins are multi-spanning membrane proteins that act as scaffolds for the organization of membrane domains important for regulating adhesion and signaling. In particular, our characterization of CD82 interactions using CD82 blocking antibodies revealed a significant decrease in adhesion of HSPCs to niche cells as well as in the *in vivo* homing and engraftment capabilities of these cells. In order to determine the molecular mechanisms of CD82's role in adhesion, we cloned CD82 into the mCherry expression vector and transfected this vector along with the mCherry control vector into KG1a cells. Stable cell lines were selected and isolated by fluorescence cell sorting. Expression of the CD82-mCherry and mCherry control constructs were verified by fluorescence imaging, and the overexpression of CD82 was confirmed by Western blot. We next performed adhesion assays to assess the effects of CD82 overexpression on cell adherence. Our data indicate that CD82 overexpression leads to at least a two-fold increase in adhesion to fibronectin, in addition to increased adhesion to an osteoblastic monolayer. These data suggest that CD82 may have a role in altering the affinity or avidity of integrins, and our primary focus has been on the $\alpha4\beta1$ integrin, also known as VLA4. Future studies will be directed towards evaluating these cell lines in proliferation and VLA4 affinity assays.

613

LRP1 mediates the Shh-induced endocytosis of the GPC3-Shh complex.

M. I. Capurro[1,2], W. Shi[1,2], J. Filmus[1,2]; [1]Division of Molecular and Cell Biology, Sunnybrook Research Institute, Toronto, ON, Canada, [2]Department of Medical Biophysics, University of Toronto, Toronto, ON, Canada

Glypicans are a family of heparan sulfate (HS) proteoglycans whose members are bound to the cell membrane through a glycosylphosphatidylinositol (GPI) link. Glypicans regulate the activity of several growth factors including Hedgehogs (Hh), Wnts and bone morphogenetic proteins. We have recently reported that Glypican-3 (GPC3), one of the 6 mammalian glypicans, regulates embryonic growth by inhibiting the hedgehog (Hh) signaling pathway. GPC3 binds Hh and competes with Patched (Ptc), the Hh receptor, for Hh binding. The interaction of Hh with GPC3 triggers the endocytosis and degradation of the GPC3/Hh complex with the consequent reduction of Hh available for binding to Ptc. Currently, the molecular mechanism by which the GPC3/Hh complex is internalized remains unknown. Here we demonstrate that the low-density-lipoprotein receptor-related protein-1 (LRP1) mediates the Hh-induced endocytosis of the

GPC3/Hh complex by showing that internalization is inhibited by the chaperone RAP that blocks the interaction of ligands to LRP1. Furthermore, we also demonstrate that the Hh-induced endocytosis of the GPC3/Hh complex is inhibited by LRP1 siRNA treatment. In addition, we show that internalization of this complex is required for the Hh-inhibitory activity of GPC3. Co-immunoprecitation, pull-down and cell binding assays demonstrate that GPC3 binds through its HS chains to LRP1. Finally, we show that GPC3 is mainly localized outside of lipid rafts/detergent-insoluble membrane microdomains, something unexpected for a GPI-anchored protein, and that the HS-mediated interaction with LRP1 is what causes the removal of GPC3 from the lipid raft domains.

614

Dynasore- an inhibitor of clathrin- mediated endocytosis (CME) is a potent activator of NFkB independent of its effect on CME.

M. Ailenberg[1], C. Di Ciano-Oliveira[1], O. Rotstein[1]; [1]Surgery, St. Michael's Hospital, Li Ka Shing Knowledge Institute and the University of Toronto, Toronto, ON, Canada

Clathrin- mediated endocytosis (CME) is a process whereby cargo is recruited into clathrin-coated pits, which then form clathrin- coated vesicles that internalize into the cell. It is involved in a variety of cellular processes e.g. internalization of signal complexes and protein and nucleic acid uptake. The GTPase dynamin is essential for CME. The role of CME in activation of downstream signaling pathways was studied using dynasore, a reversible specific inhibitor of dynamin GTPase. Here we show that dynasore is a potent stimulus for NF-κB activation. Specifically, dynasore treatment led to degradation of IκBα, phosphorylation of p65, translocation of phospho-p65 to the nucleus and activation of NF-κB - luciferase construct. Dynasore also augmented phosphorylation of MAPKs, especially SAPK/JNK. These effects were not due to LPS contamination. Further, pretreatment with the antioxidant N-Acetylcysteine (NAC) decreased dynasore- induced activation of NFκB, suggesting that dynasore might exerts its action through a pathway involving Reactive Oxygen Species. Interestingly, the effect was not recapitulated by other CME inhibitors including chlorpromazine or myristyl trimethyl ammonium bromide suggesting that dynasore's effect on downstream signaling is not mediated through inhibition of CME. Data presented underscore the notion that caution should be taken in interpretation of experiments utilizing dynasore. Effects on other GTPase known to be sensitive to dynasore may be responsible for its downstream signaling effects.

Rho-Family GTPases

615

ROCK1 & 2 perform essential non-compensatory roles in angiogenesis and angiosarcoma tumor progression.

J. Montalvo[1], C. Spencer[1,2], B. A. Bryan[1,3]; [1]Biology, Worcester State University, Worcester, MA, [2]Schepens Eye Research Institute, Harvard Medical School, Boston, MA, [3]Biomedical Sciences, Texas Tech University Health Sciences Center, El Paso, TX

The serine/threonine protein kinase paralogs ROCK1 & ROCK2 have been heavily implicated as essential modulators controlling multiple aspects of physiological and tumor angiogenesis; however the majority of published studies have utilized general pharmacological inhibitors of ROCK proteins which exhibit no paralog specificity. To determine the paralog specific roles of ROCK proteins in angiogenesis and vascular tumor formation, we utilized stable shRNA knockdown technology to ablate the expression of ROCK1 or 2 in endothelial and angiosarcoma

cells. Knockdown of ROCK1 & 2 expression results in a non-compensatory disruption of in vitro capillary network formation, cytoskeletal dynamics, and cell migration, while the expression of ROCK2, but not ROCK1, is essential for phosphorylation of myosin light chain phosphatase. Knockdown of ROCK1 or 2 results in significant survival advantages over control cells following serum starvation. Whole genome microarray analysis reveals that ROCK1 & 2 share largely overlapping roles in their ability to counteract VEGF-induced regulation of gene expression in endothelial cells, suggesting that alterations in cytoskeletal dynamics are capable of overriding the effects of mitogenic signaling. Finally, shRNA knockdown of ROCK proteins results in a significant reduction of angiosarcoma solid tumor size. Our data reveal that ROCK1 & 2 exhibit unique and essential roles in endothelial and angiosarcoma cells. Moreover, disruption of ROCK expression is capable of blocking VEGF-induced gene transcription, suggesting that therapeutic targeting of this pathway may have a profound impact on diseases reliant on aberrant angiogenesis.

616

Involvement of Rac1 in Ethanol-Induced Endothelial Barrier Dysfunction.

T. M. Doggett[1], J. W. Breslin[1]; [1]Physiology, LSU Health Sciences Center, New Orleans, LA

The microvascular barrier is critical for normal fluid homeostasis, and can be disrupted by concentrations of ethanol achieved after moderate to severe drinking. RhoA and Rac1 are two GTPases involved in endothelial barrier function. RhoA disrupts and Rac1 enhances barrier integrity. We tested the hypothesis that ethanol disrupts the endothelial barrier by increasing RhoA activity or decreasing Rac1 activity. Barrier function of human umbilical vein endothelial cell (HUVEC) monolayers was assessed by determining transendothelial electrical resistance (TER) before and after ethanol treatment (5-100 mM). RhoA and Rac1 activity was also determined in HUVEC treated with 100 mM ethanol for 1, 5, 10, 30, 60, 90, and 120 min. with an ELISA kit. To determine if the ethanol-induced decrease in TER could be inhibited by activation of Rac1, the selective Epac1 activator, 8-CPT-2'-O-Me-cAMP (8-CPT) was applied. The results show that ethanol disrupts TER in a concentration-dependent manner. Ethanol also significantly decreased Rac1 activity at 1, 5, 10, 30, and 60 min. (53% ± 5.8, 55% ± 5.1, 60% ± 5.3, 77% ± 8.9, and 73% ± 4.8 vs. control, $p<0.01$). RhoA activity remained unchanged compared with the baseline activity of vehicle-treated controls. Pretreatment with 8-CPT increased TER and attenuated the overall ethanol-induced decrease in TER, although this was mainly due to the elevated TER after 8-CPT treatment. Interestingly, when added 5 or 10 min after ethanol treatment, 8-CPT shortened the time to recover to baseline TER. The results suggest that ethanol disrupts endothelial barrier function by inactivating Rac1 and not increasing RhoA activity. In addition, Epac1-mediated Rac1 activation may be a useful target to resolve ethanol-induced hyperpermeability. The N-terminal DH-PH domain of Trio induces cell spreading and migration by regulating lamellipodial dynamics in a Rac1-dependent manner.

J. van Rijssel[1], M. Hoogenboezem[1], L. Wester[1], P. Hordijk[1], J. van Buul[1]; [1]Molecular Cell Biology, Sanquin Research and Landsteiner Laboratory at Univeristy of Amsterdam, Amsterdam, Netherlands

The guanine-nucleotide exchange factor Trio encodes two DH-PH domains that catalyze nucleotide exchange on Rac1, RhoG and RhoA. The N-terminal DH-PH domain is known to activate Rac1 and RhoG, whereas the C-terminal DH-PH domain can activate RhoA. Our study shows that the N-terminal DH-PH domain activates Rac1 and RhoG independently from each

other in HeLa cells. In addition, we show that the flanking SH3 domain binds to the proline-rich region of the C-terminus of Rac1, but not of RhoG. However, this SH3 domain is not required for Rac1 or RhoG GDP-GTP exchange. Rescue experiments in Trio-shRNA expressing cells showed that the N-terminal DH-PH domain of Trio, but not the C-terminal DH-PH domain, restored defects in fibronectin-mediated cell spreading and migration that are observed in Trio-silenced cells. Kymograph analysis revealed that the N-terminal DH-PH domain, independent of its SH3 domain, controls the dynamics of lamellipodia. Using siRNA against Rac1 or RhoG, we found that Trio-D1-induced lamellipodia formation required Rac1 but not RhoG. Together, we conclude that the GEF Trio induces lamellipodia formation through its N-terminal DH-PH domain, thus promoting fibronectin-mediated spreading and migration in a Rac1-dependent fashion.

Crucial role of the small GTPase Rac1 in insulin-stimulated translocation of glucose transporter 4 to the mouse skeletal muscle sarcolemma.

S. Ued[1], S. Kitazawa[2], K. Ishida[1], Y. Nishikawa[1], M. Matsui[1], H. Matsumoto[1], T. Aoki[1], S. Nozaki[1], T. Takeda[1], Y. Tamori[3], A. Aiba[4], C. Kahn[5], T. Kataoka[1], T. Satoh[1]; [1]Molecular Biology, Kobe University Graduate School of Medicine, Kobe, Japan, [2]Molecular Pathology, Kobe University Graduate School of Medicine, Japan, [3]Division of Diabetes, Metabolism, and Endocrinology, Kobe University Graduate School of Medicine, [4]Division of Molecular Genetics, Kobe University Graduate School of Medicine, [5]Joslin Diabetes Center, Harvard Medical School, Boston, MA

The Rho family GTPase Rac1 has been implicated in the regulation of glucose uptake in myoblast cell lines. However, no evidence for the role of Rac1 has been provided by a mouse model. The purpose of this study is to test the involvement of Rac1 in insulin action in mouse skeletal muscle. Intravenous administration of insulin indeed elicited Rac1 activation in gastrocnemius muscle, suggesting the involvement of Rac1 in this signaling pathway. We then examined whether insulin-stimulated translocation of the facilitative glucose transporter GLUT4 from its storage sites to the skeletal muscle sarcolemma depends on Rac1. We show that ectopic expression of constitutively activated Rac1, as well as intravenous administration of insulin, caused translocation of GLUT4 to the gastrocnemius muscle sarcolemma, as revealed by immunofluorescent staining of a transiently expressed exofacial epitope-tagged GLUT4 reporter. Of particular note, insulin-dependent, but not constitutively activated Rac1-induced, GLUT4 translocation was markedly suppressed in skeletal muscle-specific rac1-knockout mice compared to control mice. Immunogold electron microscopic analysis of endogenous GLUT4 gave similar results. Collectively, we propose a critical role of Rac1 in insulin-dependent GLUT4 translocation to the skeletal muscle sarcolemma, which has heretofore been predicted solely by cell culture studies.

619

Analysis of RhoA and Rho GEF activity in the cell nucleus.

C. Guilluy[1], A. D. Dubash[2], R. Garcia-Mata[1]; [1]Department of Cell and Developmental Biology, University of North Carolina-Chapel Hill, Chapel Hill, NC, [2]Department of Pathology, Northwestern University, Chicago, IL

We have recently demonstrated that a fraction of the total cellular pool of the small GTPase RhoA resides in the nucleus, and that the nuclear guanine nucleotide exchange factor (GEF) Net1 plays a role in the regulation of its activity. In this protocol we describe a method to measure both the activities of the nuclear pools of RhoA and Rho GEFs. This process required the development of a nuclear isolation protocol that was both fast and virtually free of cytosolic

and membrane contaminants, as well as redesigning the existing RhoA and Rho GEF activity assays so they work in nuclear samples. This protocol can be also used for other RhoGTPases and Rho GEFs that have also been found in the nucleus. Completion of the procedure, including nuclear isolation and RhoA or Rho GEF activity assay, takes 1h 40 min.

Computational analysis of Rho GTPase cycling: extraction of parameters and inference of pathways.

C. V. Falkenberg[1], L. M. Loew[2]; [1]Center for Cell Analysis and Modeling, University of Connecticut Health Center, Farmington, CT

The Rho family of GTPases control actin organization during diverse cellular responses such as directed migration, cytokinesis and endocytosis. Although the primary members of this family, RhoA, Rac and Cdc42 all have different downstream effects on actin, they share a basic mechanism that involves targeting to the plasma membrane and activation by GTP binding. Our hypothesis is that the details of GTPase cycling between membrane and cytosol are key to the differential upstream regulation of these biochemical switches.
We developed a computational modeling framework to analyze experimental data on GTPase cycling, including binding to the plasma membrane and to GDI. We use published in vivo experimental data to extract kinetic and equilibrium constants for Rac and GDI cycling. The complete model is reformulated as a compact non-dimensional steady state system. The cell surface to volume ratio and GDI concentration are sensitive parameters for the overall system behavior. To explore the effect of regulatory signals, we calculated the membrane fraction of GTPase over a wide range of relevant parameters. This analysis was applied to Rac re-distribution in pancreatic β-cells upon glucose stimulus.
Analysis of experimental data for Rac membrane cycling reveals that the lower apparent affinity of GDI for RacGTP compared to RacGDP can be fully explained by the faster dissociation of the latter from the membrane. While Rac membrane fraction is sensitive to the total GDI expressed in the cell, Rac dissociation rate from the membrane is independent. In contrast, based on published in vitro experimental data, Cdc42 membrane dissociation rate is dependent on GDI and effector concentrations. By increasing the GEF/GAP ratio, a larger fraction of Rac is distributed to the membrane. In β-cells, the model reveals that glucose stimulated Rac re-distribution cannot be completely attributed to modification of the GDI phosphorylation state alone. There must be another signal that decreases Rac dissociation constant with the plasma and granular membranes. PLD activation has been previously proposed as such a signaling molecule.
In conclusion, systematic experiments addressing dissociation rates and membrane fractions of Cdc42 and RhoA in vivo could be used to complete the model parameters for these GTPases. The methodology for pathway inference used for Rac redistribution in β-cell can be extrapolated to guide how specific modifications may compensate for altered GTPase-GDI balance in disease scenarios. (Supported by NIH grant TR01DK087650).

Mechanical force on ICAM1 leads to RhoA-mediated cytoskeletal changes in endothelial cells.

E. C. Lessey[1], R. Superfine[2], K. Burridge[1]; [1]Cell and Developmental Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Physics and Astronomy, University of North Carolina at Chapel Hill

RhoA mediated cytoskeletal rearrangements in endothelial cells (ECs) play an active role in transendothelial cell migration (TEM), a normal physiological process in which leukocytes are

recruited from the blood circulation into tissues. While much has been learned about RhoA signaling pathways downstream from ICAM-1 in ECs, little is known about the consequences of the tractional forces that leukocytes generate on ECs as they migrate over the surface before TEM. We have found that after applying mechanical forces to ICAM-1 clusters, there is enhanced RhoA signaling and cellular reinforcement compared to ICAM-1 clustering alone. Using the RhoA activity assay, we have determined ICAM-1 clustering alone leads to ~1.75 fold increase in RhoA activity over untreated cells, whereas the addition of force leads to ~2.5 fold higher RhoA activation over control. There is a ~3.5 fold increase in myosin light chain phosphorylation with force over control compared with a ~2.5 fold increase over control with clustering alone. In addition, we observe a 26% increase in RhoA-dependent cellular stiffening measured by pulling on ICAM-1 clusters with magnetic tweezers. We also have confirmed the cytoplasmic tail of ICAM-1 is required for the observed findings. Taken together these findings indicate that the tractional forces leukocyte generate on ECs leadings to changes in the ECs cytoskeleton. These changes may assist in downstream leukocyte TEM. Further exploring how ECs respond to forces generated by leukocytes on ICAM-1 will contribute to our understanding of inflammatory diseases where leukocyte TEM correlates with disease progression, such as atherosclerosis, ischemic cardiomyopathy, and ischemia reperfusion injury.

622

Negative Regulation of RhoA Translation and Signaling by hnRNP-Q1 Affects Cellular Morphogenesis.

L. Xing[1], X. Yao[1], K. R. Williams[1], G. J. Bassell[1]; [1]Cell Biology and Neurology, Emory University, Atlanta, GA

The small GTPase RhoA has critical functions in regulating actin dynamics which affects cellular morphogenesis through the RhoA/ROCK signaling cascade. RhoA signaling controls stress fiber and focal adhesion formation and cell motility. In the central nervous system, RhoA signaling is involved in several aspects of neuronal development which include neuronal migration, growth cone collapse, dendrite branching and spine growth. Altered RhoA GTPase signaling is implicated in cancer and neurodegenerative disease and is linked to forms of inherited intellectual disabilities. While much is known about factors regulating RhoA activity and/or degradation, little is known about molecular mechanisms regulating RhoA expression and their implications in regulating RhoA signaling. We hypothesized that the posttranscriptional control of RhoA translation may provide a mechanism to regulate RhoA signaling and the downstream effects on cellular morphogenesis. Here, we uncovered a cellular function for the mRNA-binding protein hnRNP-Q1 to control neuronal and non-neuronal cell morphogenesis which involves the negative regulation of RhoA synthesis and signaling. We show that hnRNP-Q1 directly interacts with the 3'UTR of RhoA mRNA and represses RhoA translation. Additionally, hnRNP-Q1 knockdown lead to upregulated endogenous RhoA expression and induced morphologic and molecular phenotypes associated with elevated RhoA protein levels and RhoA/ROCK signaling. These morphologic changes were rescued by treatment with the ROCK inhibitor Y-27632 and/or RhoA knockdown. These findings reveal a new functional connection between an mRNA binding protein and RhoA signaling, whereby hnRNP-Q1 plays a key role to negatively modulate RhoA expression and signaling and affect cellular morphogenesis.

623

The role of RhoB in the response to kidney ischemia.

M. A. Hallett[1], S. J. Atkinson[1,2]; [1]Medicine, Indiana University, Indianapolis, IN, [2]Biology, Indiana University Purdue University Indianapolis

The small GTPase RhoB is an important regulator of cellular response to stress. It is an early response gene to UV damage and low levels of RhoB in cancer cells correlates with resistance to chemotherapy. In these situations, RhoB is pro-apoptotic. However, loss of RhoB expression in an epithelial to mesenchymal transition induced by TGFβ, results in an increase in apoptosis. It thus appears that RhoB signaling may be either anti-apoptotic or pro-apoptotic depending on context and the nature of the stress. RhoB expression is also up regulated in response to hypoxia and ischemia. To investigate the role of RhoB signaling in ischemic injury, we used substrate depletion and antimycin A treatment to deplete cells of ATP in a cell culture model of ischemia using a mouse proximal tubule S3 segment cell line. We found that RhoB activity is increased sixty minutes after fifteen minutes of ATP depletion. Additionally, TNFAIP1 (tumor necrosis factor inducible protein 1) is found in the GTP-bound fraction of a RhoB activity assay following depletion at the same time as RhoB activity reaches its peak. TNFAIP1 also co-immunoprecipitated with total (active+inactive) RhoB following 15 minutes of depletion, but not under normal growth conditions. Cytochrome C release from mitochondria also peaked after depletion. When we isolated a mitochondria-rich fraction following depletion we found RhoB and TNFAIP1 were transiently associated with this fraction. Based on these data we suggest that increased RhoB activity following depletion or ischemic injury may facilitate delivery of pro-apoptotic molecules (such as TNFAIP1) to the mitochondria and initiation of cytochrome c release.

624

Activation of RhoC in lamellipodia regulates mDia1-mediated actin polymerization, membrane protrusion and directional cell migration independently of RhoA-ROCK signaling.

N. Mitin[1], K. L. Rossman[1], R. Currin[1], T. Marshall[1,2], S. Anne[1], J. E. Bear[1], C. Der[1]; [1]University of North Carolina, Chapel Hill, NC, [2]University of Utah

Eukaryotic cell movement requires the dynamic reorganization of the actin cytoskeleton, which is controlled by the Rho family of small GTPases. RhoA and RhoC share a high degree of sequence similarity with identical effector binding domains and have, therefore, been presumed to have redundant biological functions. However, recent studies suggest that RhoA and RhoC regulate different aspects of cellular migration, with RhoC emerging as a pro-invasion gene in a variety of cancers, although the molecular basis of RhoC-mediated cellular migration and invasion is currently not known. We now show that RhoC, and not RhoA, engages mDia1 to promote directional cell migration. Using kymography analysis, we further demonstrate that RhoA and RhoC differentially regulate membrane protrusion of the leading edge, with RhoA serving to restrict membrane dynamics, and RhoC acting to promote protrusion of the leading edge. Examining the organization of the actin cytoskeleton within lamellipodia, we find that the loss of RhoC or mDia1 causes overstabilization of actin-containing dorsal arcs, whereas depletion of RhoA or inhibition of Rho-associated kinase causes the disassembly of dorsal arcs. Furthermore, live-cell microscopy reveals that dorsal arcs that are overstabilized impair lamellipodium protrusion and cause cells to change their direction of migration, consistent with the loss-of-persistence phenotype observed in cells depleted of RhoC and mDia1. Furthermore, we have designed novel reporters of RhoA and RhoC activation utilizing bifluorescence complementation analysis imaging (BiFC) to observe the spatial activation of these Rho GTPases in lamellipodia. Whereas BiFC-RhoA is activated uniformly throughout lamella and

lamellipodium as previously seen by FRET analysis, BiFC-RhoC is activated in the protruding areas of lamellipodia colocalizing to the dendritic actin network and becomes inactivated as actin filaments assemble. Therefore, we report for the first time that RhoC is specifically activated in lamellipodia to promote mDia1-induced actin polymerization and membrane protrusion. Finally, we have identified the Rho-specific guanine nucleotide exchange factor, TEM4, as the upstream activator of RhoC required for actin polymerization and membrane protrusion. Depletion of TEM4 impairs the directionality of cell migration and the dynamics of membrane protrusion, abolishes the activation of RhoC during cell spreading and extinguishes RhoC activation in the lamellipodia as visualized by BiFC assay. In summary, we identify a TEM4-RhoC-mDia1 signaling nexus that controls directional cell migration by regulating dynamic actin polymerization in lamellipodia.

625

Investigating the Roles of RhoGAP1 and RhoGAP8 in Regulating Rho GTPase Activity During Single-Cell Wound Healing.

N. Davenport[1], W. Bement[1,2]; [1]Graduate Program in Cellular and Molecular Biology, University of Wisconsin-Madison, Madison, WI, [2]Department of Zoology, University of Wisconsin-Madison, Madison, WI

The ability to respond to physical damage is an essential and evolutionarily conserved process in single cells and tissues. The Rho family of GTPases has been shown to coordinate the cytoskeletal rearrangements needed to reestablish the integrity of the plasma membrane and underlying cortex in response to cell damage. The precision with which Rho and Cdc42 are activated and maintained in distinct activity zones throughout the healing process suggests the involvement of multiple Rho GTPase regulators at the wound. To date, a candidate screen for guanine nucleotide exchange factors (GEFs) and GTPase activating proteins (GAPs) involved in regulating Rho GTPase activity at the wound has identified a single wound regulator, Abr. By continuing the candidate screen, we have identified two additional GAPs, RhoGAP1 and RhoGAP8, as potential wound regulators. eGFP-tagged RhoGAP1 localizes between the zones of active Rho and Cdc42 in wounded *Xenopus laevis* oocytes where it may be acting as enzymatic barrier to prevent Rho GTPase activity zone mixing during wound healing. Targeting is mediated by its C-terminal region which contains both a GAP domain and a proline-rich region. Further, overexpression of RhoGAP1 results in a reduction in active Rho at wounds. We have also discovered that RhoGAP1 and RhoGAP8 colocalize at wounds which, in addition to previously reported evidence of their interaction, suggests they may form a complex to regulate Rho GTPase activity.

626

Doublecortin orchestrates microtubule and actin dynamics to promote neuronal progenitor cell migration in a manner dependent on phosphorylation by PKA.

M. Toriyama[1], N. Mizuno[1], T. Iguchi[2], M. Toriyama[1], T. Fukami[1], K. Tago[1], H. Itoh[1]; [1]Dept. of Biol. Sci., Nara Inst. Sci. and Tech, Ikoma-city, Nara, Japan, [2]Dept. Morphol. and Physiol. Sci., Univ. of Fukui, Fukui, Japan

Doublecortin (DCX), which is specifically expressed in neuronal cells, is a microtubule-associated protein. Genetic mutation of DCX causes the lissencephaly disease. Although the abnormal cortical lamination observed in lissencephaly patients is thought to be attributed to neuronal cell migration defects, how DCX is involved in the migration of neuronal progenitor cells (NPCs) remains unclear. In this study, we found that pituitary adenylate cyclase-activating polypeptide (PACAP) accelerated the migration of NPCs in a manner dependent on protein kinase A (PKA) activation. We demonstrated that PKA directly phosphorylated DCX at Ser47 in

vitro, and the phosphorylation-mimicked DCX mutant (S47E) promotes the cell migration. Furthermore, DCX (S47E) exhibited the lower binding affinity for microtubule, compared with wild type DCX. Interestingly, the activation of PKA and DCX (S47E) decreased the microtubule bundling, and induced the formation of lamellipodia mediated by Rac. PACAP and DCX (S47E) induced the activation of Rac, and DCX (S47E) interacted with Asef2, a guanine nucleotide exchange factor (GEF) for Rac1. We propose the novel mechanism how the phosphorylation of DCX by PKA regulates neuronal migration, and this signaling pathway is indispensable to proper brain lamination.

627

The role of Calcium-Independent Phospholipase A2 in homeostasis of aqueous humor drainage: Ca+2 sensitization of trabecular meshwork contraction.

P. P. Pattabiraman[1], F. B. Lih[2], K. B. Tomer[2], V. Rao[1,3]; [1]Dept of Ophthalmology, Duke Univ, Durham, NC, [2]Mass Spectroscopy Group, NIEHS, Durham, NC, [3]Dept of Pharmacology, Duke Univ

Objective: To explore the role of calcium-independent phospholipase A_2 ($iPLA_2$), which is known to control eicosanoid synthesis and tissue contractile properties, in regulation of aqueous humor (AH) outflow drainage.
Methods: Distribution of $iPLA_2$ isoforms in the outflow pathway tissues was evaluated by immunohistochemical analysis. Using irreversible, chiral, mechanism-based isoform specific inhibitors of $iPLA_2$, R-Bromoenol lactone (R-BEL, $iPLA_{2\gamma}$ specific) and S-Bromoenol lactone (S-BEL, $iPLA_2\beta$ specific), we determined the specific role(s) of $iPLA_2$ isoforms in regulation of TM cell contractile properties, Rho GTPase activity, myosin phosphatase activity and actin cytoskeletal dynamics by biochemical analyses, and evaluated for changes in AH outflow facility in enucleated porcine eyes.
Results: Both human and porcine TM cells were confirmed to express $iPLA_2\beta$ and $_\gamma$ by RT-PCR and immunoblot analyses. Immunohistochemical analysis of $iPLA_2\beta$ and $_\gamma$ showed an intense staining of both isoforms distributing throughout the outflow pathway including TM, juxtacanalicular tissue and Schlemm's canal. Inhibition of $iPLA_{2\gamma}$ by R-BEL or silencing of its expression by siRNA induced dramatic changes in TM cell morphology, and decreased actin stress fibers, focal adhesions and myosin light chain phosphorylation (MLCp). AH outflow facility in the enucleated porcine eyes increased progressively and significantly over the sham-treated control eyes, following R-BEL perfusion. This response was associated with a significant decrease in MLCp in the drug perfused TM tissue and increased formation of giant vacuoles in the innerwall of Schlemm's canal. Contrarily, S-BEL did not influence either aqueous outflow facility or TM cell contractile properties. Moreover we confirmed that the induction of cellular relaxation induced by inhibition of $iPLA_{2\gamma}$ was associated with significant decrease in the levels of Rho-GTP, Phospho-CPI-17 and phospho-MYPT1. Inhibition of $iPLA_{2\gamma}$ also significantly decreased the levels of arachidonic acid, a major free fatty acid product of $iPLA_2$.
Conclusions: This is the first study to demonstrate a critical and isoform specific involvement of $iPLA_2$ in regulation of AH outflow through the conventional pathway. Importantly, pharmacological inhibition of $iPLA_{2\gamma}$ increases AH outflow facility through the trabecular pathway by affecting the tissue contractile characteristics and Rho GTPase activity.

Ubiquitin and Proteasome Function

628

Involvement of HslV pore motif in the control of interaction between HslV and HslU and the proteolytic activity of ATP-dependent HslVU protease.

H. Yoo[1], J. Lee[1], E. Park[1], C. Chung[1]; [1]School of Biological Sciences, Seoul National University, Seoul, Korea

HslVU is an ATP-dependent protease in bacteria consisting of hexameric HslU ATPase and dodecameric HslV protease. In the HslVU complex, the HslU and HslV central pores are aligned, so that HslU transfers peptides and protein substrates through the pores into the inner proteolytic chamber of HslV. Here we show that the Leu88 residue in RMLR pore motif of HslV is critically involved in the control of HslVU complex formation and thereby its proteolytic activity. Replacement of Leu88 by Ala or Gly led to a marked increase in the binding affinity of HslV to HslU and the proteolytic activity of HslVU, whereas that by Ser or deletion of the RMLR sequence abrogated them. The L88A and L88G mutants, but not the others, also dramatically activated the HslU ATPase. Surprisingly, L88A and L88G by themselves were capable of cleaving small peptides as well as by HslV in complex with HslU and ATP, and their peptidase activities could be further activated by HslU in the absence of ATP nearly as well as in its presence in a manner that requires the C-terminal tails of HslU. L88A and L88G by themselves could also hydrolyze certain unfolded proteins, such as α-casein, although they were unable to degrade native proteins, including SulA and Arc. Remarkably, under normal growth conditions overexpression of L88A in *hslVU* null *E. coli* cells inhibited cell growth whether HslU was coexpressed or not, despite the fact that HslVU is not essential for it, suggesting that the Leu-to-Aa and Leu-to-Gly mutations deregulate HslV activity by relaxing the control mechanisms that normally safeguard essential cellular proteins from random degradation by HslV. Collectively, our results suggest that Leu88 in the pore motif plays critical role as a regulatory gate in the interaction between HslV and HslU and thereby the proteolytic function of HslVU.

629

Functional isolation of a novel PAP for proteasome activation.

W-J. Lee[1], S-M. Shim[1], Y-K. Jung[1]; [1]School of biological science/Bio-MAX institute, Seoul National University, Seoul, Korea

Various neurodegenerative diseases share a common feature, accumulation of aggregation-prone proteins which include mutant Huntingtin and Tau. One of the major roles or effects of these proteins is inhibition of the proteasome activity and aggregation of these proteins is results from the inhibition of proteasomal activity. However, a signal responsible for proteasome dysfunction is not known. Thus, discovery of novel proteasome regulators is important to understand aggregation disease and further to provide effective treatment of neurodegenerative disease. To identify new modulators regulating proteasome activity, a cell-based functional screening was established using Degron-GFP. From screening thousands of cDNAs for gain-of-function assay, 5 putative positive genes were isolated. Among them, the PAP (Proteasome-Activating Protein) was investigated in detail. Over-expression of PAP enhanced GFP^{U} degradation in a dose- and time- dependent manner in HEK 293T cells and increased proteasome activity as assayed with fluorogenic substrate. On the contrary, down-regulation of PAP expression with shRNA markedly increased accumulation of degron and inhibited proteasome assembly on glycerol gradient fractionation. Ectopic expression of PAP enhanced proteasome assembly on native gel. In addition, the expression of PAP and proteasome activity was regulated by treatment with insulin/IGF-1 in SH-SY5Y and HT22 cells. Further, ectopic

expression of PAP reduced the occurrence of mutant Huntingtin protein aggregation by approximately 50% in SH-SY5Y cells. Taken together, these results indicate that PAP acts as a potential proteasome activator and may serve as a therapeutic activator for aggregation disease, such as Huntington disease.

630

Examining the structural basis of ubiquitin ligase self-assembly and its implication as a molecular rheostat.

W. Errington[1], G. G. Privé[1,2]; [1]Biochemistry, University of Toronto, Toronto, ON, Canada, [2]Ontario Cancer Institute

Ubiquitylation is among the most widespread forms of cellular post-translational modification and is capable of mediating and eliciting an array of functional outcomes. Central to the mechanism of ubiquitylation is the E3 ubiquitin ligase, which serves to recognize the target protein and recruit it into complex with the E2 ubiquitin-conjugating enzyme. Recent insights into the mechanism of ubiquitylation demonstrate that E3 ubiquitin ligases can possess active regulatory properties beyond those of a simple assembly scaffold. Prominent among these properties is the ability of many E3 ligases to self-assemble into large complexes both in vitro and in vivo. Moreover, it has been well documented that disruption of these assemblies through mutagenesis significantly compromises their ubiquitylation activity. However, the structural bases for these self-assemblies and the mechanisms for activity enhancement remain poorly characterized. Here we present our biophysical, X-ray crystallographic and functional studies into the structure and activity of a multi-subunit BTB-cullin E3 ligase, SPOP-Cul3. Interestingly, we find that this E3 ligase possesses tandem oligomeric domains that function in concert to generate a dynamic, expandable complex with potent ubiquitylation activity. We propose that self-assembly serves to enhance ubiquitin transfer by enhancing avidity for the substrate and creating a critical mass of the catalytic machinery—thus allowing multiple substrates to be acted upon simultaneously by a large number of E2 conjugating enzymes. Additionally, we have gone on to characterize a SPOP-Cul3 homolog that is specifically deficient in high-order self-assembly and that, through heteromeric complex formation, is capable of restricting SPOP-Cul3 self-assembly. This two-component system indicates a powerful cellular mechanism by which self-assembly can be used to create a tunable means of regulating E3 ligase activity.

631

FAT10 binds to polyglutamine proteins and modulates their solubility.

Y. Nagashima[1], S. Tsuji[1], A. Iwata[2]; [1]Neurology, University of Tokyo, Bunkyo-ku, Japan, [2]Molecular Neuroscience on Neurodegeneration, University of Tokyo

Expansion of polyglutamine (pQ) chain by expanded CAG repeat causes dominantly inherited neurodegeneration such as Huntington's disease (HD), dentatorubral-pallidoluysian atrophy (DRPLA) and numbers of other spinocerebellar ataxias. Expanded pQ disrupts stability of the pQ harboring protein and increases its susceptibility to aggregation. Aggregated pQ protein is recognized by ubiquitin proteasome system and the enzyme ubiquitin ligase covalently attach ubiquitin, which serves as a degradation signal by the proteasome. However, accumulation of the aggregated proteins in the diseased brain suggests insufficient degradation machinery. Ubiquitin has several functionally related proteins that are similarly attached to target proteins through its carboxy (C) terminus glycine residue. They are called ubiquitin like molecules and some of them are similarly related to protein degradation pathway. One of the ubiquitin like molecule FAT10 is known to accelerate protein degradation through ubiquitin independent manner but its role in pQ aggregate degradation was completely unknown. Thus we investigated its role in HD cellular model and found that FAT10 were covalently attached to

huntingtin through its C terminus glycine. FAT10 binds preferably to huntingtin with short pQ chain and completely aggregated huntingtin was FAT10 negative. Knock down of FAT10 enhanced cellular toxicity of huntingtins. In addition, ataxin-1,3 and DRPLA protein were all positive for FAT10 and aggregation enhancement were observed upon FAT10 knockdown, which was similar to the findings with huntingtin. Our new finding will provide a new role of FAT10 in the pathogenesis of polyglutamine diseases.

632

The Ubiquitin Ligase Wwp1 Mediates Lysosomal Degradation of Connexin 43 through the Formation of K29-linked Polyubiquitin Chains.

M. H. Abreha[1], W. A. Basheer[1], L. E. Matesic[1]; [1]Univ South Carolina, Columbia, SC

Connexin 43 (Cx43) is a component of gap junctions (GJ). GJ are channels which facilitate intercellular communication between adjacent cells by allowing the passage of small molecules such as ions and metabolites. *In vivo*, Cx43 is rapidly turned over with a half-life that ranges between 1 and 5 hours. However, the precise molecular mechanisms regulating Cx43 turnover are not well understood. Previous studies have shown that phosphorylation and ubiquitylation of Cx43 play a role in its internalization and degradation. Although Nedd4 (a member of the HECT family of E3 ubiquitin ligases) has been shown to bind and ubiquitylate Cx43, the overexpression of this ligase in cells does not result in Cx43 degradation. Therefore, the objective of this study was to identify the molecular signaling events that mediate the degradation of Cx43. We hypothesized that Wwp1, a Nedd4-like family member known to localize to the endosome, could bind and ubiquitylate internalized Cx43 in the early endosome, resulting in the sorting of Cx43 to and degradation in the lysosome. We found that Wwp1 co-immunoprecipitated with and ubiquitylated Cx43 in HEK293T cells and that these processes were enhanced upon pretreatment of cells with phorbol 12-myristate 13-acetate. Interestingly, the utilization of a series of ubiquitin mutants that were either incapable of making a polyubiquitin chain or only capable of extending a polyubiquitin chain from one of the seven lysine residues of the ubiquitin molecule revealed that Wwp1 mediated K29-linked polyubiquitylation of Cx43. Laser scanning confocal microscopy analysis of immunofluorescently labeled HeLa cells stably transfected with Cx43 demonstrated that the ubiquitin ligase activity of Wwp1 was required to traffic Cx43 from early endosomes to CD63-positive late endosomes. In addition, lysosomal inhibition prevented the degradation of Cx43 in 293T cells over-expressing Cx43 and Wwp1. Taken together, these data support the assertion that Wwp1 polyubiquitylates Cx43 via a K29 linkage and this post-translational modification is an important signal which routes the Cx43 substrate from the early endosome to the late endosome and subsequently to the lysosome for degradation. Our findings offer insights on the mechanisms of Cx43 turnover and the regulation of GJ intercellular communication.

633

CAND1 Governs SCF Complex Assembly.

N. Pierce[1], S-O. Shan[1], R. Deshaies[1]; [1]Caltech, Pasadena, CA

Attachment of a polyubiquitin chain with at least four ubiquitins linked together through their lysine 48 residue targets proteins to the proteasome for degradation. A cascade of three enzymes carries out the synthesis of polyubiquitin chains: a ubiquitin activating enzyme (E1), a ubiquitin conjugating enzyme (E2), and a ubiquitin ligase (E3). Cullin-RING ubiquitin ligases (CRLs) are the largest family of E3s and are typified by the SCF complexes, which in humans are composed of four proteins: the scaffold Cul1, the RING containing Rbx1, the adaptor Skp1, and a substrate binding protein that contains the Fbox motif. 69 proteins in the human genome have Fbox motifs, and 42 have been shown to form SCF complexes. Although this modular

design of SCF complexes allows for recognition of a diverse set of target proteins, how SCF complex formation is regulated remains unclear.

Cullin-associated and neddylation-dissociated protein 1 (CAND1) was originally isolated as a Cul1 associated protein whose binding was mutually exclusive with the Fbox/Skp1 sub-complex. CAND1 appeared to inhibit SCF mediated ubiquitylation through the dissociation of Fbox/Skp1. Furthermore, CAND1's dissociation from Cul1/Rbx1 was coupled to the attachment of the ubiquitin like protein Nedd8, an activator of CRLs, to Cul1. For these reasons, CAND1 was recognized as a negative regulator of SCF complex assembly.

To characterize the assembly properties of SCF complexes, we developed a real time assay based on FRET that monitors the binding dynamics between the subcomplexes of Fbox/Skp1 and Cul1/Rbx1. Surprisingly, we found that CAND1 is able to actively remove Fbxw7/Skp1 from Cul1/Rbx1 by changing the dissociation rate of the complex 10 million fold. Our kinetic assays reveal the existence of a transient complex of all four SCF components with CAND1 before dissociation into sub-complexes. Amazingly, CAND1 does not affect the assembly rate of SCF Fbxw7. Nedd8ylation of Cul1 abolishes the affect of CAND1 on SCF assembly.

We establish the first kinetic framework for the dynamic assembly of SCF complexes using direct real time biophysical assays. We conclude that CAND1 is directly involved in the assembly of SCF complexes and serves as an Fbox/Skp1 exchange factor. Our kinetic framework serves as a starting point to re-evaluate the function of CAND1 in vivo.

Mechanistic basis of host-cell remodeling by the HIV-1 protein Vpu.

Z-R. Zhang[1], R. S. Hegde[1,2]; [1]National Institutes of Health, Bethesda, MD, [2]MRC Laboratory of Molecular Biology, United Kingdom

Many viral genomes encode proteins that selectively and potently target certain host cell proteins for degradation. HIV-1 also uses this general strategy to selectively downregulate CD4, an essential receptor for HIV-1 entry into cells. This downregulation is important for preventing superinfection, maximizing virion production, and achieving full infectivity of the released virons. Previous studies have established that Vpu interacts with newly synthesized CD4 at the endoplasmic reticulum and recruits an E3 ligase, which is supposed to be SCF-βTrCP complex, to mediate CD4 ubiquitination. The ubiquitinated CD4 then is extracted from ER and degraded by the proteasome in cytosol.

While this basic pathway has been defined on the basis of cell culture studies, the molecular mechanisms that mediate this ubiquitination or the downstream degradation are not well understood. Here we found that in vitro translated CD4 on the microsome from Vpu stable cell line can be ubiquitinated probably by the SCF-βTrCP complex pre-associated with the microsome membrane. The ubiquitinated CD4 can be dislocated from microsome in a cytosol dependent manner.

In order to dissect the mechanism, we recapitulated this process using minimum system containing recombinant Vpu and SCF-βTrCP complex, radiolabeled CD4 and the synthetic liposome. With both in vitro assays, future studies are expected to provide mechanistic insight into how Vpu escapes from direct ubiquitination by SCF-βTrCP complex and which factor channels the extraction of CD4 from ER membrane to cytosol.

635

Fluorescence polarization (FP) and chemiluminescent based substrate alternatives for analyzing DUB activity.

N. Russell[1], J. Brazell[1], C. Schwerdtfeger[1], F. El Oualid[2], H. Ovaa[4], F. Melandri[1]; [1]Boston Biochem, Cambridge, MA, [2]UbiQ Bio BV, Amsterdam, Netherlands

Deubiquitinating enzymes (DUBs) play an important role in a multitude of cellular processes as well as being implicated in a number of human diseases. Despite this important role, the substrate specificity and kinetic parameters of many DUBs are poorly defined. This is due to the lack of appropriate reagents where DUB activity can be monitored in real time while utilizing small amounts of the DUBs themselves which are often challenging to purify. Ub-AMC has been a workhorse substrate, but the linkage between fluorophore and Ub doesn't mimic the isopeptide bond between Ub and conjugate and many DUBs do not process Ub-AMC rapidly enough to get even useful qualitative data.
Here we describe the development of two new substrates for analyzing DUB activity that separately address these issues. First, Ub modified by a 5-TAMRA-Lys-Gly (Ub-KTG) contains an isopeptide bond between ubiquitin and the flurophore, mimicking Ub-conjugation to *in vivo* substrates. This makes the Ub-KTG substrate more relevant to understanding how DUBs act during physiological processes. The extremely photostable fluorophore provides a strong FP signal over extended time periods. Release of the fluorophore by DUB activity provides a change in FP signal that can be utilized to determine kinetic parameters. As the FP signal is concentration independent, low amounts of substrate (100 nM) can be used to obtain kinetic parameters. Ub-KTG substrate provides similar results to Ub-AMC when tested against a panel of DUBs. The second substrate developed, Ub-aminoluciferin (Ub-AML), addresses the issue of sensitivity. Rather than fluorescence as the indicator of DUB activity, DUB liberated luciferin is processed by luciferase to give a luminescence signal. Ub-AML not only produces a stronger signal, but also has an excellent signal to noise ratio over traditional fluorophores. The Ub-AML substrate was used for reliable detection of DUB activity using an order of magnitude less enzyme than needed for equivalent results when using Ub-AMC. This makes it possible to rapidly assess the activity of DUBs that poorly utilize Ub-AMC while using much lower levels of the DUBs themselves. Nedd8-AML and SUMO-AML have also been synthesized via the same method and behave very similarly in terms of DUB amount used and having a very high signal to noise ratio.

636

Parkin functions as a surveillance E3 ligase in cytoprotection against misfolded protein-induced toxicity.

C. Ho[1], L-S. Chin[1], L. Li[1]; [1]Pharmacology, Emory University, Atlanta, GA

Protein misfolding and aggregation underlie the pathogenesis of many neurodegenerative disorders, including Parkinson disease (PD) and Alzheimer disease. Recent evidence indicates that, under the conditions of proteotoxic stress, misfolded proteins are actively sequestered in a pericentriolar structure called an aggresome and subsequently degraded via macroautophagy (hereafter referred to as autophagy). The aggresome-autophagy pathway has emerged as a crucial cellular defense system against toxic buildup of misfolded proteins, but the molecular machinery and regulatory mechanisms that control this pathway remain mostly unknown. We have recently shown that parkin, an E3 ubiquitin-protein ligase which is mutated in early-onset PD, selectively binds and K63-polyubiquitinates misfolded DJ-1 and this ubiquitination serves as a targeting signal for degradation by the aggresome-autophagy pathway. We have identified another misfolded protein (MFP) that is specifically recognized by parkin. We found that parkin selectively polyubiquitinates MFP but not its wild-type counterpart. Moreover, parkin

overexpression protects cells against MFP-induced toxicity. Our results support a function of parkin as a surveillance E3 ligase for regulating misfolded protein processing by the aggresome-autophagy pathway and have important implications for understanding and treating PD and other neurodegenerative diseases.

637

The competition roles of proteasomes and autophagy in the degradation of ubiquitylated soluble cytosolic proteins.

A-Y. Liu[1], W-P. Huang[1]; [1]Department of Life Science, Natl Taiwan Univ, Taipei, Taiwan

The ubiquitin-proteasome (UPS) system is a highly conserved protein degradation pathway in eukaryotes that relies on ubiquitylation, the modification of proteins with ubiquitin moieties, to mediate proteasomal degradation of target proteins. Autophagy, which is another protein turnover process in eukaryotes, is processed by the sequestration of cytoplasm or organelles into double membrane vesicles termed autophagosomes that eventually fuse with the vacuole/lysosome for massive breakdown of proteins or organelles. In mammalian cells, ubiquitylated proteins are not only substrates for proteasomal degradation but also form aggregates in cytosol that were recently shown to be specific substrates for autophagic degradation. However, in this study, we showed that ubiquitylated EGFP did not form protein aggregates in *Saccharomyces cerevisiae*. Moreover, we found that ubiquitylation, which mediates protein degradation in proteasomes, interferes with autophagic degradation of cytosolic soluble proteins. We propose that the interactions between ubiquitin moieties and unknown ubiquitin-interacting factors restrict ubiquitylated EGFP from autophagic degradation. In addition, lack of homologues to the metazoan adaptor proteins, such as p62 and NBR1, responsible for autophagic degradation of ubiquitylated cytosolic substrates in yeast maybe partially responsible to our observation.

638

Regulation of endoplasmic reticulum-mitochondria interaction, mitochondrial fission and mitophagy by the gp78 ubiquitin ligase.

M. Fu[1], P. St-Pierre[1], I. R. Nabi[1]; [1]Univ British Columbia, Vancouver, BC, Canada

Gp78 is a critical E3 ubiquitin ligase in endoplasmic reticulum-associated degradation (READ). Gp78 is localized to mitochondria-associated smooth endoplasmic reticulum (ER) and increased ER-mitochondria association upon gp78 overexpression significantly reduces mitochondrial mobility and induces mitochondrial fragmentation. Mitochondrial depolarization with CCCP induces mitophagy in gp78 overexpressing cells independently of Parkin expression. CCCP treatment of gp78 overexpressing cells recruits the autophagic marker LC3-GFP to the gp78 and calnexin labeled ER closely associated to mitochondria defining a role for the ER in gp78-induced mitophagy. Gp78 regulation of mitochondrial mobility, fission and mitophagy is dependent on gp78 ubiquitin ligase activity and mitofusin2 (Mfn2), the mitochondrial fusion factor, was identified as a gp78 substrate. However, gp78 appears to also function independently of Mfn2 as it still stabilizes ER-mitochondria association and enhances mitochondrial fission and mitophagy in Mfn2 knockdown cells. Furthermore, in HT-1080 fibrosarcoma cells, gp78 knockdown disrupts ER-mitochondria contacts and prevents mitophagy in Mfn2 knockdown cells. This study therefore describes a novel mechanism linking gp78 ubiquitin ligase activity and polyubiquitylation to the regulation of ER-mitochondria contacts, mitochondrial dynamics and mitophagy.

Apical Polarization of Na+,K+-ATPase in Retina Pigment Epithelium (RPE); role of β2-isoform.

L. Shoshani[1], J. A. Lobato-Alvarez[1], M. L. Roldan[1], J. Bonilla-Delgado[2], N. F. Hernández-Llanez[1], A. A. Rodrigez-Reyes[3]; [1]Physiology, CINVESTAV-IPN, Mexico City, Mexico, [2]Genetics and Molecular Biology, CINVESTAV-IPN, Mexico City, Mexico, [3]Pathology, APAC Hospital Dr. Luis Sánchez Bulnes, Mexico City, Mexico

Na+,K+-ATPase also known as the sodium pump is an ion transporter that plays a central role in maintaining the sodium gradient responsible for transport of virtually all nutrients and metabolites. In epithelial monolayers Na+,K+-ATPase is enriched to a cell membrane-specific domain. Pump polarity is achieved by a complex sequence of events involving both targeting to and selective retention at the lateral cell membrane. In contrast to the majority of epithelial cell models, the sodium pump is enriched in the apical membrane domain of retina pigment epithelium RPE cells. This 'reverse polarity' of the RPE was brought to our attention given that the polarization mechanism of the sodium pump is still not clear. Our working hypothesis is that the pump polarity in RPE cells is regulated by its β−subunit and more precisely by the type of isoform that is expressed. Although it is well documented that both in situ and in vitro the sodium pump is localized to the apical membrane there is no clear information about the β - subunit isoform/s that accompany the α-subunit in the apical domain. In this study we have examined and compared the expression patterns of the three known isoforms of Na+,K+-ATPase β-subunits (β1, β2 and β3) in the human cell line ARPE-19 and in thin sections of pig and human eyes. Western blot (WB) and immunofluorescence (IF) studies were carried using ARPE-19 cells that have been cultured for 8 weeks (re-morphogenesis) on laminin covered clear inserts. The expression of the different isoforms was time and domain dependent. All three isoforms (β1, β2 and β3) were detected. Nevertheless, while β1 subunit is detected during all 8 weeks the expression of β2 and β3 subunits is up-regulated during re-morphogenesis; both are absent during the first three weeks and appear around the 4th week and thereafter as detected by WB and IF. While β1 and β3 are expressed mainly on basolateral membrane β2 is observed on apical membrane. Moreover, in thin sections obtained from RPE of pig and human eyes, IF staining of α1, β1- and β2-subunits show that the β isoform expressed on the apical domain is β2. RT-qPCR analysis shows a similar kinetics for β1 and β2 mRNAs during re-morphogenesis. This is the first expression study of all three β subunit isoforms in ARPE-19 cells. Our results indicate that the apical localization of the sodium pump in RPE is related to the expression of β2 subunit which carries an apical sorting information.

Polarized expression of human riboflavin transporters -1, -2, and -3 in human intestinal epithelial cells.

V. Subramanian[1], S. Subramanya[1], L. Rapp[2], J. Marchant[2], T. Ma[3], H. Said[1]; [1]UCI/VA Medical Centers, Long Beach, CA, [2]University of Minnesota Medical School, [3]University of New Mexico

Riboflavin (RF) is essential for normal cellular function. Humans obtain RF from exogenous sources via intestinal absorption, a process that involves transport of RF across the brush border membrane (BBM) and basolateral membrane (BLM) of polarized enterocytes. Both these transport events are carrier-mediated. All human riboflavin transporters (hRFT-1, hRFT-2 and hRFT-3) are expressed in the intestine but little is known about the membrane domain(s) at which they are expressed. Here, we used live cell confocal imaging of intestinal epithelial Caco-

2 (and renal MDCK) cells to show that hRFT-1 is expressed at the BLM; hRFT-2 is exclusively expressed at the apical membrane, while hRFT-3 is mostly localized inside intracellular vesicular structures with some expression at the BLM. We also found that the level of hRFT-2 expression in Caco-2 cells and in native human small intestine is significantly higher than that of hRFT-1 and -3; also hRFT-2 was more efficient in transporting 3H-RF than hRFT-1 and -3. These findings suggest an important role for hRFT-2 in normal intestinal RF uptake, a conclusion that was further supported by hRFT-2 gene-specific siRNA silencing approach. (DVA, DK 56061).

Tyrosine 156 regulates basolateral trafficking of epiregulin and mutation to alanine induces transformation.

B. Singh[1], G. Bogatcheva[1], R. Coffey[1]; [1]Medicine, Vanderbilt University, Nashville, TN

Objective: The EGF receptor ligand epiregulin (EREG) is overexpressed in a number of cancers where its levels directly correlate with metastasis and responsiveness to cetuximab. However, it is unknown whether EREG contributes to tumor initiation.

Methods: MDCK cells stably expressing various EREG constructs were allowed to polarize on Transwell™ filters forming distinct apical and basolateral surfaces. Localization and trafficking of EREG constructs were analyzed by confocal immunofluorescence microscopy, domain-selective cell surface biotinylation and metabolic labeling pulse-chase experiments. MDCK cells stably expressing wild-type EREG and various cytoplasmic tail mutants were observed for their ability to form cysts when grown in Matrigel™ and to form tumors in nude mice upon subcutaneous injection.

Results: Wild-type EREG localizes exclusively to the basolateral surface in polarized MDCK cells. Using sequential truncations and single amino acid substitutions in the cytoplasmic tail of EREG, we identified that a single tyrosine controls its basolateral trafficking. Mutation of this tyrosine to alanine (Y156A) completely relocalizes EREG to the apical surface. Of interest, phosphorylation of this tyrosine is required for basolateral localization of EREG. When grown in Matrigel™, MDCK cells expressing wild-type EREG constructs formed cysts with cleared lumens, like parental MDCK cells. However, MDCK cells expressing apically misdirected (Y156A)EREG formed cysts with uncleared lumens, a phenotype that correlates with transformation. In addition, (Y156A)EREG-expressing cells formed much larger and highly invasive tumors in nude mice compared to their wild-type counterparts.

Conclusion: Redirecting EREG from the basolateral to apical surface in polarized MDCK cells results in a transformed phenotype.

Palmitoylation of Ankyrin-G Promotes Its Polarized Membrane Targeting in Epithelial Cells.

M. He[1], V. Bennett[2]; [1]Molecular Cancer Biology, Duke University Medical Center, DURHAM, NC, [2]Cell Biology, HHMI/Duke University Medical Center

Ankyrins (ankyrin-R, -B, -G) are a family of membrane associated adaptor proteins, which coordinate the localizations of proteins to diverse membrane domains including axon initial segment of neurons and lateral membrane of epithelial cells. However, the mechanism for targeting ankyrin-G to membrane domains remains unclear. Using a calcium switch assay, we found that in non-polarized MDCK cells, ankyrin-G persists on the plasma membrane even though its known partners including β2-spectrin and E-cadherin redistribute to intracellular sites. Previous research revealed that ankyrin purified from erythrocytes preserve hydrophobicity and is potentially lipid-modified. Here we demonstrate that ankyrin-G is S-acylated at cysteine 70

using biotin-switch assays and mass spectrometry. Protein S-acylation is a common lipid modification on cysteines via thioester bonds, and plays significant roles in protein targeting, transportation and cell signaling. Our further radiolabeling experiment showed that ankyrin-G cysteine 70 can be S-acylated by palmitic acid. In order to characterize the biological functions of ankyrin-G palmitoylation, we generated stable MDCK cell lines based on wild type and C70A ankyrin-G. A calcium switch assay was used to measure the membrane association capacity of wild type and C70A ankyrin-G. Our results demonstrated that palmitoylation of ankyrin-G contributes to its membrane association, and restricts its lateral motility in plasma membrane.

Polarizing yeast cells with electric fields.

A. Campetelli[1], M. Piel[1], F. Chang[2], N. Minc[1]; [1]UMR-144, Institut Curie, Paris, France, [2]Department of Microbiology, Columbia Medical Center, New York

Endogenous electrical signals surround tissues and cells and are thought to participate in the regulation of many polarization events such as wound healing, metastasis and development. Application of exogenous electric fields (EFs) can orient polarity in many cell types ranging from bacteria, to neutrophils and neurons. Different cell types polarize to different directions, some orienting to the anode and other to the cathode or even perpendicular to the EF. EFs are thought to signal through the membrane by locally altering membrane potential or ion fluxes distribution around the cell; however the mechanisms for how cells sense and orient to EFs remain poorly characterized. Here, we introduce the Budding yeast Saccharomyces cerevisiae as a rigorous model for cell polarity to dissect mechanisms underlying these effects. These cells polarize by locally selecting sites of bud emergence or by growing shmoo projection for mating. We apply EFs by immobilizing yeast cells in microfluidic chambers, which allow for heat control, straight EF lines and parallelization of the assay. While, the budding pattern was generally resistant to the EF in haploid WT cells, mutants in the bud site selection pathway that normally bud in random direction, such as rsr1 (Bud1), a Ras-like GTPase, were polarized by the EF towards the cathode. In the presence of pheromones (a-factor), the EF directed polarized growth of the shmoo, but interestingly in the opposite direction, towards the anode. This shmoo orientation in the EFs depended on the formin Bni1. To understand the effect of EFs at the cell surface, we screened a set of characterized mutants in ion transporters and drugs that perturb ion transport. These experiments suggested that proper membrane potential regulation was key to mediate these effects. For instance, mutants lacking the Na+ releasing systems that display depolarized membrane potential or hyperpolarized mutants lacking K+ import directed shmoo polarization to the cathode in the EF, reverting the WT phenotype. This work begins to identify conserved factors and a process involved in EF response and brings novel insight into general mechanisms of cell polarity.

644

Negative feedback enhances robustness in the yeast polarity establishment circuit.

A. Howell[1], M. Jin[2], C-F. Wu[3], T. Elston[2], D. Lew[3]; [1]Stanford University, [2]UNC-Chapel Hill, [3]Duke University, Durham, NC

Many cells undergo symmetry-breaking polarization towards a randomly-oriented “front” in the absence of spatial cues. In budding yeast, such polarization involves a positive feedback loop that enables amplification of stochastically-arising clusters of polarity factors. Mathematical modeling suggested that if more than one cluster were amplified, the clusters would compete for limiting resources and the largest would “win”, explaining why yeast cells always make one and only one bud. Imaging with improved spatiotemporal resolution, we now demonstrate the transient co-existence of multiple clusters during polarity establishment, as predicted by the

model. Unexpectedly, we also found that initial polarity factor clustering was oscillatory, revealing the presence of a negative feedback loop that disperses the factors. Mathematical modeling predicted that negative feedback would confer robustness to the polarity circuit, and make the kinetics of competition between polarity factor clusters relatively insensitive to polarity factor concentration. These predictions were confirmed experimentally.

645

An actin-dependent phosphoinositide-bis-phosphate gradient.

A. Vernay[1], S. Schaub[1], M. Bassilana[1], R. Arkowitz[1]; [1]Institute of Developemental Biology and Cancer, University of Nice Sophia-Antipolis, France, NICE CEDEX 02, France

Candida albicans, similar to a range of human fungal pathogens, grows in different forms in response to environmental cues. In particular, its ability to switch from yeast to a filamentous form is important for pathogenicity and requires reorganization of the actin cytoskeleton.

Membrane phospholipids, such as phosphoinositide phosphates, have been shown to play important roles in a range of signaling pathways despite being relatively minor component of membranes. For example phosphoinositide phosphates are required for cytoskeleton organization, G-protein signaling, cell polarity and morphogenesis. In *Candida albicans*, neither PI(3,4,5)P_3 nor PI-3-kinase homologs have been found, raising the possibility that the PI(4,5)P_2 fulfills some functions of PIP_3. In this organism there is a single PI(4)P-5-kinase (encoded by *MSS4*) and three PI-4-kinases (encoded by *LSB6*, *STT4* and *PIK1*). In the yeast *S. cerevisiae*, both Mss4 and Stt4 kinases are required for viability, for organization of the actin cytoskeleton and are localized to the plasma membrane.

We have examined whether PI(4,5)P_2 is required for *Candida albicans* filamentous growth. We have generated strains in which the level of the Stt4 or Mss4 phosphoinositide kinases can be manipulated using the Tetracycline repressible promoter system. In repressive conditions, the *stt4* and *mss4* mutants are viable, however they are defective in filamentous growth in both liquid and solid media. Using a fluorescent lipid associated reporter (FLARE), we have observed a striking PI(4,5)P_2 asymmetry in budding cells and a steep gradient which occurs concomitant with emergence of the hyphal filament. Both sufficient PI(4)P synthesis and an intact actin cytoskeleton are necessary for this steep PI(4,5)P_2 gradient. In contrast, neither microtubules nor asymmetrically localized mRNAs are critical for this gradient. Furthermore, the Mss4 protein is localized to the tip of the bud and hyphal filament.

Our results indicate that a gradient of PI(4,5)P_2, generated in part by the sole filament tip localized PI(4)P-5-kinase Mss4 and the slow diffusion of PI(4,5)P_2 in the plasma memberane, is crucial for the yeast to filamentous growth transition.

646

The formin FHOD1 interacts with the TAN line component, nesprin-2Giant, and is required for actin-dependent nuclear movement during centrosome orientation in migrating fibroblasts.

G. W. Luxton[1,2], S. Kutscheidt[3], O. T. Fackler[3], G. G. Gundersen[2]; [1]Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN, [2]Department of Pathology and Cell Biology, Columbia University, NYC, NY, [3]Department für Infektiologie, Virologie, Universitätsklinikum Heidelberg

In migrating fibroblasts, actin-dependent movement of the nucleus behind a stationary centrosome establishes the initial anterior orientation of the centrosome between the nucleus

and the leading edge (Gomes et al., Cell, 2005). Rearward nuclear movement is mediated by retrograde flow of dorsal actin cables that are coupled directly to the nuclear envelope through trans-membrane actin-associated nuclear (TAN) lines, a novel structure composed of the outer nuclear membrane protein, nesprin-2Giant (nesprin-2G) and the inner nuclear membrane protein, SUN2 (Luxton et al., Science, 2010). To better understand TAN line formation and function, we searched for novel nesprin-2G interacting proteins and identified the diaphanous-related formin (DRF), FH1/FH2 domain-containing protein 1 (FHOD1). GST-fusions of residues 1340-1678 of nesprin-2G pulled down over-expressed HA-tagged wild type FHOD1 (HA-FHOD1-WT) or an N-terminal fragment of FHOD1 (HA-FHOD1-1-339) from cell lysates. This interaction was also detected using a yeast-two-hybrid assay; however, no direct biochemical interaction was observed. Depletion of FHOD1 by siRNA inhibited nuclear movement and centrosome orientation in wound edge fibroblasts and these defects were rescued by expression of either wild type FHOD1 (GFP-FHOD1-WT) or constitutively active FHOD1 (GFP-FHOD1-ΔC). Rescue by either construct required the FH1, FH2, and coiled-coil domains indicating that actin nucleation and dimerization of FHOD1 were critical for this process. Surprisingly, expression of GFP-FHOD1-ΔC, but not GFP-FHOD1-WT in serum-starved fibroblasts induced rearward nuclear movement in the absence of external stimuli such as lysophosphatidic acid or serum. However, nuclear movement induced by GFP-FHOD1-ΔC did not result in centrosome orientation as the centrosome failed to remain at the cell centroid. Over-expression of HA-FHOD1-ΔC induced robust actin cables that contained FHOD1 and co-localized with GFP-mini-nesprin-2G on the nuclear envelope, while over-expression of another constitutively active DRF, mDia1, did not recruit GFP-mini-nesprin-2G to the actin cables generated by mDia1 activation. The co-localization of HA-FHOD1-ΔC with GFP-mini-nesprin-2G required the actin-binding calponin homology domains of nesprin2G. Interestingly, TAN lines still formed in FHOD1-depleted fibroblasts suggesting that FHOD1 may contribute to nuclear movement by controlling the movement and/or organization of the dorsal actin cables required for nuclear movement. Our results identify FHOD1 as a new factor involved in TAN line-dependent nuclear movement in fibroblasts polarizing for cell migration.

647

Distinctive Cell Polarization Mechanisms Depend on Cell Shape and Cell-Cell Contacts.

W-C. Chen[1,2], E. Heim[3], C. M. Hale[1,2], J. S. Lee[1,4], D. Wirtz[1,2]; [1]Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, [2]Johns Hopkins Physical Science Oncology Center, Baltimore, MD, [3]University of Florida, Gainesville, FL, [4]Center for Strategic Scientific Initiatives, National Cancer Institute, Bethesda, MD

In several migratory cells, the microtubule organizing center (MTOC) is repositioned between the leading edge and nucleus, creating a polarized morphology. While our understanding of polarization in collective cell migration has progressed with the use of the scratch-wound assay, the mechanisms governing single-cell polarization are unclear. Here, we use protein micropatterning to control the shape of single cells and compare the pathways regulating MTOC and nuclear positions to those in confluent cells. We find that MTOC and nuclear positioning are critically and independently affected by extracellular guidance cues, including cell shape and confluence; MTOC off-centering correlates with the polarization of single cells; and microtubule dynamics and acto-myosin contractility and assembly are required for single-cell polarization. Additionally, we demonstrate that Par3, LIC1, LIC2, and EB1 are essential for proper MTOC positioning in confluent cells, while only LIC1 and EB1 are required in single cells. These results suggest that polarity pathways diverge based on cellular shape and the presence of cell-cell contacts.

648

Front-Rear Polarization of the Cytoskeleton develops in Cell migration from Soft to Stiff Matrix.

M. Raab[1], J. Swift[1], D. Discher[1]; [1]University of Pennsylvania, Philadelphia, PA

It has become increasingly clear that cytoskeletal polarity is strikingly different in cells functioning in an in vivo environment compared to cells studied in vitro. Reasons for this discrepancy are unknown and whether matrix rigidity plays a role in affecting cell polarity is has yet to be studied. Tissues have been measured to have varying stiffnesses or deformabilities, and examples of matrix stiffening include scarring in the heart after a myocardial infarction or scarring of the liver in cirrhosis – which lead to rigidification of tissue through extensive collagen crosslinking, and it has been reported that adherent cells, including mesenchymal stem cells (MSCs) accumulate or 'home' to such scarred tissue. It is unknown how MSCs localize and, in particular, whether cell polarity plays a role in directing their migration from soft to stiff matrix. Our data show that the position of the microtubule organizing center (MTOC) with respect to the nucleus is influenced by matrix rigidity and thus microtubule density within the cell also depends on surface stiffness. Because myosin is responsible for cell contractility which deforms and probes matrix stiffness, we investigated the role non-muscle myosin (both MIIA and MIIB isoforms) may have in cell polarity and directed cell migration to stiff matrix. Using siRNA knockdown we determined that directed migration toward stiff matrix is more sensitive to MIIB and less so to MIIA, even though mass spectrometry determines there is ~10-fold more expressed MIIA in MSCs than MIIB on the protein level. Reports have shown that MIIB localizes to the cell rear in polarized migrating cells, but as we alter the matrix stiffness we demonstrate that this polarization diminishes when matrix stiffness becomes softer than 7 kPa. Our studies also show that the MTOC begins to polarize to the cell front at matrix stiffness above 7 kPa, suggesting a similar mechanism for stiffness induced polarization of MTOC and MIIB. Scratch wound assays induced polarization of MTOC toward the wound edge on stiff substrates but failed to do so when performed on soft matrix. Interestingly, we also found the same stiffness dependent rearward polarization in MIIB in anuclear cell fragments. We find that the polarity of the cytoskeleton is not required for cell migration but for directing cells toward stiffer matrix. Based on our data, we believe cytoskeletal polarization thus acts as an elasticity-sensitive compass in directing migration toward stiff matrix.

649

Multiple pathways function together to polarize the Drosophila oocyte.

P. Sanghavi[1], S. Lu[1], G. Gonsalvez[1]; [1]Cellular Biology and Anatomy, Georgia Health Sciences University, Augusta, GA

The establishment and maintenance of polarity is a hallmark feature of most eukaryotic cells. The Drosophila oocyte is one of the most widely used models for examining mechanisms of cell polarity establishment. Elegant experiments over the past two decades have shown that mRNA localization is key to establishing polarity in the Drosophila oocyte. These mRNAs are localized using microtubules and microtubule based motors. However, very little is known regarding the organization of the microtubules within the oocyte. We have addressed this question by examining the localization of microtubule plus end binding proteins EB1 and CLIP-190 in the Drosophila oocyte. EB1 and CLIP-190 were both enriched at the posterior of the oocyte, indicating that microtubules within the oocyte are in fact polarized, with their growing plus ends preferentially localized to the posterior pole. Surprisingly, however, this polarity was not required for mRNA localization, but rather functioned downstream of a localized mRNA called oskar. We found that proper localization of oskar mRNA and subsequent expression of Oskar protein was required for recruiting growing microtubule plus ends to the posterior of the oocyte. The

posterior region of the oocyte has been shown to be very active in endocytosis in a manner that is dependent on Oskar protein. We provide evidence that recruitment of microtubule plus ends to the oocyte posterior by Oskar protein enables efficient and high levels of endocytosis in this region of the cell. Thus, our results demonstrate a functional link between mRNA localization, microtubule plus end recruitment and endocytosis.

Control of Cell Growth and Polarity in Fission Yeast by Cytokinesis.

A. Bohnert[1], K. Gould[1]; [1]Dept. of Cell & Developmental Biology, HHMI & Vanderbilt University, Nashville, TN

For cells to function properly, they must polarize in response to external stimuli and cell cycle cues. The fission yeast, *Schizosaccharomyces pombe,* is a useful model organism for studying how cell polarity is controlled, for this organism is rod-shaped and grows from its tips in a cell cycle-dependent manner. After each cell division, *S. pombe* initially grows from one end, termed the old end because it previously served as an end for the mother cell. Following an event in G2 known as new end take-off, the new end, which is created by the preceding cell division, also undergoes extension to establish bipolarity. As this growth pattern suggests, signaling factors enriched at cell tips are thought to drive this process. However, we have uncovered evidence that the process of cytokinesis, which occurs at a medial division site, also impacts the establishment of bipolar growth in subsequent cell cycles. Notably, loss of *S. pombe* Fic1, a non-essential protein previously only implicated in cytokinesis, results in a higher than normal incidence of monopolar growth in asynchronous and G2-arrested cultures. Consistent with this defect, several polarity factors, including the Rho-GEF, Rgf1, and actin patch-associated proteins, localize mainly to one tip of *fic1Δ* cells. Mutations and truncations of Fic1 that abolish its anchoring at cell tips do not affect its polarity function. However, a truncation of Fic1 that fails to localize to the division site phenocopies the cell polarity defect of *fic1Δ* cells. This indicates that medial targeting of Fic1 likely confers its polarity function and suggests that the cytokinesis machinery of which Fic1 is a part influences ensuing cell growth. Indeed, time-lapse DIC imaging showed that tip growth of *fic1Δ* cells fails only at new ends formed by cell division, and a point mutant of Fic1 that does not bind the essential cytokinesis scaffold, Cdc15, also exhibits similar polarity defects. Although *fic1Δ* cells do not exhibit defective assembly or constriction of the cytokinetic ring, genetic analyses suggest a role for Fic1 in later stages of cytokinesis and cell separation. Intriguingly, disruption of other proteins known to mediate these terminal stages in cell division exhibit similar polarity and growth defects. Collectively, our data highlight a previously unappreciated role for the process of cytokinesis in modulating bipolar cell growth in *S. pombe*, and these findings predict a mechanism wherein the cellular division machinery delays polarization at new ends until cytokinesis is effectively completed.

How does Cdc42p polarize actin cables?

H. Chen[1], A. S. Howell[1], H. Kang[1], D. J. Lew[1]; [1]Department of Pharmacology and Cancer Biology, Duke University, Durham, NC

The prevailing model for how yeast cells generate polarized actin cables pointing towards the bud is that GTP-Cdc42p directly recruits and activates the formin Bni1p to the incipient bud site, promoting local nucleation of actin cables. This model is based on the presence of a GTPase-binding domain (GBD) in Bni1p. However, the GBD can interact with several Rho proteins, and redundant cable-orientation pathways exist that render Bni1p itself dispensable. Thus, the direct Cdc42p-Bni1p link remains speculative and its importance remains untested. We recently engineered a strain in which polarity establishment was synthetically rewired to be an actin-

dependent process. Unlike in wild-type cells where polarity establishment precedes actin polarization, actin cables and Bni1p become polarized coincident with polarity regulators in the rewired cells. However, the other formin, Bnr1p, is not recruited to the polarization site until several minutes later. This time interval between Bni1p and Bnr1p recruitment suggests a unique role for Bni1p to initiate actin cable polarization in the rewired cells. Indeed, *BNI1* is absolutely essential for viability of the rewired cells, and the unregulated Bni1p catalytic domain cannot support polarization. Fusing a heterologous Cdc42p-binding domain to the formin catalytic domain restores growth to the rewired cells, indicating that directly linking formin activity to Cdc42p bypasses the otherwise necessary regulations. Contrary to the prevailing view, deleting the endogenous GBD neither abolishes Bni1p function nor prevents it from localizing to the incipient bud site. Additional truncations showed that formin interactions with the “polarisome” components Spa2p and Bud6p are also dispensable, and that uncharacterized N-terminal domains can mediate an essential crosstalk between Cdc42p and Bni1p.

The yeast cell polarity protein Bem3 requires and affects vesicle trafficking.

D. Mukherjee[1], A. Sen[1], D. Boettner[2], J. McCaffery[3], S. Lemmon[2], C. Staiger[1], R. C. Aguilar[1];
[1]Purdue University, West Lafayette, IN, [2]University of Miami, [3]The Johns Hopkins University

Cell polarity is essential for a wide array of cellular functions including cell migration and cell fate determination. Although both RhoGTPase signaling and vesicle trafficking pathways play central roles in cell polarity establishment, the mechanisms by which they are coordinated are still unclear. In order to address this topic, we used S. cerevisiae as a model organism for studying the interplay between the cell polarity protein Bem3 (Bud Emergence protein 3) and vesicle trafficking.

Bem3 is a peripherally-associated membrane protein that functions as a Cdc42 RhoGAP (RhoGTPase Activating Protein). Here, we demonstrate that its targeting to sites of polarized growth depends on the integrity of the endocytic and recycling/secretory pathways. Specifically, knock-out of SLA2 and RCY1 led to Bem3 accumulation in depolarized puncta and in intracellular compartments, respectively. Indeed, we observed that the membrane fraction of Bem3 was partitioned between the plasma membrane and intracellular membrane-bound compartments. These Bem3-positive compartments were polarized towards the site of bud emergence and appeared to be present only during the pre-mitotic phase of apical growth. In addition, electron micrographs clearly showed accumulation of Bem3-positive vesicles at sites of polarized growth. Cell biological and biochemical approaches identified these intracellular Bem3 structures as belonging to the endosomal and secretory systems.

Strikingly, we found that Bem3 is not just a passive cargo of vesicle trafficking pathways. Specifically, expression of this protein from a GAL1 inducible promoter led to an increase in size of the Bem3-positive compartments, and this was proportional to the intracellular concentration of Bem3. Importantly, the secretory pathway marker, Sec4, was recruited to these compartments and in the absence of Bem3, was unable to efficiently reach sites of polarized growth. Additionally, we demonstrated that these Bem3 effects on the secretory pathway were independent of its GAP activity.

This work unveils unsuspected and important details of the relationship between vesicle trafficking and elements of the cell polarity machinery: 1. A peripherally associated protein relies on vesicle trafficking for maintaining its proper localization. 2. Bem3 requires and in turn, controls vesicle trafficking. 3. It establishes the first GAP-independent function of the Cdc42 regulator Bem3.

Spatial control of Cdc42 GEF Gef1, a TUBA/DNMBP homolog by conserved NDR kinase Orb6.

M. Das[1], D. Wiley[2], A. Sarkeshik[3], J. R. Yates III[3], F. Verde[1]; [1]Mol. Cell. Pharmacology, University of Miami, Miami, FL, [2]Mol. Cell. Pharmacology, University of Miami, [3]Dept of Chemical Physiology, The Scripps Research Institute

Conserved NDR kinases regulate cell morphology in eukaryotes. We have previously reported that fission yeast NDR kinase Orb6 maintains cell polarity by spatially regulating Cdc42 GTPase, a key morphology control factor. Loss of Orb6 kinase activity leads to ectopic localization of the Cdc42 GEF Gef1, normally found at the cell tips, to the cell sides. Gef1 is an ortholog of the mammalian Cdc42 GEF DNMBP/TUBA, which is implicated in the control of kidney cell polarization. Like TUBA, Gef1 contains a Dbl homology domain followed by a Bin/Amphiphysin/Rvs (BAR) domain instead of a PH domain.

By mass spectrometry analysis, we determined that Orb6 kinase phosphorylates a single site in the Gef1 N-terminus, serine S112. The N-terminus is necessary and sufficient for Gef1 localization to the cell cortex. Since S112 is part of a RXXS amino acid sequence, we speculated that it mediates the interaction of Gef1 with a 14-3-3 protein. Consistent with this idea, we found that Gef1 co-purifies with 14-3-3 protein Rad24 and that rad24Δ; mutant cells display ectopic localization of Gef1, similarly to orb6 mutants. Finally, we found that the rounded phenotype of rad24Δ; cells is suppressed by deletion of gef1, indicating that Gef1 mediates the morphology control function of Rad24.

To address the effect of blocking Gef1 phosphorylation by Orb6 kinase, we engineered a non-phosphorylatable gef1S112A mutant. We found that this mutation leads to increased cortical localization of Gef1, similar to orb6 and rad24 mutants. Thus these results suggest that Orb6 kinase maintains cell polarity by restricting the amount of Gef1 that can localize to the cell tips. This function is mediated by the interaction of Gef1 with 14-3-3 protein Rad24, that sequesters it in the cytoplasm. Our findings provide a molecular mechanism for the morphology control function of Orb6 kinase. Further, they indicate that NDR kinases can also utilize 14-3-3 proteins as mediators of their functions, as previously shown for the related conserved LATS kinase family.

Tea5p, a Pseudokinase that Functions in Cell Polarization.

R. A. Lutz[1], M. A. Ellis[1], F. Chang[1]; [1]Microbiology and Immunology, Columbia University, New York, NY

Cell polarization introduces asymmetry. This enables cells to acquire and maintain a given shape and localize proteins and cellular processes to specific sites. The fission yeast *Schizosaccharomyces pombe* shows a highly regulated pattern of polarized growth. After division, the rod-shaped cells initiate growth at only one cell end. Later the second cell end starts to grow during new end take off (NETO). A pathway defined by microtubule +TIP proteins tea1p and tea4p has been shown to regulate NETO and cell morphogenesis. Here in a genetic screen for new NETO mutants, we identify a new factor tea5p. Tea5p is likely a pseudokinase as it lacks key residues required for kinase activity. Tea5p functions downstream of tea1p in localizing active cdc42p GTPase and the formin for3p to the second cell tip, but significantly, is only required for a subset of tea1p functions. Genetic studies suggest that tea5p functions in cdc42p activation via a signaling pathway consisting of the NDR kinase orb6p and the cdc42p activator gef1p. Thus, tea5p constitutes a novel connection between microtubule +TIP proteins and activation of cdc42p at cell ends. These studies begin to define distinct pathways in the establishment of cell polarization by microtubules.

655

Optical control of MAPK signaling and polarized growth in budding yeast.

D. Strickland[1], Y. Lin[2], C. M. Hope[1], J. Zayner[3], C. Antoniou[3], T. R. Sosnick[3], E. L. Weiss[2], M. Glotzer[1]; [1]Mol Gen & Cell Biol, Univ Chicago, Chicago, IL, [2]Molecular Biosciences, Northwestern Univ, Evanston, IL, [3]Biochem & Mol Biol, Univ Chicago, Chicago, IL

The polarized assembly of protein complexes is fundamental to the establishment of cellular morphology. During mating, yeast orient polarized growth along a gradient of peptide pheromone secreted by a potential mate. Detection of the pheromone activates a mitogen-activated protein kinase (MAPK) cascade and the small GTPase Cdc42 by triggering the assembly of multi-protein complexes at the plasma membrane. In order to experimentally manipulate the assembly of cellular signaling complexes, we have created tunable, light-controlled interacting protein tags (TULIPs) based on dual genetic fusion with an engineered LOV2 domain from *A. sativa* phototropin 1 and a non-native binding partner. The affinity profile and dissociation kinetics of TULIPs are highly tunable, facilitating use in signaling pathways with varying sensitivities and response times. We used TULIPs to confer novel light sensitivity to several functionally distinct components of the yeast mating MAPK and Cdc42 pathways, thereby eliciting light-triggered cell cycle arrest and light-directed polarized growth. Current efforts are aimed at identifying factors that are sufficient to drive polarization, along with temporal requirements for their activity.

A Model of Fission-Yeast Cell Shape Driven by Membrane-Bound Growth Factors.

T. Drake[1], D. Vavylonis[1]; [1]Lehigh Univ, Bethlehem, PA

Fission yeast serves as a model for how cellular polarization machinery is used to regulate cell growth. Recent studies identify active Cdc42, found in a cap at the inner membrane of growing tips, as a master growth regulator, likely through control of exocyst tethering and formin-based nucleation of actin cables. To investigate how biochemistry might control shape, we propose a simple model based on the hypotheses that (i) the delivery and internalization rate of wall or membrane components limits cell expansion and (ii) a growth factor, such as Cdc42, signals for delivery of these components. We numerically simulate cell growth according to an axisymmetric, finite-element computational model that couples growth-factor-directed orthogonal expansion of the cell membrane and cell-wall remodeling to reaction and diffusion of the growth factor on that membrane. We explore limiting conditions for polarized growth and consider the additional effects of membrane elasticity and flow. We find a relationship between cap size and diameter, and motivate future experiments on the link between cell signaling and shape. Fission-yeast Cdc42 is regulated by a number of proteins whose absence lead to defects in shape or polarized growth, such as cells of varying diameter, round cells, and branched cells. Among these proteins, Gef1 and Scd1 assist the activation of Cdc42 at the tips and Rga4 restricts the location of its activation. We compare model results to cell morphologies of mutants of Cdc42 regulators and suggest possible mechanistic roles for these regulators. An extension to three dimensions adds the capacity to reproduce bent-cell morphology and to investigate the stability of axisymmetric solutions.

Obesity Impairs Leydig Cells Function in Adults Rats Due to Down Regulation of Androgen Receptor and 17β-HSD.

M. E. Pinto[1], D. L. Ribeiro[2], S. R. Taboga[1], R. M. Góes[1]; [1]Department of Biology, São Paulo State University, São José do Rio Preto, SP, Brazil, São José do Rio Preto, Brazil, [2]ICBIM-Histology, Federal University of Uberlândia, Uberlândia, MG, Brazil, Uberlândia, Brazil

Obesity changes the hypothalamic-pituitary-gonad axis and affects negatively different aspects of reproductive function. However, little is known about the response of Leydig cells to the obesogenic condition. Therefore, this investigation aimed to evaluate the effects of high-fat diet-induced obesity on Leydig cell steroidogenic capacity. Adult male Wistar rats were fed for 15 weeks with balanced (Control, 4% fat) or high-fat (Obese, 20% fat) diet. Various biometric and metabolic parameters were monitored, such as body weight, adiposity index, determination of testosterone and insulin plasma levels and insulin tolerance test (ipITT). Testis were processed for histological and morphometric analysis, immunohistochemistry for androgen receptor (AR), 3β-hydroxysteroid dehydrogenase (3β-HSD) and 17β-hydroxysteroid dehydrogenase (17β-HSD), and western blotting for AR and 17β-HSD. The daily sperm production (DSP) was also determined. Obese rats presented an increase of 16 % in body weight, 50% in adiposity index and a remarkable diminution of 70% in testosterone. In addition, obesity led to hyperinsulinemia (C: 3.4 ± 1.2; O: 5.1 ± 0.8 mg/ml), causing insulin resistance that was detected by ipITT. The histological and morphometric analysis showed that the cytoplasmic (C: 165 ± 10.5; O: 126 ± 9.5 μm^2) and nuclear (C: 42 ± 2.5; O: 33 ± 1.8 μm^2) area of Leydig cells decrease, while the nuclear/cytoplasmic ratio remains the same. This diminution indicates that there was a reduction of secretory activity in these cells. Immunohistochemistry showed no significant reduction in the frequency of AR-, 3β-HSD- and 17β-HSD- positive Leydig cells in obese animals, but the content of AR and 17β-HSD decreased in crude testis samples of these animals. Furthermore, obesity reduced about 22% the daily sperm production. Our data corroborate previous studies which report that obesity is associated with impairment of steroidogenesis and spermatogenesis, and demonstrate that it is associated with reduction in AR and 17β-HSD expression. Financial Support: FAPESP.

Direct Differentiation of Human Pluripotent Stem Cells into Haploid Spermatogenic Cells.

C. A. Easley[1,2], B. T. Phillips[1,2], J. M. Barringer[2], H. Valli[1], B. P. Hermann[1,3], C. R. Simerly[1,2], K. E. Orwig[1,2], G. P. Schatten[1,2]; [1]OB/GYN and Reproductive Sciences, University of Pittsburgh, Pittsburgh, PA, [2]Pittsburgh Development Center, Magee Womens Research Institute, Pittsburgh, PA, [3]Biology, University of Texas at San Antonio

Male prepubescent and adult patients rendered sterile by cancer therapies, immunosuppressants or injury prior to delivering a sperm sample are permanently sterile and are unable to produce offspring. Unfortunately there are no proven treatments to re-establish fertility in these patients. Consequently, patient-specific stem cell treatments represent one potential future cure to restore fertility. Here we show that human induced pluripotent stem cells (hiPSCs) and embryonic stem cells (hESCs) differentiate directly into advanced male germ cell lineages such as PLZF-positive spermatogonial stem-like cells (SSCs) and post-meiotic, round spermatid-like cells in vitro without genetic manipulation. Furthermore, our differentiation procedure mirrors spermatogenesis in vivo by replicating an SSC-like lineage followed by a small fraction of cells becoming haploid expressing both acrosin and protamine 1, found

uniquely on both spermatids and sperm. These results demonstrate that male pluripotent stem cells have the capability to differentiate into advanced germ cell lineages, including post-meiotic round spermatid-like cells. These results also represent a potential technique for both studying spermatogenesis in vitro as well as further consideration for restoring fertility in sterile male patients including developing models for discovering the mechanisms of the remaining causes of idiopathic male infertilty.

659

Smt3 Posttranslational Modifications Mediate Critical Regulatory Events during Drosophila Spermiogenesis and Spermatogenesis.

J. Rollins[1,2], K. Hwang[2], P. L. Morris[2,3]; [1]Department of Chemistry and Biochemistry, College of Mount Saint Vincent, Riverdale, NY, [2]Center for Biomedical Research, Population Council, New York, NY, [3]The Rockefeller University, New York, NY

Introduction: *Drosophila* spermatogenesis is a dramatic, temporally-orchestrated developmental stage-specific process. Sperm production includes marked changes in mitosis and meiosis, chromosomes, transcription, translation, and posttranslational modifications, with striking nuclear remodeling during spermiogenesis. The posttranslational small ubiquitin-like modifier (SUMO) protein has been shown to play diverse roles in many highly conserved cellular processes such as spermatogenesis in various species including man and rodents. The purpose of this study was to define the precise stage-specific timing of fly Smt3 (*Drosophila* SUMO)-mediated events during germ cell development, determine whether Smt3-deficiency affects sperm production, and initially identify Smt3-modified proteins for comparison with those during mammalian spermatogenesis.

Methods: For bioimaging, unconjugated Smt3 and Smt3-modified proteins were detected by immunofluorescence using both whole mounts and squash preparations of testis from wild-type and heterozygous Smt3-deficient mutant stocks, avoiding homozygous larval lethality. Smt3-SUMOylated proteins were determined by immunoprecipitation (IP) and Western blot analyses. Protein extracts prepared from human and rodent testes were used for comparison. Male fertility of fly mutants was assessed by matings with wild-type females.

Results: In wild-type flies, Smt3-SUMOylated proteins show strikingly different patterns in most stages of spermatogenesis including spermatogonia undergoing mitosis, resting and meiotically active spermatocytes, and round and elongating spermatids in various stages of nuclear condensation during spermiogenesis. Smt3 was not detected in hub cells. The testes of heterozygotes showed reduced levels of Smt3 and an altered SUMOylated protein profile compared to wild-type. Interestingly, the reduction of Smt3 signals was readily observed in meiotic spermatocytes; no change for mitotic spermatogonia was apparent. Heterozygote males exhibited a reduced fertility and their testes show a marked defect in sperm transfer to the seminal vesicles. Smt3-modification of an essential cell cycle kinase was observed only during anaphase-to-telophase transition. SUMO-modifications were confirmed using human and rodent testis with normal spermatogenesis.

Conclusion: Our data are suggestive that 1) precise timing of SUMOylation events in developing fly germ cells is required for normal spermatogenesis; 2) Smt3-deficiency can result in failure of spermatids to properly undergo spermiogenesis and sperm transfer, findings consistent with marked reduction in fertility. Taken together, our results indicate important roles for Smt3 and SUMOylation during and after meiosis in *Drosophila* testis.

Is altered epidermal growth factor signalling responsible for decreased epididymal connexin 43 in azoospermic men?

E. Dubé[1], J. Dufresne[1], P. Chan[2], D. G. Cyr[1]; [1]INRS-Institut Armand-Frappier, University of Quebec, Laval, QC, Canada, [2]McGill University

Gap junctions enable direct communication between adjacent cells. Gap junctional pores are formed by connexons comprised of connexins (Cxs). Cx43 expression by Sertoli cells is essential for spermatogenesis in the testis and is regulated by thyroid hormones and androgens in both testis and epididymis. There is no information on the expression or regulation of Cx43 in the human epididymis. The objectives of this study were to determine if Cx43, Cx32 and Cx26 are present in the human epididymis and to determine if these are altered in infertile azoospermic men. Epididymides were obtained from fertile, non-obstructive and obstructive azoospermic patients and subdivided into caput, corpus and cauda. Real-time RT-PCR analysis revealed that Cx43, Cx32 and Cx26 mRNA levels were present throughout the epididymis of fertile men. In both non-obstructive and obstructive azoospermic patients, Cx43 and Cx32 were significantly decreased in the cauda epididymis. No significant effect was noted for Cx26. Previous microarray data suggested that EGFR mRNA levels were lower in the epididymis of infertile men. EGFR mRNA levels were significantly decreased in the cauda epididymidis of azoospermic patients. Cx43 and EGFR were localized between basal and principal cells and between principal cells. In the obstructive azoospermic patient, Cx43 was predominantly in the cytoplasm of basal cells as compared to fertile patients where Cx43 was along the plasma membrane. To determine whether or not EGFR regulated Cx43, a human caput epididymal cell line was used to assess the regulation of Cx43 by EGFR. Using EGF stimulation and pathway-specific inhibitors we showed that EGF could induce both the ERK1/2 and PI3K/AKT pathways. EGF increased the expression of Cx43 over 24 hrs. In the short-term, Cx43 phosphorylation was increased by EGF via ERK1/2, and not via the PI3K/AKT signalling pathway. However, the EGF-induced increase in total Cx43 protein levels was inhibited by the PI3K inhibitor LY294402, indicating that expression of Cx43 can be regulated by the PI3K/AKT pathway. These results suggest that EGFR is down-regulated in the epididymis of azoospermic men and that this decrease may contribute to lower levels of Cx43 in the epididymis. Such effects may be responsible for altered coordinated epididymal function in the human epididymis of infertile men. Supported by NSERC and CIHR.

Effects of Dehydroepiandrosterone on Androgen Receptor Protein Expression in Testes and Epididymides in Two Strains of Mice.

O. Suzuki[1], M. Koura[1], Y. Noguchi[1], K. Uchio-Yamada[1], J. Matsuda[1]; [1]Lab. Animal Models for Human Diseases, Natl Inst Biomed Innovation, Ibaraki-shi, Japan

Strain differences in *in vitro* fertilizability still constitute a serious problem in mouse reproduction. To improve the *in vitro* fertilizability of mouse sperm, we examined the effects of implanting time-release pellets of dehydroepiandrosterone (DHEA), a testosterone precursor, on androgen receptor protein (AR) expression in testes and epididymides in two strains of mice. DHEA pellets (5 mg/pellet, 21-day release form, Innovative Research of America) or placebo pellets were implanted subcutaneously in 9-week-old male mice from two strains: C57BL/6CrNSlc (B6) and 129X1/SvJJmsSlc (129X1). After 21 days, testes and epididymides were collected from each male. Proteins from these tissues were extracted using ReadyPrep protein extraction kit for Total Proteins (Bio-Rad). Quantitative Western blotting using testicular protein extracts with glyceraldehyde-3-phosphate dehydrogenase as an internal control showed that the expression of androgen receptor protein was significantly higher in B6 than in 129X1 males ($p < 0.05$ by

two-way ANOVA), while there was no significant effect of DHEA on the amount of AR in either strain (DHEA vs placebo: 0.028±0.006 vs. 0.021±0.005 in B6 and 0.012±0.002 vs. 0.010±0.002 in 129X1, arbitrary unit, mean±SEM, n=3). Comparison of epididymal AR expression by quantitative Western blotting indicated no significant difference between strains or between DHEA- and placebo-treated males (DHEA vs placebo: 0.023±0.007 vs. 0.032±0.001 in B6 and 0.030±0.003 vs. 0.025±0.008 in 129X1, n=3). Interestingly, in B6 testes, two-dimensional electrophoresis indicated that one protein spot was denser in DHEA-treated males than in placebo-treated males. In contrast, DHEA did not change the density of the corresponding spot in 129X1 testes. Thus, 21-day-release pellets of 5 mg DHEA had no significant effect on AR expression in two organs in two strains, but the DHEA pellets induced a strain-dependent change in the testicular protein expression, which might be due to the differential AR expression between two strains. DHEA treatment of male mice has the potential to modulate steroid receptor expression, which might alter *in vitro* fertilizability in mice.

Characterization of the pannexin 1 promoter.

J. Dufresne[1], D. G. Cyr[1]; [1]INRS-Institut Armand-Frappier, University of Quebec, Laval, QC, Canada

Pannexins (Panxs) are transmembrane proteins that form hemichannels and are implicated in cellular communication through the secretion of biomolecules. We have previously shown that Panx1 and Panx3 are expressed in the male rat reproductive tract and are regulated by androgens in the epididymis. We also reported the presence of a splice variant for Panx1 in which exon 3 is missing. In the present study, our objectives were to characterize the promoter of Panx1 in order to better understand its gene regulation in the rat epididymis. Total RNA was extracted from the epididymis of an adult rat and RACE (Rapid Amplification of cDNA Ends) experiments were performed. Multiple transcription start sites (16) were identified, encompassing the region between the positions -481 to -369 relative to the ATG. Using a SMARTer RACE kit, 14 sites for the transcription initiation were first identified. The use of a RLM (RNA Ligase mediated)-RACE kit, which allow cDNA amplification only from full-length mRNAs, resulted in the identification of only 3 transcription start sites, at positions -443, -429, and -393. Computational analysis revealed that the more distal transcription start site (position -481) was part of an initiator (Inr) consensus motif and was located immediately 5’ to a cAMP responsive element and a binding site for PEA3 (Polyomavirus enhancer activator 3). Several SP1 binding sites were also present in the region where the transcription initiation sites were identified. Genomic sequence analysis revealed the presence of a CpG island at the same location (position -563 to -56). To determine importance of this region in gene transactivation, 2 kb of the Panx1 promoter was amplified and cloned into a vector containing a luciferase reporter gene. High levels of luciferase activity were detected in transfected rat caput epididymal (RCE) cell line. Deletion constructs indicated that the highest transactivation levels were achieved with shorter constructs (-973 to -346 and -550 to -346). Similar results were obtained using CV-1 cells which do not express Panx1. These results suggest that Panx1 gene expression may be regulated via changes in promoter methylation and by specific transcription factors. Elucidation of such mechanisms should allow the understanding of the role of Panx1 in the epididymis. Supported by NSERC.

The High-Fat Diet Leads to Premature Detachment of Germ Cells and Reduces Daily Sperm Production in Rats.

V. Reame[1], D. L. Ribeiro[2], S. R. Taboga[1], M. E. Pinto[1], R. M. Góes[1]; [1]Department of Biology, São Paulo State University, São José do Rio Preto, SP, Brazil, São José do Rio Preto, Brazil, [2]ICBIM-Histology, Federal University of Uberlândia, Uberlândia, MG, Brazil, Uberlândia, Brazil

The present study evaluated the consequences of obesogenic environment during different phases of development on the testicular structure and sperm production of rats at adulthood. Adult male Wistar rats were assigned in the following groups: 7 month old animals previously fed for 15 weeks with balanced (CT1) or high-fat diet (O/A); 4 month old animals subjected to normal feeding (CT2) or to obesogenic environment during gestation, lactation up to sexual maturity (O/E-A). Both O/A and O /E-A rats showed an increase in the body weight, waist circumference, epididymal and retroperitoneal fat weights and glicemia but only the later were diabetic (CT1: 106 ± 3.6; O/A: 129 ± 10.9; CT2: 109 ± 3.0; O/E-A: 179 ± 11.7 mg of glucose/dl). Obesity resulted in insulin resistance and decreased serum levels of testosterone (CT1: 340 ± 59; O/A: 103 ± 21; CT2: 382 ± 40; O/E-A: 112 ± 25 ng/dl) independently of the developmental period. The diameter of the seminiferous tubules increased in O/A (CT1: 211±2.5; O/A: 219±2.3 µm) and decreased in O/E-A (CT2: 364 ± 6.13; O/E-A: 343 ± 5.15 µm). The histophatological and quantitative analysis demonstrated that there was a greater detachment of cells from the seminiferous epithelium in the obese (O/A: 35 ± 3.2%; O/E-A: 41 ± 15.5%) than in controls (CT1: 3.0 ± 1%; CT2: 9 ± 1.4%) groups. Regardless of developmental period, the obesogenic environment reduced the number of final spermatids in the testis, daily sperm production and sperm count in the epididymis, but did not alter the sperm transit time through the caput/corpus and cauda of this organ. Ours findings show that regardless the developmental period the high-fat diet ingestion reduces the sperm production, due premature germ cell detachment and testosterone withdrawal. These data also indicate as longer the period of exposure to obesogenic environment higher is the impairment in daily sperm production. Financial Support: FAPESP.

The calcium-binding protein, Dysferlin, differentially localizes in cells during early development of the sea star, *Patiria miniata*.

T. M. Onorato[1], G. M. Wessel[2]; [1]Natural Sciences, LaGuardia Community College/CUNY, Long Island City, NY, [2]Molecular Biology, Cell Biology and Biochemistry, Brown University, Providence, RI

Mass spectrometry analysis was performed on egg plasma membrane-enriched fractions subjected to SDS-PAGE and candidate proteins were identified from the sea star, *Patiria miniata* (*P. miniata*), oocyte transcriptome. One interesting candidate protein identified was Dysferlin, a member of the ferlin family of proteins involved in calcium-regulated membrane fusion. Fer-1, a homologue of Dysferlin, is involved in calcium-mediated membrane fusion during spermatogenesis in *C. elegans*, and in vertebrates, it is mutated in distrophic skeletal muscle cells. In sea urchin embryos, Dysferlin has been implicated in calcium-mediated intracellular signaling in response to membrane wounding. We raised an affinity-purified polyclonal antibody against a peptide from the predicted dysferlin domain and immunofluorescence was utilized to characterize dysferlin expression during early development in *P. miniata*. Dysferlin is localized to the cortex of immature oocytes and eggs. Interestingly, Dysferlin was detected in the germinal vesicles of young immature oocytes. Next, we investigated Dysferlin localization during sperm-egg binding. Immature oocytes and eggs were incubated with sperm for 10 minutes, fixed and immunolabeled. Dysferlin appears enriched in

areas of the plasma membrane where egg-sperm interaction is occurring. Finally, we aimed to characterize Dysferlin localization after fertilization. In addition to the periphery of the cell, Dysferlin localized in nuclear regions of blastomeres from an 8-cell embryo. In swimming gastrulae, mesenchymal cells contained low levels of Dysferlin, while ectodermal cells expressed higher levels of dysferlin localized in apical regions. Collectively, these preliminary results indicate Dysferlin in differentially localized in cells during early development of *P. miniata*.

Maintaining the Integrity of Sea Urchin Eggs Using Liposomal Glutathione.

L. Jayant[1], C. Priano[1]; [1]Science, Borough of Manhattan Community College, New York, NY

This study examined the potential protective effect of liposomal glutathione (L-GSH) on L. variegatus sea urchin eggs. GSH is an antioxidant believed to protect against cell damage. Preliminary results showed that at a concentration of 1.08 mg/mL, L-GSH was capable of maintaining the integrity of sea urchin eggs for 6 days. This is significant because most studies have reported that the shelf life of an unfertilized sea urchin egg is less than 1 day. Following exposure to L-GSH, eggs were monitored by direct microscopic observation and counted. In a control experiment, eggs kept in sea water with no L-GSH began to disintegrate after 24 hours and were heavily infested with protists. In contrast, eggs exposed to L-GSH maintained intact cell membranes for up to six days. Moreover, exposure to L-GSH appeared to prevent infestation by protists up to day 6. Future studies will focus on examining the viability of sea urchin eggs in the presence of L-GSH and determining whether these eggs can be fertilized to produce embryos. In addition, studies will be done in which sea urchin embryos will be exposed to cell damaging agents, such as UV radiation, in the presence and absence of L-GSH. The results of these experiments will provide insight into whether there is a protective effect of L-GSH on animal cell membranes and developing embryos.

666

The Role of Lipids in the Induction of Apoptosis in *Xenopus* Oocytes.

D. W. Petcoff[1], A. A. Bulow[1]; [1]Biology, Metropolitan State College of Denver, Denver, CO

Xenopus oocytes can survive for extended periods (a few days to two weeks) in culture. However, once matured to eggs by the action of progesterone, death will occur within 24 hours. This striking contrast in viability provides an excellent model for studying a variety of factors that impinge on the balance of life and death. In particular, sphingolipid pathways have been shown to alter the balance of life and death in a variety of cell types, with ceramide tipping the balance towards apoptosis. The objective of our studies on lipids that regulate apoptosis is to shift the balance away from apoptosis in order to increase oocyte life span. This will enhance our ability to use oocytes for translation and expression of exogenous mRNA and proteins, and for in vitro fertilization. Using a microinjected near-infrared dye caspase substrate (LI-COR Biosciences), we have demonstrated an increase in caspase activity in individual Xenopus oocytes during spontaneous death, after peroxide addition, or in response to ceramide (200 nM). Both natural (porcine brain) and synthetic (C-6) ceramide, when microinjected or added to the medium result in a significant increase in caspase activity within 90 minutes of exposure. Over a longer time course, morphological indications of apoptosis become evident. These results demonstrate that ceramide can trigger apoptosis in Xenopus oocytes, and that ceramide may play a role in spontaneous death in cultured oocytes. We are currently investigating the kinetics of ceramide-induced apoptosis during both progesterone and insulin-stimulated oocyte maturation, along with various strategies to inhibit apoptosis in these cells.

667

Biphasic traveling calcium wave during fertilization is generated independently of a sperm-supplied egg activation factor SPE-11 in *Caenorhabditis elegans*.

J. Takayama[1], S. Onami[1]; [1]RIKEN QBiC, Kanagawa, Japan

A mature egg transforms into a totipotent embryo in a process known as egg activation. The egg activation in most animals is initiated by a change of intracellular calcium concentration in a pattern characteristic to each species. However, there are no genetic analyses for the calcium response and the molecular mechanisms for egg activation are still poorly understood. Here we report a detailed spatiotemporal pattern of the fertilization calcium response in *Caenorhabditis elegans* and that the calcium response is independent of SPE-11, a sperm-supplied factor required for egg activation.
Time-lapse movies of the calcium dynamics during fertilization were obtained by using a fluorescent calcium indicator and by spinning disk confocal microscopy. The calcium dynamics of the oocyte region was quantified by using computational image-processing methods. The quantification revealed that the fertilization calcium response is a biphasic traveling wave. The wave composed of a fast local wave that arises from the sperm entry point seemingly at the time of the sperm entry, followed by a slow global wave that propagates throughout the oocyte. No response was observed after the oocyte exits from the spermatheca where it is fertilized. The biphasic waveform could be explained by a well-known mathematical model, the bistable reaction-diffusion equation, under initial conditions that assume a transient calcium elevation at the one end of the oocyte. These results are consistent with the view that fertilization triggers a transient calcium elevation and the calcium-induced calcium release machinery propagates the calcium wave.
To gain insights into the molecular mechanism for the generation of the calcium wave and its role for egg activation, we observed the fertilization calcium response of mutants defective in sperm function: *spe-9*, *spe-41* and *spe-11*. Neither *spe-9* nor *spe-41* mutant sperm can fuse with the oocyte probably due to deficits in oocyte recognition and/or fusion, whereas *spe-11* sperm fuses with the oocyte but fails to activate it. We found that calcium fluorescence hardly changes in *spe-9* or *spe-41* mutants as the oocyte passes through the spermatheca, whereas a wild type-like wave is observed in *spe-11* mutants although they fail to activate eggs. These results suggest that fertilization calcium wave was generated by a process that requires SPE-9 or SPE-41 function and that a factor(s) other than SPE-11 triggers the calcium wave.

Insulin Treatment of Diabetes Mellitus Improves Sperm Quality and Fertility Rate.

H. Kim[1], D. Kim[2]; [1]Graduate School of Medicine, Gachon University of Medicine and Science, Incheon, Korea, [2]Division of Biological Science, Gachon University of Medicine and Science, Incheon, Korea

Diabetes mellitus (DM) is one of the most widespread diseases that threaten human health in the modern world, affecting over 171 million people. In recent studies, the prevalence of infertility was higher in diabetic compared to non-diabetic patients. Sexual dysfunctions related to the diabetic state have been described, but their pathophysiological pathways are not yet to be clearly demonstrated. The goal of the current paper was to elucidate if treatment with insulin can improve fertility in diabetic sperm. This study determined that sperm quality, fertilization capacity, and subsequent embryo development in 3 experimental groups: control, diabetic, and diabetic treated with insulin for 7 days. The functional analysis of male reproduction was determined by measuring sperm motility using computer-assisted sperm analysis (CASA). In the diabetic group, the percentage of motile sperm was significantly lower than in control. Sperm samples were stained with Annexin-V to detect apoptosis. Samples were also stained with

Propidium Iodide (PI) to distinguish live cells from dead cells. Diabetic group showed a higher number of Annexin-V-positive sperm than control. Comet assay revealed increased DNA fragmentation in diabetic sperm when compared to control. These parameters normalized in diabetic sperm treated with insulin. Furthermore, to examine the fertility of the diabetic sperm, in-vitro fertilization (IVF) were performed. Treatment with insulin therapy increased significantly the fertility rate of sperm. The embryo developmental rates to the blastocyst stage were also higher in diabetic sperm treated with insulin than diabetic sperm. We conclude that the lack of insulin was directly related to the diabetes-induced sexual dysfunction, and Insulin supplementation restored these parameters.

669

Phospholipase D Inhibitors FIPI and 1-Butanol Inhibit Calcium Release at Fertilization.

C. Fees[1], R. Bates[1], B. Stith[1]; [1]Integrative Biology, University of Colorado Denver, Denver, CO

Fertilization in *Xenopus* involves sperm activation of Src which in turn, activates phospholipase Cγ to increase IP3 and release calcium (Sato, Fukami and Stith, Sem Cell Dev Bio 285-92, 2006). Our large scale quantification of lipids at fertilization (Petcoff et al. J Lipid Res 2365-78, 2008), and prior work showing an increase in choline and 1,2 DAG during fertilization (Stith et al., Mol Bio Cell 8:755, 1997), suggests that phospholipase D1b production of Phosphatidic Acid (PA) plays a role in fertilization. Furthermore, as measured by HPLC/evaporative light scattering mass detection, PA mass increased at fertilization, and synthetic PA addition will stimulate Src tyrosine kinase to increase phospholipase Cγ tyrosine phosphorylation, IP3 mass and calcium release.

We have now perfected the whole cell measurement of intracellular calcium during *Xenopus* fertilization through prior injection of calcium indicator dye Fluo-4 into whole eggs. After examining various methods, we have perfected injection of eggs without artificial activation.

We can visualize transient sperm-egg interaction by recording the intensity, duration and diameter of “puffs” of calcium release. After one to two puffs, there is a subsequent larger calcium wave generated. PLD inhibitor 1-butanol (0.25%) reduced the PA increase at fertilization and blocked calcium release whereas 2-butanol (which is unable to inhibit PLD) did not. FIPI, a potent and specific inhibitor of phospholipase D, did not sperm egg interaction as noted by no change in the average number or size of the “puffs” of calcium release. However, FIPI inhibited Src activation, induction of the fertilization calcium wave and subsequent fertilization events (videos will be shown). This suggests that PLD and PA production do not play a role in the initial calcium release at the sperm binding site but PA may play a role in the large calcium release (wave).

Furthermore, addition of synthetic PA (but not anionic control lipid PS) to *Xenopus* oocytes or eggs also produced a large calcium release. Synthetic PA induction of calcium release was inhibited by IP3 receptor blocker 2APB, or a Tyrosine Kinase Inhibitor (Herbamycin A). Calcium ionophore ionomycin causes a much faster calcium release (2 vs. 11 min) that is not blocked by 2APB or herbamycin A. PA also increased IP3 mass to a level seen by sperm addition and this is in contrast to a much smaller increase induced by ionomycin.

As compared with other lipids (PIP2, LPA, PS and 11 other major phospholipids), PA specifically bound Xenopus Src but not PLCγ (Echelon PIP Strips).

670

Evidence that mechanisms of nuclear fusion are conserved from yeast to the green alga, Chlamydomonas.

J. Ning[1], W. J. Snell[1]; [1]Department of Cell Bilogy, University of Texas Southwestern Medical Center, Dallas, TX

Zygote formation in many eukaryotes is completed when the nuclei of the two merged gametes fuse to form the diploid nucleus, yet the cellular and molecular mechanisms that underlie nuclear fusion remain poorly understood. During fertilization in the unicellular, biflagellated alga Chlamydomonas, haploid plus and minus gametes adhere to each other by their flagella, thereby activating a cAMP-dependent signaling pathway that prepares the gametes for cell-cell fusion. Upon fusion, the cytoplasms of the two gametes coalesce, and soon thereafter their nuclei fuse (karyogamy). After an obligatory period in the dark, the zygotes undergo meiosis and germinate to produce 4 haploid progeny. Recently, we identified a Chlamydomonas homolog of the Saccharomyces cerevisiae nuclear fusion protein, KAR5. Based on RT-PCR and other transcript analysis we found that CrKAR5 is expressed only in gametes, and not asexual vegetative cells. Moreover, CrKAR5 transcripts are not detectable in asexual cells of either mating type and are expressed at low levels in gametes of both mating types. Unexpectedly, transcripts undergo a nearly 20-fold increase during gamete fusion and during gamete activation induced either by flagellar adhesion or by incubation of gametes in db-cAMP, but only in minus gametes. Preliminary results with an epitope-tagged form of CrKAR5 suggest that the protein is nuclear. In cells depleted of CrKAR5 transcripts by artificial micro RNA (amiRNA), zygote germination is substantially reduced. Our results indicate that basic mechanisms of nuclear fusion are broadly conserved in eukaryotes. Experiments are in progress to generate cells with a disrupted CrKAR5 gene. Supported by NIH GM56778 to W. J. S.

Purification of Yeast Zygotes: Interrogation of the Haploid-to-Diploid Transition.

S. Zapanta Rinonos[1,2], J. T. Saks[1], A. M. Tartakoff[1]; [1]Department of Pathology, Case Western Reserve University School of Medicine, Cleveland, OH, [2]Cell Biology PhD Program, Case Western Reserve University School of Medicine, Cleveland, OH

The zygote, formed by fusion of two haploid cells, serves as the transition from haploid to diploid states. To generate *S. cerevisiae* zygotes for purification, haploid mating pairs of cells in the S288C background were transformed to cause expression of cytoplasmic green fluorescent protein (GFP) or mCherry-tagged polysomes. Cells of opposite mating type (mCherry MATa x GFP MATalpha) were co-incubated on an agar surface to allow zygote formation, harvested at various times (1.75 or 2.5 hours), followed by a two-step flow cytometry-based sorting protocol to isolate zygotes (cells exhibiting red-green double positivity). This bi-color technique (red vs. green) provides a convenient visual assessment of zygotic purity and maturation. Fluorescent deconvolution microscopy distinguishes pre-zygotes (fused haploid cells with discontinuous red and green cytoplasmic compartments) vs. more mature zygotes (that show cytoplasmic continuity). The final yield of zygotes is approximately 10% of input cells, and the average purity is greater than 95%. According to the duration of the cross, unbudded or budded zygotes can be recovered. We have applied this purification protocol for our ongoing studies investigating the biological significance of transcripts that are regulated at early stages vs. later stages of zygote maturation. The current zygote purification technique thus provides a convenient model system for “-omic” studies of fertilization, for recovery of initial progeny, and for systematic investigation of morphogenesis.

Integrin adhesion drives the emergent polarization of active cytoskeletal stresses to pattern cell delamination.

C. Meghana[1], N. Ramdas[2], F. Meeran[2], M. Rao[3], G. Shivashankar[4], M. Narasimha[5]; [1]Deptartment of Biological Sciences, Tata Institute of Fundamental Research, Mumbai, India, [2]National Centre for Biological Sciences, [3]National Centre for Biological Sciences, Raman Research Institute, [4]National Centre for Biological Sciences, Mechanobiology Institute and Department of Biological Sciences, National University of Singapore, [5]Tata Institute of Fundamental Research

Cells in epithelia respond to and integrate a variety of biochemical and mechanical cues to generate stereotypic patterns during development and homeostasis. Here we investigate how cells of the amnioserosa, an active participant of Drosophila dorsal closure respond to a local subcellular mechanical stimulus. We show that a subcellular laser perturbation (that ensures plasma membrane integrity) triggers cell delamination/extrusion. An initial phase of cell expansion precedes extrusion enabling us to estimate cellular prestress (tension). We characterize the spatial reorganization of the cytoskeleton and the temporal hierarchy of their deployment in the perturbed cell and its nearest neighbours during cell delamination. We find an emergent polarization of actin (lamellipodial protrusions and cortical enrichment), myosin (streaming movement of medial myosin and cortical enrichment) and microtubules (polarized rearrangement) at the interface of the perturbed cell and its nearest neighbours in response to the perturbation. We identify novel roles for microtubules- in the streaming movement of myosin and timely completion of delamination in response to the subcellular perturbation. We further demonstrate that the reorganization of actin and myosin is dependent on integrin adhesion and precede changes associated with microtubules. Our results indicate that cell delamination is patterned locally through differential contributions of adhesion, cytoskeleton and local mechanical cues.

673

Regulation of planar cell polarity and Vangl2 trafficking by Tmem14a.

E. Chea[1,2], B. Ciruna[1,2]; [1]Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada, [2]Developmental & Stem Cell Biology, Hospital for Sick Children, Toronto, ON, Canada

Planar cell polarity (PCP) coordinates the uniform structure, orientation, and movement of cells within a tissue. In zebrafish, PCP is also required for the directed re-intercalation of neuroepithelial cells following asymmetric cell division in the neural tube. PCP is regulated by a conserved core group of signalling proteins that include Frizzled, Dishevelled, Vangl, Prickle, Flamingo, and Diego. Mutations in human VANGL1 and VANGL2 have been linked to neural tube defects. However, little is known about the intracellular trafficking pathways that target Vangl to the cell membrane. Tmem14a is a 99-amino acid tetraspanin protein with unknown function that was identified in our lab as a potential interactor of Vangl2 in a membrane yeast-two hybrid screen. Here, we show that GFP-tagged Tmem14a is localized to a polarized trans-Golgi compartment of zebrafish neuroepithelial cells. Morpholino knockdown of Tmem14a activity results in PCP phenotypes such as convergent extension defects at gastrulation and disrupted neural tube morphogenesis. Morphant embryos also exhibit curved body axes at 1-2 dpf, suggesting additional roles for Tmem14a in regulating apical/basal polarity and ciliogenesis. Preliminary analyses reveal that motile cilia lining the floorplate of Tmem14a morphant embryos are disorganized, a phenotype similar to maternal-zygotic *vangl2* mutants. Preliminary analysis

of GFP-Vangl2 expression in Tmem14a morphants also revealed defects in GFP-Vangl2 membrane localization. Our results suggest that Tmem14a acts as a regulator of PCP signalling through its potential role in trafficking Vangl2 to polarized compartments of the cell membrane.

674

Septin controls polarized actomyosin distribution during PCP-dependent collective cell movements.

A. Shindo[1], S. Kim[1], T. Park[1], J. Wallingford[1]; [1]Molecular Cell and Developmental Biology, University of Texas at Austin, Austin, TX

The Planar Cell Polarity (PCP) pathway is a critical regulator for cell behaviors during development, and convergent extension (CE) is an essential collective cell movement regulated by the PCP pathway. During this process, cells align and interdigitate to narrow and lengthen a tissue. PCP signaling is necessary for cell polarity during CE, but little is known about how PCP signaling controls the machinery that executes cell behaviors, for example actomyosin. Fritz is one of the PCP effector proteins that acts downstream of core PCP proteins (such as Dishevelled and Vangl2) to control specific processes in Drosophila. We show that vertebrate Fritz is necessary for CE and physically interacts with septins, cytoskeletal elements that provide cortical rigidity. Knockdown of Fritz or septin7 leads to abnormal cell membrane dynamics (rapid undulations) and defects in both cell shape and cell-cell contact. We have also found that Fritz controls septin7 and actin localization at the medio-lateral cell cortex. Fritz or septin7 KD disrupts polarized actin localization, and ectopic actin accumulation is observed instead. From these results, we conclude that polarized actin distribution is regulated by Fritz and septins downstream of PCP signaling to control membrane stability and cell shape during collective cell movement.

675

Contact mediated transport of signaling proteins over long distance by Drosophila cytonemes.

S. Roy[1], T. B. Kornberg[1]; [1]Cardio Vascular Research Institute, Univ California-San Francisco, San Francisco, CA

Cytonemes are types of filopodia that have been proposed to be involved in long distance signaling between producing and target cells. The present work characterizes cytonemes emanating from a group of collectively migrating tracheal cells forming air sac primordium that associate with the wing imaginal disc. These tracheal cells are dependent upon FGF and Dpp produced in the wing disc and they have at least two types of cytonemes - one that is responsive to FGF to which they segregate FGFR, and another to which they segregate the Dpp receptor, Thickveins (Tkv). Both FGFR and Tkv have punctal distributions that localize specifically in responding cytonemes, and the ligands colocalize with their respective receptors. These puncta are motile. Puncta containing both ligand and receptor are in cytonemes that appeared to touch ligand-expressing cells. Extracellular GFP reconstitution between cytonemes of recipient cells and ligand-expressing cells provided evidence for such direct contacts for signal reception. These findings confirm cytoneme-based movement of signaling proteins and are consistent with the idea that cytoneme-based transport of signaling proteins is the mechanism for cell-cell communication in which controlled amounts of signaling protein can be targeted to a specific recipient cell.

676

A novel role for members of the PAR polarity complex in tracheal terminal cell development in Drosophila.

T. Jones[1], M. Metzstein[1]; [1]Department of Human Genetics, University of Utah, Salt Lake City, UT

Cell shape is key to cell function, but the processes that generate elaborate cellular morphologies are not well understood. To investigate this problem, we use *Drosophila* tracheal terminal cells, a component of the insect respiratory system. These cells undergo two distinct morphogenetic processes: subcellular branching morphogenesis, and subcellular apical lumen formation. Wild-type terminal cells initiate branching from a central branch, containing the cell body. Side branches then grow out and bifurcate, with a general reduction in cell diameter. Terminal cells also contain a single continuous, air-filled lumen, which extends through the central branch and into all subsequent side branches. Interestingly, despite their apical characteristic, these lumens form without cellular junctions but instead may arise by a process of vesicle trafficking and fusion.

We have found that both branching and lumen morphogenesis in terminal cells are regulated by components of the PAR-polarity complex. This complex is composed of the proteins Par-6, Bazooka (Par-3), aPKC, and Cdc42 and is best known for roles in establishing asymmetry during cell division and in initiation and maintenance of apical/basal polarity in epithelia. We find Par-6, Bazooka, and aPKC, as well as known interactions between them, are required for subcellular branch initiation, but not for branch outgrowth. We also find that these polarity proteins are downstream of an FGF signaling pathway that is known to regulate terminal cell branching and outgrowth. We have isolated two novel alleles of Par-6, one of which specifically truncates the Par-6 PDZ domain and analyzed single and double mutants of *par-6* and other PAR-polarity proteins. From this analysis we conclude that dynamic interactions between PAR-complex members controls the branching pattern of terminal cells. In contrast, we find that while Par-6 and aPKC are both required for subcellular lumen formation, neither Bazooka, nor a direct interaction between Par-6 and aPKC is needed for this process. Thus a novel, non-canonical role for the polarity proteins Par-6 and aPKC is used in formation of this subcellular apical compartment. Our results demonstrate that proteins from the PAR complex can be deployed independently within a single cell to control two different morphogenetic processes.

677

Using Drosophila to dissect the role of eIF2alpha phosphorylation in development.

E. Malzer[1,2], L. Dalton[1], D. Crowther[1,2], D. Lomas[1], S. Marciniak[1]; [1]CIMR, University of Cambridge, Cambridge, England, [2]Department of Genetics, University of Cambridge, Cambridge, England

In response to multiple stresses, phosphorylation of the translation initiation factor eIF2alpha attenuates new protein synthesis. In mammals, four stress-activated eIF2alpha kinases have been identified (GCN2, PERK, HRI and PKR) and are antagonized by two eIF2alpha phosphatases, constitutively expressed CReP (PPP1R15b) and ER stress-inducible GADD34 (PPP1R15a). Although all eukaryotes posses at least one eIF2alpha kinase, the cognate phosphatases are less common. Importantly, they appear to be absent in yeast and nematodes. We noted that Drosophila CG3825 shares homology with the mammalian PPP1R15 proteins. We confirm functional homology using biochemical and genetic strategies. It has been shown previously that Ppp1R15a/b double knockout is embryonic lethal in mice at an early stage, but the precise requirement for selective eIF2alpha dephosphorylation during development remains unexplained. We show that silencing of CG3825 in Drosophila by RNAi similarly results in

developmental delay and use this model to dissect further the role of eIF2alpha phosphorylation in development.

678

Rfx2 is required for the intercalation and ciliogenesis of epidermal multi-ciliated cells in *Xenopus*.

M-I. Chung[1], S. LeBoeuf[1], J. Wallingford[2]; [1]University of Texas at Austin, Austin, TX, [2]Section of Molecular cell and Developmental Biology, University of Texas at Austin, and the Howard Hughes Medical Institute, Austin, TX

Specialized mucociliary epithelia are essential for many major organs, such as the respiratory system. The embryonic epidermis of *Xenopus* embryo has similarities with mammalian mucociliary epithelia. Therefore, the epidermis of *Xenopus* provides a good model to study the morphogenesis of mucociliary epithelia. The embryonic skin of *Xenopus* embryo contains specialized multi-ciliated cells that are distributed in a spacing pattern. The ciliated cell precursors first differentiate from the inner or sensorial layer of the ectoderm and then intercalate radially into the outer epithelial cell layer to form multi-ciliated cells. However, the mechanisms of controlling the multi-ciliated cells intercalation remain unclear. We observed that a transcription factor, Rfx2, is expressed from early multi-ciliated cell precursors to mature multi-ciliated cells in the epidermis, suggesting that Rfx2 might be essential for different steps regulating the formation of epidermal multi-ciliated cells. When we targeted delivery antisense oligonucleotides to knock down Rfx2, we observed the similar number of α-acetylated tubulin-expressing cells in both control and Rfx2 knockdown embryos, indicating that multi-ciliated cell specification is unaffected by loss of Rfx2. However, most multi-ciliated cell precursors fail to intercalate properly into the outer epithelial cell layer in Rfx2 knockdown embryos. In addition, some multi-ciliated cells with mild intercalation phenotypes in Rfx2 knockdown embryos have only a few short axonemes, as compared to control epidermis, where dozens of long cilia are assembled on multi-ciliated cells. We also consistently observed the shorter cilia phenotypes in the neural tube and gastrocoel roof plate in Rfx2 knockdown embryos. Together, these data show that the transcription factor Rfx2 is essential for the multi-ciliated cells intercalation and ciliogenesis.

679

Differential remodeling of peripheral glial subtypes during the larval to adult transition in Drosophila.

J. J. Fernandes[1], S. Banerjee[1], M. Siefert[1]; [1]Zoology & Center for Neuroscience, Miami Univ, Oxford, OH

INTRODUCTION: In the Drosophila larva, 8 pairs of abdominal nerves, A1-A8, extend from the ventral ganglion to innervate muscles in the body wall. This pattern is re-organized during metamorphosis to generate the adult pattern- three pairs of anterior abdominal nerves directly exit the abdominal ganglion, and the remaining five pairs of posterior nerves (A4-A8) form a fused Terminal Nerve Trunk (TNT). Segmental nerves defasciculate from the TNT at multiple levels to innervate the body wall muscles. The OBJECTIVE of this study is to understand how glia, which wrap around each peripheral nerve are rearranged during the transition to allow five pairs of nerves to form a fused TNT. Peripheral nerves in the Drosophila larva are surrounded by four layers- the most external is the neural lamella, a deposition of extracellular matrix, followed by 3 glial layers - the perineurial layer just below the lamella, subperineurial glia which form septate junctions and wrapping glia which are the innermost. METHODS: Glia specific antibodies and layer specific markers (Stork et al, 2008; J. Neurosci.) were used for labeling, followed by visualization with confocal microscopy. RESULTS: A 3-fold increase in glial nuclei is

seen at the end of the first day of metamorphosis (24h APF; n=15). At this time, the outermost layer (the lamella) and the innermost layer (wrapping glia) are absent (n= 8 and 10 respectively). Interestingly, cells of the perineurial layer are the most abundant (80% of total glia; n=14); the rest are sub-perineurial (n= 12). Persistence of this layer is not surprising given that it forms the auto-cellular septate junctions that serve as the blood brain barrier. These data allow us to CONCLUDE that glial layers undergo differential remodeling (retraction of some layers and expansion of others) in the early pupa, which is initiated before nerve fusion. FUTURE DIRECTIONS: Each glial class will be examined during and after TNT formation. BrDU labeling will be used to follow proliferation, single cell labeling will be used to examine cellular extents, and ultrastructural studies will examine relative organization of glia and axons in peripheral nerves during the transition. These studies will lay the groundwork for manipulating individual glial layers to better understand their contribution to TNT formation.

680

A dual role for the NaKATPase during brain ventricle development.

J. T. Chang[1], L. A. Lowery[2], H. Sive[1]; [1]Whitehead Inst-Massachusetts Inst Technol, Cambridge, MA, [2]Harvard Medical School

We demonstrate that the NaKATPase plays a dual function during vertebrate brain ventricle development, using the zebrafish as a model. The first is regulation of neuroepithelial polarity and permeability, which can be modulated by RhoA; while the second function is not sensitive to RhoA, and likely includes cerebrospinal fluid (CSF) production. Both the alpha subunit, (*atp1a1*) and the *FXYD1* subunit, which we newly isolated, set up neuroepithelial polarity and continuous apical junctions, leading to a cohesive neuroepithelium. Partial loss of *atp1a1* function prevents brain ventricle inflation, however, while neuroepithelial polarity appears normal, neuroepithelial permeability is strikingly increased relative to controls, as measured by a novel dye retention assay. Conversely, neuroepithelial permeability is reduced by expression of activated RhoA or overexpression of Atp1a1, in a dose-dependent fashion. Expression of activated RhoA restores continuous junctions after severe loss of Atp1a1 or FXYD1, and leads to normal inflation in FXYD1 loss of function embryos. However, inflation is not rescued after Atp1a1 loss of function + RhoA, indicating that a RhoA-independent activity, likely CSF production, is required for inflation. In a wild type embryo, formation of both a cohesive neuroepithelium, as well as brain ventricle inflation require the pump function of the Atp1a1 subunit, and intracellular Na^+ concentration ($[Na^+]_i$) increases after pump inhibition. High $[Na^+]_i$, is associated with failure to form a cohesive neuroepithelium, whereas after a more modest increase in $[Na^+]_i$, the neuroepithelium appears intact but has increased permeability. These data suggest that the NaKATPase directs brain ventricle development through two pathways, one of which promotes formation of a neuroepithelium capable of retaining fluid, and the other that leads to production of CSF.

681

EXC Proteins Regulate Early Endosome Trafficking to Maintain Apical Surface in Narrow Tubules of C. elegans.

K. Grussendorf[1], H. Al-Hashimi[1], B. C. Mattingly[1], M. Buechner[1]; [1]Molecular Biosciences, University of Kansas, Lawrence, KS

Single-celled tubules must continually regulate their narrow apical diameter in order to maintain normal fluid flow, and in the case of Schwann cells, to maintain close contact for electrical insulation of neurons. The nematode excretory canals provide a genetically manipulable model of such tubules. In *C. elegans*, loss-of-function mutations in any of a set of *exc* genes cause the

excretory canal lumen to swell into large fluid-filled cysts, as a result of mechanical failure of the canal apical surface.

Three of the EXC proteins show genetic interactions with each other, and interfere with the ability of early endosomes at the apical surface to progress to recycling endosomes. *exc-5* encodes a guanine exchange factor homologous to the mammalian FGD proteins that activate CDC42; defects in human FGD4 cause Schwann Cell malformation in Charcot-Marie-Tooth disease type 4H. *exc-9* encodes the small LIM-domain protein CRIP, and *exc-1* contains two Ras domains homologous to those of human IIGP (interferon-inducible GTPase). While the three genes are expressed in various tissues in the nematode (*exc-5* in the pharynx, *exc-9* in the uterine seam, and *exc-1* in glial cells), all three are expressed in the excretory canals. Overexpression of *exc-5* rescues mutants in the other two genes, and overexpression of *exc-1* rescues *exc-9* mutants. Yeast-2-hybrid experiments show that constitutively active EXC-1 binds to itself and to EXC-9.

Constructs expressing subcellular organelle markers within the excretory canals showed that loss of EXC function caused a large accumulation of labeled EEA-1 (early endosome antigen) in areas of the apical surface where the tubule lumen collapsed, and loss of RME-1 (human EHD1) expression in those same areas. Most importantly, the buildup of EEA-1 was found to precede loss of structural integrity in embryonic canals. These results strongly suggest a model in which the function of EXC proteins is integral for vesicle progression from early endosomes to recycling endosomes at the apical surface of the excretory canals, and that EXC proteins are essential for maintenance of tubule integrity at the luminal surface of narrow single-celled tubules.

Marker constructs modified from constructs provided by Barth Grant, John White, and Brian Ackley. Financial support from NINDS R03-NS067323.

Basal constriction, a novel cell shape change regulated by Wnt5b, Src kinase and FAK signaling.

I. Brachmann[1], J. H. Gutzman[1,2], E. G. Graeden[1,3], J. Chen[4], H. Sive[1,3]; [1]Whitehead Institute for Biomedical Research, Cambridge, MA, [2]present address: University of Wisconsin-Milwaukee, [3]Massachusetts Institute of Technology, Cambridge, MA, [4]Stanford University, Stanford, CA

Basal constriction occurs during formation of the zebrafish midbrain-hindbrain boundary constriction (MHBC), and this appears to be a widespread, but largely uncharacterized, epithelial shape change during invertebrate and vertebrate organogenesis. At the MHBC, basal constriction requires Laminin in the basement membrane (Gutzman J. et al., Mech Dev. 2008) and we have recently identified Wnt5b and Focal adhesion kinase (FAK) as crucial for basal constriction, acting independently of Laminin. Wnt5b RNA is concentrated at the MHB and, in transient transgenics, RNAi against Wnt5b expressed from a CNS-specific promoter prevented basal constriction. Frizzled2 and Ryk receptors are required for basal constriction and their activity is strongly synergistic, while the Src kinases, Fyn and Yes, are also required for basal constriction, putatively acting upstream of FAK. Autophosphorylated FAK (on Y397) is enriched at the MHBC of 24 hpf embryos and transplant assays show that FAK is required cell autonomously for basal constriction. Using a photoactivatable FAK antisense construct, we showed that FAK is required at the time of basal constriction in MHBC cells. Expression of human FAK or phosphomimetic FAK (Y397E) rescues basal constriction after Wnt5b loss of function, indicating that Wntb5b and FAK function in a linear pathway to direct basal

constriction. Together our data demonstrate a role for a non-canonical Wnt pathway in basal constriction during brain morphogenesis.

Hydraulic stress induced bubble nucleation and growth during pupal metamorphosis.

M. Prakash[1]; [1]Dept. of Bioengineering, Stanford University, Stanford, CA

Here I describe the role of physical fluid stress during pupal metamorphosis in flies. During early stages of pupation of larvae into adult flies, a physical gas bubble nucleates at a precise spatial and temporal location, as part of the normal development program in Diptera. Although its existence has been known for the last 50 years, the origin and control of this "gas nucleation" event has remained completely mysterious. Where does the driving negative pressure for bubble nucleation come from? How is the location of the bubble nucleation site encoded in the pupae? How do molecular processes control such a physical event? What is the role of this bubble during fly development? By developing imaging techniques including X-ray microscopy and bio-physical measurements for live insect pupal structures, here I elucidate the physical mechanism for the appearance and disappearance of this bubble. Via growth rate measurements of this bubble in a developing pupae subjected to variable fluid stress environments for three different species (Drosophila melangastor, Musca domestic, Sarcophaga bercaea), I directly measure the evaporative stress and the resulting negative pressure in the pupal cavity. The sharp increase in this negative pressure specifically encodes the exact timing of the nucleation event. Furthermore, controlled buckling of the main tracheal conduits breaks symmetry and thus govern the physical location of the nucleation site. Gaining physical insights into this hydraulic mechanism also allows us to finally predict the mechanics and inherent design of pupal shell architecture in various species.

Map1b Is Involved In Neural Convergence During Neurulation In Zebrafish.

V. Olmo[1], P. Jayachandran[1], N. Neemani[1], R. Brewster[1]; [1]University of Maryland Baltimore County, Severn, MD

The neural tube (the precursor of the brain and spinal chord) is shaped during neurulation from a flat sheet of cells on the dorsal surface of the embryo known as the neural plate. Neural convergence, an early stage of neurulation that is conserved across vertebrates, results in the narrowing and elongation of the neural plate. In zebrafish, this morphogenetic process is brought about by polarized migration towards the dorsal midline within the neural plate. Preliminary data from our laboratory suggests that microtubule (MT) stabilization is important for this process. First, the stability of MTs increases as neurulation proceeds, as visualized using a marker for detyrosinated MTs. In addition, MTs appear destabilized in *linguni* mutants, which are defective in neural convergence, but not convergence of the underlying mesodermal layer. These observations suggests that the MT destabilization phenotype is specific to neural convergence, as opposed to being a general developmental defect. Based on these observations, we predict that microtubule associated proteins (MAPs) are likely implicated in inducing MT stability during neural convergence.
We report here on the role of Map1B during neurulation. Map1B is a developmentally regulated phosphoprotein predominantly expressed in nerve cells. It is one of the first structural MAPs to be expressed at high levels in growing axons and growth cones. *MAP1B* mouse knockout studies have revealed a significant role for this protein during central nervous system development, but it has not yet been implicated in neurulation. To address whether Map1b plays a role in neural convergence, we examined its expression using *in situ* hybridization. *Map1b* is ubiquitously expressed during early stages of neural tube development and becomes more

concentrated in the hindbrain region at later stages. To address whether Map1b is required for neural convergence, we treated embryos with morpholinos to knockdown Map1B protein and analyzed expression of Dlx3, a marker for the edge of the neural plate. This assay revealed that the width of the neural plate was 1.5 times wider in the *Map1b* morpholino-injected embryos as compared to uninjected embryos. Interestingly, a similar phenotype has been observed in embryos depleted of the receptor Neogenin and its ligand RGMa, both of which have been implicated in neural tube formation in previous studies. We are currently investigating whether Neogenin/RGMa signaling induces activation of Map1b to influence MT stability during neural convergence. These studies reveal a novel role for Map1b in mediating the morphogenetic movements that shape the vertebrate nervous system.

Identification of Mist, a GPCR Involved in Cellular Contraction and Epithelial Morphogenesis in the *Drosophila* Folded gastrulation Pathway.

A. J. Manning[1], K. Peters[1], S. L. Rogers[1]; [1]Biology, Univ North Carolina-Chapel Hill, Chapel Hill, NC

The ability to perceive and respond to information from the environment is a fundamental property of living cells. Morphogenesis of the early *Drosophila* embryo offers a powerful system to study the mechanisms and principles of signal transduction and we have been using the Folded gastrulation (Fog)-concertina (cta) signaling pathway as a model. During gastrulation, the secreted protein Fog causes epithelial sheet remodeling by inducing the presumptive mesodermal cells to constrict apically and internalize. The same pathway is used reiteratively throughout *Drosophila* development to induce actin and myosin based cell shape changes. Our lab has developed a cell culture based assay to study the components of this pathway. S2R+ cells, but not S2 cells, respond to exogenously added Fog protein by forming an acto-myosin contractile ring. RNAi-mediated depletion any of the known Fog-cta pathway components blocks the ability of S2R+ cells to contract in response to Fog. We conducted a targeted RNAi screen to identify any *Drosophila* G-protein coupled receptors (GPCRs) involved in this pathway and identified a single orphan GPCR which is necessary for Fog-induced contractility in S2R+ cells. We have named this receptor Mesoderm-invagination signal transducer (Mist). Moreover, we found that this receptor is sufficient to confer Fog-responsiveness to normally unresponsive S2 cells. Mist is expressed in a stripe along the ventral side of the embryo prior to gastrulation corresponding to the ventral furrow primordium and is enriched apically during cellular constriction. Mist is also concentrated in epithelial furrows in larval imaginal discs. RNAi and overexpression of Mist in these tissues phenocopy similar genetic disruptions of known Fog pathway components. Further, reduction of Mist by RNAi rescues the embryonic lethality of ubiquitous Fog overexpression. We are in the process of creating a Mist genetic mutant for analysis. Our data suggest that Mist is a key signaling molecule that participates in epithelial remodeling events throughout *Drosophila* development.

Exploring fc20, a Drosophila Eggshell Protein That Exhibits Prion-Like Behavior.

T. N. Harvey[1], G. L. Waring[1]; [1]Biological Sciences, Marquette University, Milwaukee, WI

Extracellular matrices are highly organized networks that not only provide mechanical strength to tissues but also serve as repositories for secreted molecules that regulate a variety of cellular processes. We are studying a highly specialized extracellular matrix, the Drosophila eggshell, to gain insight into how the assembly of such complex molecular networks is controlled *in vivo*. Largely proteinaceous, the eggshell consists of morphologically distinct layers that include an oocyte proximal vitelline membrane (VM) and an outer tripartite endochorion. Vitelline

membrane proteins are secreted during the early stages of eggshell formation (stages 9-10) and several possess hallmarks of the 38 amino acid signature VM domain. Endochorion proteins, characterized by their high glycine content, are secreted during the mid (stages 12-13) and late (stage 14) phases of eggshell formation. Located within a VM gene cluster, fc20 is expressed during stage 10, contains a VM domain, and consists largely of the repeating pentapeptide FGGPG. To investigate fc20, a His-tagged fc20 transgene was created. Western blot analyses revealed that fc20 undergoes N-terminal cleavage during stage 12. Interestingly, the Western signal from the C-terminal derivative is much more intense than the fc20 proprotein. Using immunofluorescence confocal microscopy and anti-histidine antibodies, a faint fc20 signal was detected surrounding the oocyte. A transient, but much more pronounced signal was observed in the anterior of stage 12 egg chambers, the region where endochorionic respiratory appendages form. This localization pattern is distinct from sV23, a major VM protein, but similar to s36, an early endochorion protein. These results suggest that despite possessing the signature VM domain, fc20 likely functions in endochorion morphogenesis. Taken together, we hypothesize that while made during the period of VM formation, fc20 is sequestered in an aggregated or largely insoluble form until the early phases of chorion formation when it is cleaved to its soluble C-terminal derivative. The effect of premature removal of the fc20 N-terminus on eggshell assembly, fc20 solubility, and fc20 localization is currently being investigated using a his-tagged fc20 transgene in which the region encoding the putative N-terminal prodomain has been deleted.

687

RapGAP9 regulation of morphogenesis and development in *Dictyostelium.*

H. Mun[1], T. Jeon[1]; [1]Chosun University, Gwangju, Korea

The small GTPase Rap1 is involved in the control of diverse cellular processes, including integrin-mediated cell adhesion, cadherin-based cell-cell adhesions, cell polarity formation, and cell migration. Recent reports have demonstrated the importance of Rap1-specific GTPase-activating proteins (GAPs) in the spatial and temporal regulation of Rap1 activity during cell migration and development in Dictyostelium. Here, we identified another Rap1 GAP-domain containing protein by bioinformatic search of Dictyostelium database and temporarily referred to as RapGAP9. The putative Rap1 GAP domain of RapGAP9 showed high sequence homology with those of other GAP-domain containing proteins in other organisms, 45.8% and 41.1% sequence identities with those of human Rap1GAP and Dictyostelium RapGAP3, respectively, which mediates the deactivation of Rap1 at the late mound stage of development. To further investigate the functions of RapGAP9, we prepared rapGAP9 null cells by homologous recombination and found that RapGAP9 is required for proper development and morphogenesis processes. Loss of RapGAP9 resulted in a slightly delayed development and an altered morphology of fruiting body with a shorter length of stalk and spore. In the vegetative stage, rapGAP9 null cells are more flattened and spread than wild-type cells and displayed a small increase of cell-substratum attachment, compared to wild-type cells. These data suggest that RapGAP9 is involved in cell adhesion and multicellular development. Localization assay showed that RapGAP9 localizes to the cell cortex and the protruding region in moving cells. Upon chemoattractant stimulation, RapGAP9 transiently and rapidly translocated to the cell cortex from the cytosol.

ADAM13-regulated Wnt activity is required for Xenopus eye development.

S. Wei[1], G. Xu[2], L. Bridges[3], T. Nakayama[4], R. Grainger[4], J. White[2], D. DeSimone[2]; [1]Biology, West Virginia University, Morgantown, WV, [2]Cell Biology, University of Virginia, Charlottesville, VA, [3]Biochemistry and Molecular Biology, East Carolina University, [4]Biology, University of Virginia

Pericellular proteolysis by ADAM family metalloproteinases has been widely implicated in cell signaling and development. We recently found that *Xenopus* ADAM13, an ADAM metalloproteinase, plays an essential role in activation of canonical Wnt signaling during cranial neural crest (CNC) induction by regulating a novel crosstalk between Wnt and ephrin B (EfnB) signaling pathways. In the present study we show that the metalloproteinase activity of ADAM13 is required for normal eye development in *X. tropicalis*. Knockdown of ADAM13 results in reduced expression of eye field markers *pax6* and *rx1*, as well as that of the pan-neural marker *sox2*. Activation of canonical Wnt signaling or inhibition of forward EfnB signaling rescues the eye defects caused by loss of ADAM13, suggesting that ADAM13 functions through regulation of the EfnB-Wnt pathway interaction. Downstream of Wnt, the head inducer Cerberus was identified as an effector that mediates ADAM13 function in early eye field formation. Furthermore, ectopic expression of the Wnt target gene *snail2* restores *cerberus* expression and rescues the eye defects caused by ADAM13 knockdown. Together these data suggest an important role of ADAM13-regulated Wnt activity in eye development in *Xenopus*.

689

Reddish-violet coloration owing to novel chromatophores in the teleost fish, *Pseudochromis diadema*.

M. Goda[1], M. Ohata[2], H. Ikoma[1], Y. Fujiyoshi[1], M. Sugimoto[2], R. Fujii[2]; [1]Biophysics, Kyoto University, Kyoto, Japan, [2]Biomolecular Science, Toho University

In teleost, chromatophores had been classified into six categories, melanophores, xanthophores, erythrophores, cyanophores, leucophores and iridophores. Here, we report that the reddish-violet coloration on the diadema pseudochromis *Pseudochromis diadema* is displayed by novel chromatophores with a reddish pigment and reflecting platelets. We named the novel cells ‘erythro-iridophores’. On optical microscope, erythro-iridophores displayed two hues, red and dark violet, when viewed under ordinary transmission light and epi-illumination optics, respectively. Our electron microscope observations revealed that the erythro-iridophores constitute a single layer that is lined by the dermis of the scale. The cytoplasm of the eythro-iridophores contained stacked, very thin reflecting platelets, resembling the damsel fish-type iridophores, but no typical pigmentary chromatosomes, e.g., erythrosomes. However, our high-performance thin-layer chromatography (HPTLC) analysis of the pigment eluted from the erythro-iridophores indicated that carotenoid is the main pigment generating the reddish color. These observations and analysis suggest that there are two colorations in the erythro-iridophores, i.e., a pigmentary red coloration and an interference phenomenon of a non-ideal type on the stacked reflecting platelets. Furthermore, our physiological examinations showed that the coloration of the erythro-iridophores under epi-illumination optics changed to blue in response to a K^+-rich saline solution, but the red coloration remained under transmission light. The motile activities of the erythro-iridophores may participate in the changes in the reddish-violet shades of the pseudochromis fish. We suggest that the erythro-iridophore belongs to a new category of chromatophore.

Using zebrafish to model and characterize human fetal lethal congenital contracture syndrome 1 (LCCS1).

L-E. Jao[1], W. Folk[1], B. Appel[2], S. Wente[1]; [1]Vanderbilt University, Nashville, TN, [2]University of Colorado School of Medicine

Mutations in the gene encoding the mRNA transport factor Gle1 have been causally linked to a devastating motoneuron disease, lethal congenital contracture syndrome 1 (LCCS1). This autosomal recessive disorder is characterized by fetal immobility, multiple joint contractures, small jaws, underdeveloped lungs, and degeneration of anterior horn motoneurons. Using zebrafish as a model system, we investigated the link between Gle1 function and LCCS1 pathology. Through Ensembl database searches, we identified gle1 in the zebrafish genome as the sole orthologue of human *GLE1*. Zebrafish *gle1* and human *GLE1* share similar gene structures; both produce two isoforms through alternative splicing. RT-PCR and in situ hybridization showed that *gle1* transcripts are maternally inherited and widely expressed during zebrafish early development. To elucidate the function of Gle1 during development, we studied the consequences of Gle1 loss of function using a *gle1* insertional mutant line and the antisense morpholino knockdown strategy. Disrupting Gle1 function led to cell death in the head and spinal cord, small eyes, curved body axis, edema, underdeveloped intestine, and diminished pharyngeal arches. The mutant fish also became increasingly immotile with time and died around 5 days post fertilization. These phenotypes, characterized by pleiotropic abnormalities and immobility, parallel several key human LCCS1 syndromes. Gle1 depletion also results in motoneuron reduction and aberrant motor axon arborization. Unexpectedly, the motoneuron deficiency is caused by apoptosis of neural precursors, rather than by acute neuronal death. Mosaic analyses further indicate that Gle1 activity is required extrinsically in the environment for normal motor axon arborization. Together, our studies provide the first functional characterization of Gle1 in vertebrate development. We propose that actively dividing cells demand robust Gle1 activity to support the high metabolic rate during proliferation. Such selective vulnerability of highly proliferating cells to impaired Gle1 function is likely the common pathogenic mechanism that leads to the pleiotropic phenotypes in human LCCS1 fetuses.

691

A Gal4 enhancer trap line useful to study morphogenesis of craniofacial perichondrial cells, floor plate and dorsal midline radial gila in the zebrafish larva.

S. Nakayama[1], T. Ikenaga[1], K. Kawakami[2], K. Hatta[1]; [1]Graduate School of Life Science, University of Hyogo, Ako-gun, Japan, [2]Division of Molecular and Developmental Biology, National Institute of Genetics

Zebrafish are good models to study vertebrate development because of transparency during embryogenesis, rapid development, and availability of powerful genetic tools. Enhancer trap screening has been performed intensely, and has been used to understand zebrafish development. Here, we analyzed expression pattern of one Gal4 enhancer trap line, *SAGFF(LF)134A*, in detail, by combining with *Tg(UAS:GFP)* line. First, on craniofacial cartilages, strong GFP signals were detected in not only chondrocytes but also perichondrial cells, enveloping chondrocytes to form single-layered structure, in *SAGFF(LF)134A*, while only chondrocytes were visualized in the *Tg(-4.9sox10:GFP)* line. Lineage tracing by using a local gene activation technique (IR-LEGO system) suggested that perichondrial cells were derived from the mesenchyme in pharyngeal arches adjacent to the precursor of the chondrocytes. Secondly in the spinal cord, strong GFP signal was found in the floor plate, and later in the dorsal midline radial glia. In order to observe the changes in morphology of floor plate cells, we generated *SAGFF(LF)134A /UAS:KikGR* double transgenic fish and photoconverted a single

floor plate cells by UV irradiation. The time laps imaging revealed that the floor plate cell changed its shape from cuboidal/trapezoidal to cyathiform in 48 hours. These results indicate that the line would be useful to study morphogenesis of tissues that had not been well characterized including perichondrial cells, floor plate cells at later stages and dorsal midline radial glia in the spinal cord.

692

Turnover of signals that activate and delimit the epidermal wound reporters during *Drosophila* development.

M. T. Juarez[1], W. McGinnis[1]; [1]Univ California-San Diego, La Jolla, CA

A localized wound response promotes efficient repair mechanisms after a break in the epidermal barrier. Failure to properly coordinate an epidermal wound response impedes reepithelialization and contributes to decreased survival after injury. The single-cell epidermal layer of the *Drosophila* embryo provides an excellent system with molecular and cellular tools to dissect the components that localize the epidermal wound response. We have defined a genetic pathway that depends on *Flotillin-2*, *Src42A*, *Duox*, and *Sec24CD* to balance the activation and inhibition of transcriptional wound response genes during epidermal wound healing in the *Drosophila* embryonic epidermis. *Flotillin-2* encodes a membrane-associated protein that promotes signal localization via lipid raft formation. *Src42A* encodes a member of the Src-Kinase family of protein tyrosine kinases and facilitates signal transduction. *Duox (Dual oxidase*) provides enzymatic activity to produce hydrogen peroxide. *Sec24CD* encodes a coat protein of COPII vesicles in the ER/Golgi trafficking pathway. A widespread epidermal wound reporter can be activated by a simultaneous puncture wound and injection of specific chemical compounds. Interestingly, treatments with chemicals that inhibit lipid raft formation or Src-Kinase activity have the same wound reporter phenotype as the loss-of function mutants in *Flotillin-2* or *Src42A*. Additional experiments have shown that injection of hydrogen peroxide is sufficient to activate a widespread epidermal wound reporter, and this result complements the phenotype observed in *Duox* mutant embryos. We are currently testing double mutant combinations of *Flotillin-2, Src42A, Duox, Sec24CD*, and the chemical wound response inhibitors to establish epistatic relationships in the pathway. To determine the mechanism of wound response signal turnover, we will monitor how vesicle transport contributes to the rapid spread of transcriptionally activated epidermal wound response genes during injury. Several trafficking markers are available to track transport during wound healing of loss-of-function or gain-of-function mutant alleles and chemical treated embryos. Using *Drosophila* to determine factors that coordinate the activation and inhibition of the epidermal wound response and the signaling that occurs between cells at the site of injury brings new understanding to a complex problem faced by all multi-cellular organisms.

693

Ethanol-induced defects in zebrafish neural development.

P. Muralidharan[1], S. Sarmah[1], J. McClintick[2], H. Edenberg[2], J. Marrs[1]; [1]Biology, Indiana University Purdue University-Indianapolis, Iindianapolis, IN, [2]Biochemistry and Molecular Biology, Indiana University School of Medicine

Fetal Alcohol Spectrum Disorder (FASD) is caused by prenatal alcohol exposure, producing a spectrum of defects including facial abnormalities, sensory (visual and auditory) deficits, impaired fine motor skills and learning deficits including mental retardation. Our laboratory and others have shown that fetal alcohol syndrome can be modeled in zebrafish by ethanol exposure during early development. We hypothesized that embryonic ethanol exposure may alter the gene transcriptional profile that produces the FAS associated defects. To test that idea,

we examined the ethanol induced gene expression changes in zebrafish using Affymetrix gene microarray analyses at early and mid-gastrulation (just prior to neurogenesis) stages. Expression of multiple genes involved in neurogenesis and patterning changed significantly after ethanol exposure, e.g., Delta, Hairy- and enhancer of split-related (Her) genes, Hoxb group of genes. Consistently, ethanol treated embryos showed defects in neural plate formation, neural patterning, neural differentiation, and cranial/lateral line ganglia formation, showing defects in a dose-dependent manner. However, the mechanisms by which ethanol affects normal neurogenesis is not yet clear. Ethanol induced changes in the temporal and spatial expression pattern of the transcription factor, neurogenin1 (ngn1), a basic Helix-Loop-Helix (bHLH) transcription factor that controls initial neurogenesis steps. Quantitative PCR experiments showed that ngn1 expression in the ethanol treated embryos was reduced at gastrulation stages and was increased during neurogenesis compared to that of the control embryos. We hypothesized that ethanol affects neural patterning by competing with retinaldehyde dehydrogenase, thus impairing retinoic acid synthesis. We observed that not only the phenotypic defects but many of the neural differentiation and patterning defects induced by ethanol exposure were rescued by a co-treatment with retinoic acid in the medium. Future work focuses on dissecting the molecular mechanisms behind ethanol defects and the retinoic acid rescue on neural development. Understanding neural development mechanisms disrupted by ethanol exposure will help identify potential therapeutic targets for neural defects in FAS.

694

Effects of Ethanol and Folate on Peripubertal Mouse Mammary Gland.

P. A. Masso-Welch[1], M. E. Tobias[2], S. C. Vasantha Kumar[2], J. Tamburlin[2], S. T. Koury[2];
[1]Biotechnical and Clinical Lab.Sciences, University at Buffalo, Buffalo, NY, [2]University at Buffalo

Alcohol consumption has been clearly linked with increased breast cancer risk in women, with risks incurred even at low levels of consumption. The proposed mechanisms whereby ethanol exerts its effects include decreased folate levels and diminished DNA repair capacity, coupled with acetaldehyde-generated DNA damage. Based on these proposed mechanisms, we hypothesized that ethanol would have increased deleterious effects during periods of rapid mammary gland epithelial proliferation, such as peripuberty. We also hypothesized that folate deficiency alone might mimic the effects of ethanol, and that folate deficiency would exacerbate the effects of ethanol. CD2/F1 female mice (N=8 per group) were pair-fed control and ethanol-containing liquid diets +/- 0.2g/L folate supplementation from 5 weeks until 9 weeks of age. Mice were sacrificed after this 4 week feeding regimen, and mammary glands were harvested for preparation of whole mounts and paraffin sections. Folate levels of liver and kidney were assessed to verify folate status. Analysis of mammary gland whole mounts revealed that mammary gland structure was significantly altered in folate-replete mice fed ethanol, compared to control-fed mice (no ethanol/ folate-replete). These ethanol/folate replete mice showed an increased total number of ductal branches, due to an increased number of terminal short branches; no effect was seen on the number of terminal end buds or primitive alveolar buds. Systematic histological analysis of paraffin sections using NIH Image J software revealed that diets containing ethanol in the presence of folate significantly increased the total number of ducts, ductal epithelial area, and number of ducts with epithelial multilayering. Serum estradiol was increased by ethanol feeding, only in mice that were folate replete. These results demonstrate that folate deficiency alone does not mimic the effects of ethanol, and that folate deficiency in the presence of ethanol blocks proliferative effects of ethanol on the mammary ductal tree. Future studies are examining the effects of peripubertal ethanol and folate exposure on gene expression in the mouse mammary gland.

695

Beta-parvin mediates integrin-cadherin cross talk during *Xenopus* gastrulation.

C. Studholme[1], M. Marsden[1]; [1]Biology, University of Waterloo, Waterloo, ON, Canada

During *Xenopus* gastrulation cell rearrangements that drive axial extension require interactions between α5β1 integrin and fibronectin (FN). While FN ligation is essential one of the proposed roles for integrin adhesion is the modulation of cadherin activity. While this receptor cross talk has been well described the mechanisms underlying the modulation of cell adhesion remain elusive. We have characterized the integrin associated adapter protein beta-parvin in Xenopus. In early Xenopus embryos beta-parvin mRNA is expressed maternally and following zygotic expression is enriched in tissues that undergo integrin-mediated cell movements. Expression of dominant negative constructs indicate that beta-parvin is essential for both FN assembly as well as the cell rearrangements that characterize gastrulation. The N-terminal CH domain of beta-parvin (RP1) enables integrin-mediated adhesion and migration on FN in vitro. Significantly, when expressed in vivo this domain can rescue convergent extension in the absence of FN. Over-expression of RP1 results in an increase in Rac activity that is essential for cell intercalations. Conversely, the C-terminal CH domain (RP2) promotes cadherin mediated cell-cell adhesion, while negatively effecting integrin adhesion. We propose that beta-parvin is in a pathway upstream of both integrin and cadherin and mediates receptor cross-talk through the Rho family of GTPases.

696

***Trim25-like* is required for epithelial development in zebrafish.**

C. D. Bryan[1], G. T. Eisenhoffer[1], J. Rosenblatt[1]; [1]Oncological Sciences, Huntsman Cancer Institute, Salt Lake City, UT

The establishment and maintenance of an epithelium is critical for its function as a barrier, yet relatively little is known about the genes that regulate epithelial development and cellular turnover. The epidermis of the developing zebrafish is a bilayer and serves as an excellent model to study many epithelial bilayers that coat mammalian organs. Here, we identify the *Trim25-like* gene in zebrafish as an important regulator of epidermal development. In humans, TRIM25 is over-expressed in many breast tumors and like other members of this tripartite motif (TRIM) family of proteins, it contains a RING domain with E3 ubiquitin ligase activity and is a putative transcription factor. Loss of *Trim25l* in developing zebrafish causes shedding of epithelial cells and leads to an early larval death. To determine how these epithelial cells are expelled, we examined the actin cytoskeleton and markers of cell death in the periderm and basal layer and find that many of the peridermal cells are shed alive and not through apoptotic cell extrusion. Moreover, many of the remaining cells are binucleate, suggesting that these cells have a problem progressing through cell division. Injection of full length RNA encoding *Trim25l* results in rescue of both the binucleate and cell shedding phenotype. Conversely, overexpression of *Trim25l* in wild-type animals leads to a disorganized epidermis and the formation of epithelial cell masses. To identify potential downstream targets regulated by *Trim25l*, we compared the expression profiles of wild-type and *Trim25l* mutant zebrafish. Our microarray analyses identify several genes that control both cell adhesion and the extracellular matrix. This data will help us uncover the role of *Trim25l* in the development of a functional epidermis and how over-expression of a related gene in mammals may contribute to epithelial cell transformation.

697

The EXC-1 GTPase regulates endosomal trafficking to maintain tubule shape in the C. elegans excretory canal.

K. Grussendorf[1], M. Buechner[1]; [1]Molecular Biosciences, University of Kansas, Lawrence, KS

Tubulogenesis involves the formation and regulation of tubule shape and diameter along both the apical (lumenal) and basal sides. Once the tubule shape is formed this structure then needs to be regulated and maintained. The *C. elegans* excretory canal provides a simple model to study these processes. The excretory canal is a single-cell tube that is located near the terminal bulb of the pharynx, which extends two hollow processes to the left and right lateral side of the worm, where they bifurcate and extend anteriorly and posteriorly to form an H-shaped structure. Our lab focuses on the set of *exc* genes that are involved in maintaining the structure of the apical surface of the canal. Mutations in the *exc* genes allow formation of fluid-filled cysts in the lumen of the canal.

The Exc-1 loss-of-function (lof) phenotype shows cysts in the canals that are often located at the ends of the canal. These cysts vary in size and number; from cysts not much wider than normal lumen up to cysts expanded to the entire diameter of the worm. We have cloned the *exc-1* gene, which encodes a homologue of the RAS GTPase family, specifically the family of Interferon Inducible GTPases (IIGP). This protein is expressed in the canals, and also in the *C. elegans* amphid sheath, a glial structure that ensheaths the amphid neuron sensory endings.

The Exc-1 gain-of-function (gof) phenotype, created by overexpression of *exc-1*, forms a tubule with a normal apical surface but is defective in the formation of the basal surface, a phenotype seen with other *exc* genes when overexpressed (*exc-5* and *exc-9*). EXC-1 shows genetic interactions with these other members of the *exc* family; genetic studies suggest that EXC-1 acts downstream of the EXC-9 LIM domain protein, and upstream of the EXC-5 guanine exchange factor. *exc-1* (lof) mutants also shows similar subcellular disruption of subcellular trafficking markers EEA-1 and RME-1 within the excretory canals. These results suggest that EXC-1 acts together with EXC-5 to allow efficient movement from early endosomes to recycling endosomes. We are using yeast two-hybrid assays to assess binding of EXC-1 to possible target proteins.

Diameter and rigidity of multi-walled carbon nanotubes are critical factors in mesothelial injury and carcinogenesis.

H. Nagai[1], Y. Okazaki[1], S. Chew[1], N. Misawa[1], Y. Yamashita[1], S. Akatsuka[1], T. Ishihara[1], K. Yamashita[1], Y. Yoshikawa[2], H. Yasui[2], L. Jiang[1], H. Ohara[1], T. Takahashi[3], G. Ichihara[4], Y. Miyata[5], H. Shinohara[5], S. Toyokuni[1]; [1]Department of Pathology and Biological Responses, Nagoya University, Nagoya, Japan, [2]Department of Analytical and Bioinorganic Chemistry, Kyoto Pharmaceutical University, Kyoto, Japan, [3]Department of Molecular Carcinogenesis, Nagoya University, [4]Department of Occupational and Environmental Health, Nagoya University, [5]Department of Chemistry and Institute for Advanced Research, Nagoya University

Multi-walled carbon nanotubes (MWCNTs) have potential for widespread applications in engineering and materials science. However, due to their needle-like, nanoscale shape and

high durability, concerns have been raised that MWCNTs of certain characteristics may induce asbestos-like pathogenicity. Even though recent studies have demonstrated various types of reactivities induced by MWCNTs, the physicochemical features of MWCNTs that determine or trigger the cytotoxicity and carcinogenicity in mesothelial cells remain unclear. Here we show that the deleterious effects of non-functionalised MWCNTs on human mesothelial cells are associated with their diameter-dependent piercing of the cell membrane. Thin MWCNTs with high crystallinity (ƒÓ ~ 50 nm) showed mesothelial cell piercing and cytotoxicity in vitro and subsequent mesotheliomagenicity in vivo. In contrast, thick (ƒÓ ~ 150 nm) or tangled MWCNTs (ƒÓ ~ 2-20 nm) were much less toxic and carcinogenic, whereas all MWCNTs affected macrophages similarly. This work suggests that control of the diameter of MWCNTs may contribute to reduce the risks to human health.

Comparative studies of matched normal and cancer lung cells reveal multiple events underlying tumor cell growth and hypoxia responses.

D. Cadinu[1], X. Yao[1], M. Alam[1], X. Ma[1], R. Henke[1], M. Zhang[1], L. Zhang[1]; [1]Molecular and Cell Biology, Center for System Biology, University of Texas at Dallas, Richardson, TX

Hypoxia is a common and often cure-limiting characteristic of malignant tumors. Understanding the responses of tumor and normal lung cells to hypoxia can provide important insights into the molecular mechanism underlying uncontrolled tumor cell growth and therapeutic resistance. Lung cancer remains the leading cause of cancer death in the US and worldwide. Studies of lung cancer cells to hypoxia are important for understanding and treatment of lung cancer. Hence, we decided to perform comparative studies of a matched pair of normal and lung cancer cell lines. These cell lines, the normal lung cell line HBEC30, and the cancer lung cell line HCC4017, were previously established by Drs. Minna and White's labs (Whitehurst et al., 2007). We found that cancer and normal cells respond to hypoxia differentially. Additionally, a genome-wide analysis of DNA methylation patterns shows that in response to hypoxia, a segment of DNA containing an array of genes such as FBXO25 and MYOM2 are preferentially methylated in cancer cells, but not in normal cells. Metabolomic and proteomic experiments are underway to characterize the molecular events underlying the differential responses of cancer and normal cells to hypoxia.

700

Gene expression profile of human prostate cell lines (+/-CD82) through microarray analysis.

P. Dodla[1], C. Miranti[2], S. Sridhar[3]; [1]Cell and Molecular Biology, Grand Valley State University, [2]Lab of integrin signaling &tumorigenesis, VanAndel Research Institute, [3]Biomedical Sciences, Grand Valley State University, Allendale, MI

KAI1/CD82, a member of tetraspanin super family, is a prostate tumor metastasis suppressor gene. During metastasis progression, CD82 expression is either decreased or completely lost. CD82 loss has also been identified in other cancers including cancers of the esophagus, colon, cervix, breast, skin, bladder, lung, pancreas, liver and thyroid. The exact mechanism by which CD82 regulates metastasis suppression is still unclear.

Previous studies performed in our lab, with Agilent Microarray technology on prostate cancer cell lines PC3 5V (- CD82) and PC3-29 (+CD82), have identified genes regulated by CD82. Alternatively, we performed microarrays on normal prostate cell lines (PEC 31) with or without CD82, along with another set of tumor cells PC3-5V (-CD82) and PC3-57 (+ CD82) to compare and further validate the results observed from our previous arrays. The top 100 most common

and significant genes from all three arrays were compared and the 20 most significant genes have been grouped based on the role they play in the cell. Out of these, the top ten genes identified to be involved in metastasis are currently being validated by qPCR and RT-PCR protocols. The results from these studies will allow us to identify the genes and/ proteins regulated by CD82. This will allow us to further identify the pathways and downstream signaling molecules involved and decipher a role for CD82 in metastasis tumor suppression.

701

Functional validation of candidate colon cancer genes identified by a Sleeping Beauty transposon based forward genetic screen.

L. Zhao[1], T. Starr[2], D. Largaespada[3], R. Cormier[1], P. Scott[1]; [1]Department of Biomedical Science, University of Minnesota Duluth, Duluth, MN, [2]Department of Obstetrics, Gynecology and Women's health, University of Minnesota, Minneapolis, MN, [3]Department of Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN

Objective: Sleeping Beauty (SB) Transposon-based forward genetic screens identified Cnot1 and Cnot2, subunits of CCR4-NOT complex, as candidate colon cancer-causing genes. The principal objective of this study is to determine if alteration of these genes results in oncogenic phenotypes in vitro. CNOT1 and CNOT2 participate in multiple CCR4-Not complexes with multiple functions. One function implicated in cell cycle regulation is deadenylation leading to degradation of specific target mRNAs. So a second goal is to determine if the mechanism underlying CNOT1 and CNOT2's effects on cell viability is mediated via deadenylation. Methods: Human homologs of candidate cancer genes CNOT1 and CNOT2 and genes encoding potential interactors, CNOT6L, CNOT8 and ZFP36 were knocked-down by siRNA in SW480 colon cancer cell line. Knockdown was validated by qRT-PCR. Cell viability was measured by MTT assay. mRNA levels of two potential target genes, CDKN1B (P27KIP1) and CDX2, were determined by qRT-PCR. Results: siRNA transfection resulted in ~ 60% knockdown of CNOT1 and CNOT2 mRNA levels and depletion of each of these two genes led to ~70% reduction in SW480 cell viability, suggesting that genetic alteration may cause them to act as oncogenes. To begin to test whether CNOT1 and CNOT2's effects on cell viability are mediated by deadenylation, we examined mRNA levels of two deadenylation targets, CDKN1B and CDX2. CDKN1B and CDX2 mRNA levels are increased by 1.5 and 2.5-fold respectively in CNOT1-depleted but not CNOT2-depleted cells. As a further test of the role of deadenylation, CNOT1-interacting proteins known to contribute to deadenylation, ZFP36, CNOT6L and CNOT8, were evaluated to determine if they share a common phenotype with CNOT1. mRNAs encoding these proteins were knocked-down by siRNA. Cell viability, and CDKN1B and CDX2 mRNA expression were evaluated. Cell viability in ZFP36, CNOT6L and CNOT8-depleted cells was reduced by 40%, 60% and 70%, respectively. Depletion of ZFP36, CNOT6L and CNOT8 resulted in an increase of the relative levels of CDKN1B mRNAs by 1.5, 1.7 and 1.3-fold respectively. Interestingly, knockdown of ZFP 36 and CNOT8 resulted in 1.5 and 1.8-fold increases of CDX2 transcripts but a 40% decrease in CNOT6L depleted cells. Conclusion: These results suggest that CNOT1 and CNOT2 may contribute to oncogenesis in colon cancer and suggest a model in which CNOT1 works in complexes to regulate the mRNA level of some genes by deadenylation. For example, CNOT1, CNOT6L, CNOT8 and ZFP36 may work together to regulate the level of CDKN1B while CNOT1, CNOT8 and ZFP36 may regulate the level of CDX2. To test these models the deadenylation function of these complexes and physical interaction of subunits will be investigated in future work.

702

Paclitaxel treatment is associated with reduced or inactive micro-RNAs in breast cancer MCF7 cells.

S. Lobert[1], K. Morris[2], B. Jefferson[1]; [1]School of Nursing, University of MS Medical Center, Jackson, MS

Antimitotic agents, such as paclitaxel, that are commonly used in chemotherapy protocols, target β-tubulins and halt cell cycle progression in G2/M phase. Paclitaxel stabilizes microtubules in mitotic spindles and increases in β-tubulin class III have been associated with resistance to paclitaxel, possibly due to its ability to reduce microtubule stability. We found that 40nM and 400nM paclitaxel treatment induce an increase in both β-tubulin classes IIA and III mRNA. Because micro-RNAs are known to regulate mRNA levels, we investigated changes in micro-RNAs associated with paclitaxel treatment using micro-RNA arrays. Four micro-RNAs were upregulated (200c, 191, 92a and 203)and three were downregulated (100, 146a and 138). We have previously reported regulation of β-tubulin classes I, IIA, IIB and V by micro-RNA 100, one of the down-regulated micro-RNAs [Lobert et al., *Cytoskeleton* (2011). 68:355-362]. One of the upregulated micro-RNAs miR-200c is predicted to target β-tubulin classes I, IIA and III. We found that MCF7 cells transfected with miR-200c had significantly reduced levels of β-tubulin classes I, III and IVb. MiR-200c is regulated by the zinc finger repressor protein ZEB1. Furthermore, ZEB1 mRNA is a target of miR-200c. We found that ZEB1 increases with 40 nM and 400 nM paclitaxel treatment. These data together indicate that, although miR-200c increases 40-fold with paclitaxel treatment, this micro-RNA is inactive, possibly due to impaired export from the nucleus. β-tubulin isotypes are suggested to be biomarkers for cancer patient survival and clinical disease progression. These data suggest that changes in β-tubulin isotypes in response to treatment with paclitaxel may be surrogates for changes in activity of micro-RNA tumor suppressors.

703

Validation of candidate gastrointestinal cancer genes with ion channel functions, identified from Sleeping Beauty transposon-mediated mutagenesis screens in mice.

B. L. Than[1], T. K. Starr[2], D. A. Largaespada[3], R. T. Cormier[1], P. M. Scott[1]; [1]Department of Biomedical Sciences, University of Minnesota Medical School, Duluth, MN, [2]Department of Obstetrics, Gynecology and Women's Health, University of Minnesota Medical School, Minneapolis, MN, [3]Department of Genetics, Cell Biology and Development, Masonic Cancer Center, University of Minnesota, Minneapolis, MN

Colorectal cancer (CRC) is the second leading cause of cancer-related deaths in the US. To identify the genetic alterations contributing to CRC, our labs have used Sleeping Beauty (SB)-transposon-mediated mutagenesis screens in *Apc*$^{+/+}$ and *Apc*^{Min} mice. These screens have identified a set of common insertion site (CIS) associated candidate cancer genes, that when dysregulated, may contribute to CRC development. Depletion of several CIS genes identified from the SB screen in *Apc*^{Min} mice resulted in a significant decrease in human CRC cell viability. The SB screen in *Apc*$^{+/+}$ mice has generated a list of CIS genes including two ion-channel encoding genes: *Kcnq1* (potassium voltage-gated channel, KQT-like subfamily, member 1) and *Cftr* (cystic fibrosis transmembrane conductance regulator, ATP-binding cassette sub-family C, member 7) which act together to promote chloride ion secretion in the normal colon. We hypothesize that these candidate genes, when dysregulated, contribute to the development of CRC. The function of the candidate genes is being tested in a mouse model of *Kcnq1* haploinsufficiency that was introgressed into the *Apc*^{Min} model of GI cancer and in human CRC cell line DLD-1. In the mouse model, *Kcnq1* expression is abrogated by targeted germline mutagenesis, resulting in a null allele. In cell culture, expression of each candidate gene is

depleted by siRNA knockdown, confirmed by quantitative real time PCR and followed by measurements of cancer-related phenotypes which include cell viability measured by the MTT assay. We found that *haploinsufficiency* for *Kcnq1* significantly enhances *tumorigenesis* in Apc^{Min} mice. In support of this result, a 60% knockdown of *KCNQ1* in DLD-1 cells resulted in ~1.4x increase in cell viability, compared with a control siRNA treatment at day seven after transfection. The normal physiological functions of *KCNQ1* indicate it may work with *CFTR* to prevent inflammation in the GI tract, thus suggesting that loss of *KCNQ1* or *CFTR* may be oncogenic via an inflammatory mechanism. To begin testing this idea, colon tissues of $Kcnq1^{+/+}$ and $Kcnq1^{-/-}$ mice were compared for expression of the inflammatory mediator *Nfkb*. *Nfkb* mRNA level was increased by ~1.6x in $Kcnq1^{-/-}$ mice. To begin testing the potential connections between *KCNQ1* and *CFTR*, *CFTR* was successfully depleted by 40% in DLD-1 cells and the effect on cell viability and inflammatory mediators' expression is being determined. In summary, our results of both *in vivo* and *in vitro* studies confirm a tumor suppressor role for *KCNQ1* in the GI tract. Current work is focused on investigating the model that genetic alterations of *KCNQ1* and *CFTR* promote oncogenesis by a common pathway, possibly by an inflammatory mechanism.

704

Understanding the mechanistic basis for genetic redundancy of the Retinoblastoma protein in C. elegans.

D. Fay[1]; [1]Molecular Biology, University of Wyoming, Laramie, WY

Our laboratory has been largely focused on understanding the developmental and cellular functions of the Retinoblastoma protein (pRb) ortholog in C. *elegans*, LIN-35. In contrast to the mammalian and fly systems, loss of LIN-35 function in C. elegans leads to only subtle developmental defects and *lin-35* homozygous mutant worms are viable and fertile. We have exploited this lack of overt phenotype to screen for mutations that show strong phenotypic effects when combined with loss of *lin-35*. More specifically, we have used synthetic-lethal screening approaches to identify genes whose functions overlap with those of *lin-35*. In doing so, we have discovered a number of distinct functions for LIN-35/pRb within the context of C. *elegans* development. In addition, we have sought to mechanistically link LIN-35/pRb activities to those of the identified synthetic-lethal mutant protein products. This approach has led to the elucidation of several different regulatory networks in which LIN-35/pRb participates to control diverse aspects of development. Implicated functions for LIN-35/pRb include roles in cell fate decisions, morphogenesis, organ function, and cell proliferation. Our poster will summarize some our studies reported over the past ten years and discuss how our findings may have relevance to the roles of pRb as a tumor suppressor in humans.

705

Characterization of the Role of L.4.1 in Growth Suppression in a Drosophila melanogaster model.

E. D. Chambers[1,2], J. Kagey[2], K. Moberg[2]; [1]Biology, North Carolina Agricultural and State University, Greensoro, NC, [2]Cell Biology, Emory University School of Medicine, Atlanta, GA

Drosophila melanogaster is a powerful genetic model for studying of cancer cell pathways and tumor suppressor genes. The six hallmarks of cancer are self-sufficiency in growth signals, insensitivity to growth-inhibitory signals, evasion of apoptosis, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis. Genetic manipulation in *D. melanogaster* allows for the rapid identification and characterization of genes involved in these six key processes. Our group recently identified *L.4.1* as a novel homozygous recessive point mutation that produced overgrowth phenotypes by blocking apoptosis in the adult mosaic eye of

D. melanogaster. The studies utilize a conditional growth suppressor screen that used a block in cell death. Combined use of *D. melanogaster* and inactivation of the apoptosis pathway through mutations in the *dark[82]* gene makes it possible to observe phenotypes from novel homozygous recessive point mutations in flies that would otherwise induce apoptosis. The objective for the present study was to characterize the role of *L.4.1* in cell growth regulation, mitosis, and differentiation pathways through genetic mosaics. Specific protein markers were used to analyze differences in the described pathways between mutant and wild-type L.4.1 eye discs. Confocal microscopic analysis was used for illumination of specific protein levels between mutant and GFP marked homozygous wild type tissue within the mosaic eye. Compared to wild-type, *L.4.1* mutants had a significant decrease in DIAP staining, suggesting that mutant *L.4.1* overgrowth is conditional upon a block in apoptosis. Clones of *dark[82]*, *L.4.1*, and eye discs entirely mutant for *dark[82], L.4.1* demonstrated a significant delay in differentiation. This was confirmed by a corresponding decrease in the Elav protein; a marker for cell differentiation. This data suggests that the delay in differentiation has a correlation with prolonged cellular proliferation within the cell. The *D.melanogaster* genome contains many human orthologs which function in similar cellular pathways and processes. Genetic mapping of the L.4.1 gene could thus be a valuable tool in studying genes that play a role in the development of human cancer.

706

Defining novel pathways that arrest genetically unstable tetraploid cells.

N. J. Ganem[1], K. P. O'Rourke[1], K. Lundquist[1], D. Pellman[1]; [1]Pediatric Oncology, Dana-Farber Cancer Institute, Harvard Medical School, Howard Hughes Medical Institute, Boston, MA

Tetraploid cells, which are a common byproduct of cell division failures, are genetically unstable and have the capacity to facilitate tumorigenesis. Consequently, p53-dependent tumor suppression mechanisms exist to limit the continued proliferation of these cells by promoting G1 cell cycle arrest. However, unlike other common cellular insults that activate p53 and promote G1 arrest, such as the DNA damage response, the mechanisms governing G1 arrest in response to tetraploidy remain largely unexplored. To gain insight into these mechanisms, we have developed a novel genome-wide RNAi screening assay to comprehensively identify proteins that are necessary to activate or maintain G1 cell cycle arrest after the induction of tetraploidy. Results from this screen, in combination with complementary bioinformatic approaches, have begun to illuminate the nature of the stresses associated with tetraploidy. More importantly, this work sheds light on the adaptive mechanisms that near-tetraploid tumors have evolved in order to overcome these stresses. These findings have the potential to lead to the identification of new pathways that can be targeted by chemotherapeutics to specifically reinforce G1 arrest in grossly aneuploid cancer cells.

707

Mir-301b modulates proliferation, invasion and cancer stem cell differentiation through the inhibition of multiple RNA targets.

M. A. Duhagon[1,2], E. Hurt[3], J. R. Sotelo-Silveira[4,5], R. Fort[1,2], X. Zhang[6], W. L. Farrar[6]; [1]Laboratorio de Interacciones Moleculares, UDELAR- Facultad de Ciencias, Montevideo, Uruguay, [2]Genética, UDELAR-Facultad de Medicina, Montevideo, Uruguay, [3]NCI-Frederick Oncology, NCI-Frederick, Frederick, Uruguay, [4]Biología Celular y Molecular, UDELAR- Facultad de Ciencias, Montevideo, Uruguay, [5]Genética, IIBCE, Montevideo, Uruguay, [6]LCP- Cancer Stem Cell Section, NCI-Frederick, Frederick, MD

MicroRNAs modulate gene expression through their complementary binding to untranslated 3' UTRs of specific mRNAs, which leads to the reduction of their mRNA stability and translation. Due to the widespread action, microRNAs have been involved in all cellular processes,

including stem cell biology and cancer. Cancer stem cells (CSCs) are a subpopulation of cells found in most type of solid and circulating tumors. They express several embryonic stem cell properties (gene expression programs, low differentiation, self renewal ability, multipotency) in comparison to the rest of the tumor cells, being the only cells capable of initiate a tumor in mice xenografts. They have become a major clinical issue in cancer because they greatly increase the invasion and chemoresistance potential of the tumor.
We thought to investigate the role of microRNAs in prostate CSC differentiation. We used an in vitro model of prostatospheres (PS) from prostate cell lines (DU145, LNCaP) grown in stem cell medium and induced to differentiate by exposure to serum. Gene expression analysis and tumor xenograft data presented here support our model. In order to study microRNAs differentially expressed during differentiation we extracted ARN from cells prior and after differentiation and we performed competitive hybridization on microRNA arrays. We found out that mir-301b is downregulated upon differentiation. Indeed, its overexpression significantly inhibits in vitro differentiation. Mir-301b is a conserved microRNA located in an intronic region of PPIL2 gene at cr22q11.21. It belongs to the gene family of mir-130a, mir-130b and mir-301a. It is expressed in most of the established prostate cell lines, showing an increased expression which correlates with cell line aggressiveness.
We then investigated the influence of mir-301b in several CSCs properties. We found that mir-301b is overexpressed in the CSCs subpopulation, reduces cell proliferation and greatly increases cell invasion. In order to study the genes modulated by this microRNA we performed global gene expression analysis of cells overexpressing mir-301b. We discuss pathways and genes modulated by this microRNA. For the downregulated genes that have a predicted mir-301b pairing sequence, we analyzed RNA levels and protein expression in large prostate cancer studies (“mir-301b activity”). That allowed as selecting a set of clinically relevant candidate direct targets. We present and discuss the significance of the data.

708

Brahma regulates malignant transformation through the modulation of stromal-epithelial interactions.

L. Damiano[1], K. M. Stewart[1], J. M. Zape[1], J. K. Mouw[1], J. N. Lakins[1], J. Debnath[2], J. Nickerson[3], V. M. Weaver[1]; [1]Department of Surgery and Center for Bioengineering and Tissue Regeneration, University of California San Francisco, San Francisco, CA, [2]Department of Pathology, University of California San Francisco, [3]University of Massachusetts Medical School

Cell-extracellular matrix (ECM) binding through integrins activate signaling processes that control cell differentiation, proliferation and survival. Integrin expression and activity are key regutators of tumor progression. In particular, the α5β1 integrin and its ligand fibronectin are overexpressed in invasive cancers. However, the molecular basis for altered α5 integrin levels during malignant transformation remains an area of active investigation. We found that α5 integrin and fibronectin are upregulated following growth factor and Ras trasnsformation of mammary epithelial cells. In the same cells the Brahma (BRM) subunit of the SWI/SNF chromatin remodeling complex is downregulated. Given that studies have suggested that the SWI/SNF chromatin remodeling protein Brg1 alters the expression of α5 integrin, we investigated the relationship between oncogenic transformation, BRM and integrin α5. Using α5 integrin blocking antibodies, we found that oncogene-driven transformation in the non-malignant mammary epithelial MCF10A cell line depends upon increased expression of the α5 integrin subunit, as assessed by growth in three dimensional (3D) reconstituted basement membrane (rBM). Interestingly, expression levels of the Brahma (BRM) catalytic subunit of the chromatin remodeling complex were inversely correlated with α5 integrin expression. Provocatively, loss of BRM caused the rapid and specific upregulation of α5 integrin and the acquisition of a premalignant phenotype as observed by pronounced luminal filling of 3D organoids by

immunofluorescence staining. This effect was dependent on the ATPase activity of BRM as demonstrated by the lack of reversion of malignant properties by an ATPase defective BRM mutant. Decreased BRM expression was observed in aggressive breast cancer cell lines. Furthermore, the ectopic expression of BRM in the transformed MCF10A-ErbB2 and MCF10A-RasV12 cell lines partially reverts their malignant phenotype in 3D rBM growth through decreased α5 integrin expression. Taken together, our data suggest that BRM may act as a tumor suppressor by modulating ECM-epithelial interactions and tumor cell transformation through the expression of the α5 integrin subunit.

709

A putative oncogene, SWAP-70, a Phosphatidylinositoltrisphosphate Binding Protein Involved in Cell Motility.

Y. Fukui[1], C-L. Shu[1], S. Ihara[2]; [1]National Health Research Institute, Zhunan town, Taiwan, [2]Tokyo University, Japan

SWAP-70, a phosphatidylinositol trisphosphate (PtdIns(3,4,5)P3) binding protein, has been suggested to be involved in transformation of mouse embryo fibroblasts (MEFs) as well as membrane ruffling after growth factor stimulation of the cells. A mutant, SWAP-70-374, was found to be able to bind to F-actin in vitro, whereas wild-type SWAP-70 failed to do so. This mutant was present at the plasma membrane without any stimulation while the wild-type protein was present only in the cytosol unless cells were stimulated with EGF. Expression of this mutant in MEFs resulted in morphologic transformation, fast growth, and loss of contact inhibition, suggesting that SWAP-70 with this mutation can transform the cells. ERK1/2 was activated in SWAP-70-374-transformed cells. Use of MEK inhibitors revealed that the ERK1/2 pathway does not affect the cell growth of MEFs but is responsible for loss of contact inhibition. To investigate the function of SWAP-70 further, drugs that can inhibit SWAP-70-dependent cell responses were screened. Among various drugs, sanguinarine was found to inhibit transformation of MEFs by SWAP-70-374. This drug was able to inhibit SWAP-70-mediated membrane ruffling as well, suggesting that its effect was closely related to the SWAP-70 signaling pathway. These results suggest that SWAP-70-374 can activate some signaling pathways, including the ERK1/2 pathway, to transform MEFs.
Recently, point mutations have been detected in the SWAP-70 gene of three tumors. Examination of contribution of these mutations to tumorigenesis is now underway.

710

CD44: Relationship to RANKL expression and osteoclast differentiation.

A. Gupta[1], M. Chellaiah[1]; [1]Department of Oncology and Diagnostic Sciences, University of Maryland Dental School, Baltimore, MD

The advanced stage of prostatic carcinoma eventually metastasizes to the bones in 85–100% of cases. Recent preclinical evidence suggests bone metastasis, activation of osteoclasts and increased bone resorption resulting from androgen ablation in prostate cancer patients may increase the risk of bone loss. Therefore, we used prostate cancer cell lines (PC3) originally derived from advanced androgen independent bone metastasized prostate cancer. The expression levels of osteopontin (OPN) and CD44 has been associated with the metastatic potential of several tumors. Our previous observations have indicated that osteopontin and CD44 are possible molecular biomarkers for prostate cancer progression [Desai et al., Mol. Cancer (2007), 6, 18; J Cell Biochem (2009), 108; 272]. Studies by others have shown that CD44 signaling has a role in tissue damage and bone destruction in the course of chronic inflammatory process. In view of this, we examined the role of CD44 in Receptor Activator of NF-Kappa B Ligand (RANKL) expression, osteoclast differentiation, and bone resorption. A

decrease in RANKL expression was observed in PC3 cells transduced with a TAT- fused CD44 peptide comprising the Ser323/325 amino acids as compared with PC3 cells transduced with control TAT- or scrambled peptide. Conditioned media from PC3 cells transduced with Ser323/325 CD44 peptides failed to support osteoclast differentiation. A decrease in the surface levels of CD44 was observed in these cells. These observations nevertheless provide support for the possible role of CD44 signaling in RANKL expression. Since further studies are needed to elucidate the mechanism of RANKL expression, we have generated stable PC3 cells knockdown of CD44. CD44 knockdown reduced RANKL expression in PC3 cells. RUNX2 is linked to RANKL production. CD44 knockdown reduces RUNX2 levels and hence RANKL expression in PC3 cells. We suggest that CD44 signaling may serve as a mechanism to modulate RANKL expression through RUNX2. Taken together, our observations have shed a light on the mechanism by which CD44 may promote osteoclast differentiation and bone loss; thus pointing ‘CD44’ as a valuable prognostic biomarker as well as a potential target for cancer therapy (Supported by RO1 grant by NIH-NIAMS (MAC) and T32 training grant to AG).

Synergistic Effects of Chitosan and Docosahexanoic Acid on Osteopontin Expression and Secretion in an Ovarian Cancer Cell Line, SKOV-3.

E. L. Williams[1], T. Taylor[1], A. Hicks[1], D. MaCaulay[1], D. Peterson[1], J. Stone[2], C. Kelly-Brown[2], L. Carson[2], G. C. Regisford[1]; [1]Biology, Prairie View A&M University, Prairie View, TX, [2]CARC, Prairie View A&M University

Ovarian cancer has the highest death rate of all gynecological diseases in developed countries. Current treatment for this deadly disease is surgical dubulking followed by chemotherapy or radiotherapy, but reoccurrence is still high. Hence, there is a need for alternative treatments, and more specifically a natural therapeutic product. Recent studies have shown that natural products, such as Chitosan and Omega-3 fatty acids, inhibit the proliferation of cancer cells. Chitosan is an N-deacetylated analog chitin, the second most abundant polysaccharide. Docosahexanoic acid (DHA) is an Omega-3 fatty acid and is found most exclusively in aquatic animals. Recent reports have implicated osteopontin (OPN), a cell surface and secretory glycoprotein, as an important biomarker for ovarian cancer. Therefore, the objective of this study was to determine the effect of chitosan and DHA on OPN expression levels in an ovarian cancer cell line, SKOV-3 cells. We hypothesized that chitosan and DHA will decrease OPN expression in a dose-dependent manner. To test our hypothesis, SKOV-3 cells were treated with (a) Control, (b) 250 ng/mL of chitosan, (c) 100 µM of DHA, (d) 250 ng/mL of chitosan and 100 µM of DHA for 24 and 48 hours. Western Blot analysis

712

Argininosuccinate Lyase is a Novel Cancer Therapeutic Target.

H-L. Huang[1], M-D. Lai[1]; [1]The Institute of Basic Medical Sciences, Tainan, Taiwan

Many studies have been carried out to study carbohydrate and lipid metabolism in past decades. Recently, the amino acid metabolism in human cancer was found to be different from that in normal cells too. Cancer cells often grow in a poor environment such as nutrient deprivation. In addition, the endoplasmic reticulum stress is often observed in human cancer. Until now, the signal link between endoplasmic reticulum stress (ER stress) and amino acid metabolism is largely unknown. Therefore we hypothesized that (1) Can ER stress regulate the expression of arginine anabolic enzyme, argininosuccinate lyase (ASL)? And (2) the alteration of the expression of ASL may serve as novel cancer therapeutic targets. The ASL is a cytosolic protein, which is the fourth enzyme of the urea cycle, catalyzes the cleavage of argininosuccinate into arginine and fumarate. In this report, we tested the hypothesis that ASL is

important for the progression of hepatocarcinoma. The expression of ASL was induced by ER stress both in Human and mouse liver cell lines and in mice livers. ASL over-expressed in Hepatocarcinoma (HCC) was also been observed. HuH-7, HepG2 and ML-1 cells were transfected with ASL shRNA and stable transfectants were established. Knockdown of ASL expression either in mouse or human liver cell lines inhibited proliferation rates and anchorage-independent growth. Cells with downregulated ASL grew slower in BALB/c and NOD/SCID mice. Examination of the expression of protein related with cell cycle or apoptosis revealed that only cyclin A2 was decreased. The cyclin A2 mRNA was unaltered by ASL shRNA and the proteasome inhibitor restored the expression of cyclin A2 in HuH-7 and ML-1 cells. Cyclin A2 protein expression was also decreased when 293 cells were transiently transfected with ASL shRNA. On the other hand, overexpression of ASL further enhanced cyclin A2 protein expression in HuH-7 cells or 293 cells. Here we found that attenuation of ASL expression could decrease the tumorigenecity both in vitro and in vivo. Therefore, we concluded that ASL is important for the growth of tumor cells and may represent a novel therapeutic target.

713

Aromatic Hydrocarbon Receptor Down-regulates MYCN Expression and Predicts Favorable Clinical Outcome of Neuroblastoma.

P-Y. Wu[1], W-M. Hsu[2], H-F. Juan[1], H. Lee[1]; [1]National Taiwan University, Taipei, Taiwan, [2]National Taiwan University Hospital and National Taiwan University College of Medicine

Neuroblastoma (NB) is a heterogeneous neoplasm derived from sympathoadreanal lineage of the neural crest progenitor cells and is the most common malignant disease of infancy. MYCN amplification is a prognostic factor of NB. It indicates a highly malignant disease and poor patient prognosis. However, how MYCN affects the NB cell behavior remains unclear. By tissue oligonucleotide microarray and Ingenuity Pathway Analysis (IPA), aromatic hydrocarbon receptor (AHR) was found to reversely correlate with the MYCN expression in NB tumors. AHR expression in 85 NB tumors correlated well with histological grade of differentiation but reversely correlated with advanced disease stages and MYCN amplification. In addition, positive AHR expression by immunostaining of NB tumors predicted a favorable prognosis. AHR was known as the mediator of the toxicity of dioxin-like compounds. However, recent studies demonstrated that AHR is important in regulating cell death, proliferation, and differentiation. We hypothesize that AHR could regulate MYCN expression in NB. AHR over-expression promotes SK-N-DZ cell neuronal differentiation. Furthermore, ectopic expression of AHR suppressed MYCN promoter activity resulting in down-regulation of MYCN in mRNA and protein expression level. By using AHR shRNA, MYCN mRNA expression level was up-regulated after knock-down of AHR in SK-N-SH cell line. Our results suggested that AHR not only relates to the MYCN expression but also plays an important role in regulating tumorigenesis of NB.

The relationship between structure and function of oncogenic protein, HBx.

M-Y. CHO[1,2], H. CHO[1,2]; [1]Department of Molecular Science of technology, Ajou University, Suwon, Korea, [2]Department of Biochemistry and Molecular Biology, Ajou University, Suwon, Korea

Chronic infection with hepatitis B virus (HBV) is strongly associated with the development of hepatocellular carcinoma and the X protein (HBx), encoded by HBV genome, is thought to be important in carcinogenesis as well as in viral replication. HBx is a small peptide comprising of 154 amino acids and it is shown that HBx interacts with a variety of cellular binding partners including p53 tumor suppressor protein, playing as a multifunctional regulator in host cells. However, functional domains of HBx have been poorly identified. One noticeable feature on

HBx protein is cysteine residues which confer 4 intra-disulfide linkages. In addition, inter-disulfide linkages may lead to the dimerization/oligomerization of HBx protein. To probe functional roles of disulfide linkages in HBx protein, we established cystein mutant constructs which lack disulfide linkages. We found that steady-state levels of wild-type HBx, Cys- (all Cys residues changed to Ala), C69 (one Cys at 69 remained), C26,69 (two Cys residues at 26 and 69 remained) mutants greatly differ, suggesting that disulfide linkages of HBx are involved in the maintenance of HBx stability. Ectopic expression of wild-type of HBx was primarily localized in the nucleus then moved to the cytoplasm. In contrast, its Cys mutants were mainly found in the cytoplasm, showing different subcellular localization. We further found differences in transactivation abilities among these HBx mutants. Thus, our results provide the evidence that disulfide linkages of HBx are closely related to cellular function of HBx.

715

Does Cdk6 Modulate Eya-2-Directed Transcription?

J. I. Crary[1,2], D. Kohrt[1], P. Hinds[2], M. J. Grossel[1]; [1]Biology, Connecticut Coll, New London, CT, [2]Molecular Oncology Research Institute, Tufts Medical Center, Boston, MA

Cyclin dependent kinase (cdk)6, is known to regulate G1 phase of the cell cycle by partnering with D-type cyclins to phosphorylate pRb. Recent evidence has shown an emerging role for cdk6 in differentiation, a function not shared with cdk4. In this study, a yeast two-hybrid screen of a human fetal brain library identified the Eya2 protein interacting with cdk6. Eya2, a developmentally important co-activator, partners with the Six4 protein to regulate transcription. The interaction of cdk6 and Eya2 was confirmed by GST pull-down assay, and by co-immunoprecipitation from both transfected and endogenous cell lysates. GST binding assays also demonstrated that Six4 competed with cdk6 for Eya2 binding. Functional outcomes of this interaction could include transcriptional effects. Initial results of luciferase assays indicate that cdk6 quenches Eya2/Six4-directed transcription from MEF-3 sites. Elevated levels of Eya2 have been shown to be associated with poor short overall survival in advanced ovarian cancer (Zhang et al. Cancer Research 65, 2005).

716

A Human Telomerase Holoenzyme Assembly Occurs in Nucleoli in Human Cancer Cells.

J. Lee[1], S. Jeong[1], K. Prabhat[1], I. Chung[1]; [1]Yonsei University, Seoul, Korea

Human telomerase is a ribonucleoprotein (RNP) complex that adds telomeric DNA repeats at the end of human chromosomes in tissue progenitor cells and cancer cells. Active human telomerase is composed of at least three subunits, including the human telomerase reverse transcriptase (hTERT), the telomerase RNA (TERC), and dyskerin. Until now, it was not clear where these three subunits assemble each others. Here, we show the telomerase biogenesis mechanism where an active human telomerase holoenzyme assembly occurs. hTERT colocalizes with both TERC and dyskerin in nucleoli, which is the site for maturation of RNP complex, and these telomerase holoenzyme components localizes at cajal bodies in late S phase. Also, the amount of hTERT bound to TERC and dyskerin peaks during S phase, evidence for cell cycle-dependent regulation of telomerase holoenzyme. Depletion of TCAB1 by using RNA interference leads to a loss of the telomerase RNP accumulation in cajal bodies, accumulates catalytic active telomerase in nucleoli without affecting active telomerase assembly and catalytic activities. These findings indicate that telomerase holoenzyme assembly occcurs in nucleoli prior to cajal body-specific processing of telomerase RNP, suggesting new insight for telomerase biogenesis in nucleus.

717

NRIP roles in prostate development and carcinogenesis.

S-L. Chen[1]; [1]National Taiwan Univ, Taipei, Taiwan

Nuclear receptor interaction protein (NRIP) is also named DCAF6 or IQWD which is a WD40 repeat-containing protein. Previously, we demonstrated that NRIP is a transcription coactivator to enhance androgen receptor (AR)-driven gene expression and protects AR protein stability (Tsai et al., 2005; Chen et al., 2008). Additionally, we found that DDB2 is AR-interacting protein and degrades AR via CUL4A-DDB1 E3 ligase complex, and NRIP stabilizes AR protein by displacing DDB2 from AR-DDB2 complex. NRIP is an androgen-targeted gene, and prostate is a classically androgen/AR dependent organ. In this study, we used NRIP knockout mice to investigate NRIP role in prostate development. Our results showed that anterior prostate (AP) of NRIP KO mice develops delay but not ventral lateral prostate (VLP) and dorsal lateral prostate (DLP) at 8th wk but becomes normal at 12th week. It is due to AR deficiency of AP in NRIP KO mice at 8th wk hence scarce of AR delays branch formation. AP contains lower AR expression than DP and VLP, the latter two develop normal as wild type due to the crucial amount AR enough regardless of NRIP. protection. The delayed development of AP contain more K5, K8, tunnel markers, high Ki 67 in NRIP KO mice at 8th wk, because AR in luminar cells reportedly induces branch differentiation such as high K8, low Ki67, and high tunnel activity, As to why at 12th week, AP development of NRIP KO mice becomes normal as wild type that may be another factor such as DDB2, p53 expression plays a role to affect AR protein increase at 12 wks in NRIP KO mice. Additionally, we also confirmed that NRIP protects AR from DDB2 degradation via Cul4A-DDB1 complex in primary culture cells from NRIP KO mice. Moreover, NRIP expression is a cancer marker. NRIP and AR protein expression are significantly correlated in prostate cancer patients. In sum, NRIP can stabilize AR protein and play a role in prostate development and carcinogenesis.

Muscle Structure, Function, and Disease

Distinct defects in zebrafish heart development due to exposure of ethanol at different critical stages of cardiac morphogenesis.

S. Sarmah[1], J. A. Marrs[1]; [1]Department of Biology, Indiana University-Purdue University Indianapolis, Indianapolis, IN

Prenatal alcohol exposure can produce range of abnormalities and developmental defects to the developing fetus, referred to as fetal alcohol syndrome (FAS). FAS is characterized by a particular pattern of facial anomalies, poor growth, neurodevelopmental abnormalities, and defects in several organ systems including heart, kidney, vision, and hearing. FAS babies often have atrial and ventricular septal defects, and other structural cardiovascular defects. The mechanisms by which ethanol disrupts heart morphogenesis is not yet elucidated. We are using zebrafish embryos to investigate ethanol-induced cardiac defects and to dissect mechanisms underlying these defects. To determine heart developmental stage(s) most susceptible to ethanol exposure, we treated embryos in ethanol (0.6% and 0.9% v/v) during different critical stages of embryonic heart development. 1) Ethanol exposure during mesodermal cell migration to anterior lateral plate mesoderm region showed subtle abnormalities in chamber shape and size. 2) In contrast, ethanol treatment during cardiac specification until midline fusion of cardiomyocytes significantly delayed fusion of the bilateral population of myocardial cells (either developmental time or somite stage matched embryos) as revealed by cardiac myosin light

chain 2 (*cmlc2*) *in situ* hydridization and by live imaging of *tg(cmlc2: gfp)* embryos. Treated embryos exhibited smaller heart chambers and frequent heart looping defects compared to control at 36 hours postfertilization (hpf). 3) Ethanol exposure during stages from heart cone rotation until chamber formation severely affected heart looping, chamber size, and morphology. At 32 hpf, ethanol induced embryos show narrower, more elongated, poorly looped heart tubes, as compared to normally looped and expanded heart chambers in control embryos. We hypothesized that ethanol competes with retinol and impairs RA synthesis, which interferes with cardiogenesis. In an attempt to rescue the ethanol-induced defects, embryos were co-treated with ethanol and 10^{-9} M retinoic acid (RA). Strikingly, supplementing all-*trans*-RA restored cardiomyocyte migration, fusion and rescued morphological defects. We are now examining molecular mechanisms of ethanol-induced heart development defects. Understanding these mechanisms will significantly help us understand heart defects in FAS and might provide potential therapeutic targets for patients with this regrettably frequent birth defect.

719

Identification of Human Myofibril-inducing RNA.

A. Kochegarov[1], A. Moses[1], M. C. Hanna[1], W. Lian[1], L. F. Lemanski[1]; [1]Texas A&M University-Commerce, Commerce, TX

The Mexican axolotl, Ambystoma mexicanum, has a naturally-occurring lethal recessive mutation which affects cardiac development in embryos. Hearts in mutant embryos develop without actomyosin filaments forming into organized sarcomeric myofibrils, hence the hearts fail to beat. Normal hearts, however, start to beat at embryonic stage 35. Interestingly, endoderm from normal embryos can rescue the development of mutant hearts. When mutant hearts are co-organ-cultured with normal anterior endoderm, or in medium conditioned by normal anterior endoderm, the mutant hearts contract and form myofibrils of normal morphology. This finding led to the idea that secreted factors from the endoderm promote normal heart development. In further studies in this laboratory, it was found that an RNA from normal axolotl embryonic endoderm, termed myofibril-inducing RNA (MIR), also rescues mutant hearts. In the present study, it has been found that treatment of mutant axolotl hearts with RNA extracted from human adult heart or human fetal heart also restores expression of tropomyosin and promotes formation of normally-organized myofibrils. We have cloned 400 randomized RNAs from human fetal heart. To accomplish this, cDNAs were synthesized from a mixture of fetal heart RNAs with the CloneMiner™ II cDNA Library Construction Kit (Invitrogen) and inserted into a pDONR™ 222 vector. This vector with recombinant cDNAs was transfected by electroporation into E. coli bacteria and grown into transfected colonies on agar plates, using kanamycin resistance genes. We randomly selected colonies and grew them individually in LB medium and then extracted plasmids from the bacteria. PCR with M13 primers conjugated at T7 binding sites was performed. We then purified the PCR product (cDNAs) and synthesized cRNAs with a MAXIscript T7 Kit (Ambion). Mutant hearts were dissected from axolotl embryos and treated with the synthesized cRNAs. Clones #6 and #13 promoted cardiac contractions in the mutant hearts. These hearts then were stained with immunofluorescently-labeled monoclonal anti-tropomyosin CG3 antibodies; significant tropomyosin expression in the form of organized myofibrils was observed. We plan to sequence these rescuing RNA clones to determine the active human RNA sequence component that promotes myofibril formation and rescues the mutant hearts. Supported by NIH grants HL61246 and HL58435 and an American Heart Association Grant.

Physiology, Vasculature and Morpohology of Murine Myocardium with Reduced Actin Capping Protein.

M. Hart[1], P. Kratz[1], M. Bentley[2], P. Knoblich[1]; [1]Biology, Minnesota State University, Mankato, MN, [2]Minnesota State University, Mankato, MN

Increasingly, hypertrophic cardiomyopathies (HCM) are linked to mutations of sarcomeric proteins. Capping protein (CP) is an actin binding protein, anchoring the barbed end of actin filaments to the Z-line of the sarcomere. We characterized the cardiac physiology, vasculature and morphology of transgenic CPβ2 mice. Using micro-computed tomography (micro-CT), transgenic mice showed an increased left ventricular chamber volume and increased cardiac vasculature compared to wildtype mice. Transgenic mice displayed normal vascular localization of PECAM and VEGF using fluorescent microscopy. Radiotelemetric pressure sensitive catheters were implanted into the aortic arch of 6 month transgenic and wildtype mice and blood pressure and activity monitored for 8 weeks. Transgenic mice had decreased systolic and diastolic pressure, increased heart rate (HR) and lowered activity levels. Finally, using Scanning Electron Microscopy (SEM), alterations in myofibril organization were characterized. Transgenic myocardium displayed disarray relative to wildtype counterparts.

721

Cardiomyocyte Changes Induced by Hyperglycemia.

K. Van Dalfsen[1], V. D. Moore[1]; [1]Chemistry, Elon University, Elon, NC

Diabetes is a serious worldwide health concern with the majority of cases attributed to type 2 diabetes. A complication of type 2 diabetes that affects heart function, known as diabetic cardiomyopathy (DCM), contributes to the mortality of the diabetic population. High blood sugar (hyperglycemia) has been identified as a major contributor to DCM's development and previous studies have found that apoptosis is involved in hyperglycemia-induced heart cell damage. However, the specific cellular mechanisms regulating hyperglycemia-induced damage remain unclear. Apoptosis is coordinated by a number of different proteins and factors at the cellular and mitochondrial levels, including the BCL-2 family of proteins which control mitochondria changes during apoptosis. This family of proteins contains distinct pro- and anti-apoptotic members and has been implicated in both survival as well as apoptotic events in cardiomyocytes. Several studies have demonstrated biochemical markers of apoptosis in in vitro and in vivo hyperglycemia cardiomyocyte models. However, the role of BCL-2 proteins in cardiomyocyte apoptosis due to hyperglycemia has not been thoroughly examined. We hypothesize that hyperglycemia induces changes to BCL-2 proteins in cardiomyocytes which leads to apoptosis, thus contributing to the development of diabetic cardiomyopathy. To test this hypothesis, HL-1 cells, a well-characterized cardiomyocyte cell line derived from mouse atrial cardiac muscle, were studied under normoglycemic and hyperglycemic conditions. We found various pro- and anti-apoptotic proteins, such as BCL-2, MCL-1, BID and BAX, are expressed in HL-1 cardiomyocytes. Exposure to high glucose for 24 hours modifies protein expression levels revealing important changes that can potentially affect apoptosis. Hyperglycemia also clearly induces apoptosis as indicated by decreased cell viability as well as caspase-3 activation. By gaining insight into the contribution of BCL-2 protein changes to DCM the underlying disease pathophysiology as well as novel therapeutic targets for type 2 diabetes could be revealed.

722

Effect of Hypoxia on Muscle Resident Stromal Cells: A Key Factor that Influences Muscle Regeneration.

G. Drouin[1,2], V. Couture[1,2], S. Haroun[1,2], N. Faucheux[2,3], G. Grenier[1,2]; [1]Department of Orthopedic Surgery, Université de Sherbrooke, Sherbrooke, PQ, Canada, [2]Centre de Recherche Clinique Étienne-Lebel, Université de Sherbrooke, Sherbrooke, Québec, Canada, [3]Department of Biotechnology and Chemical Engineering, Université de Sherbrooke

Tissue regeneration is influenced by progenitor cells whose efficiency depends on several factors: the composition of the extracellular matrix, soluble factors produced by neighboring cells or made available through the systemic environment, and oxygen. In severely damaged tissue, the destruction of blood vessels alters oxygen availability. Concomitant to this damage, the multipotent stromal cell population often exhibits phenotypic changes. However, it is not clear how reduced oxygen levels influence the cells. In this study, we examine the effects of oxygen levels on muscle resident stromal cells (mrSCs) isolated from resting and damaged muscles.

We performed colony-forming assays to assess proliferation in normoxic and hypoxic conditions by seeding mrSCs from resting muscle. Following 2 weeks of culture, we found that the number of colonies formed in hypoxic conditions were significantly higher as compared to normoxia (2.9-fold; $p<0.0001$). Moreover, the average colony area was 6.1 fold greater in hypoxia than normoxia ($p<0.0001$). We also tested whether mrSCs from damaged tissue displayed a greater capacity to form colonies than those from resting muscle. Our results show that the number of colonies was not significantly different between the two muscle types in normoxia. However, cells from damaged muscle were able to form significantly more colonies in hypoxia as compared to cells from resting muscle (1.5-fold; $p<0.006$), although they displayed the same average colony area.

These results show for the first time that oxygen levels influence mrSC behavior, and cells that are cultured under hypoxic conditions show increased capacity to proliferate. More interestingly, it demonstrates that mrSCs isolated from severely damaged tissue have a greater capacity to adhere and expand under hypoxic conditions. In summary, our data suggests that under hypoxic conditions, cells from damaged tissue display a functionally different phenotype than those from resting muscle.

723

Structural functions of skeletal muscle-specific calpain in Ca^{2+} efflux from the sarcoplasmic reticulum.

K. Ojima[1], Y. Ono[2], C. Ottenheijm[3], S. Hata[2], H. Suzuki[4], M. Oe[1], I. Nakajima[1], S. Muroya[1], H. Granzier[3], H. Sorimachi[2]; [1]Animal Products Research Division, NILGS, Tsukuba, Japan, [2]Calpain Project, Tokyo Metropolitan Institute of Medical Science, Japan, [3]Department of Physiology, University of Arizona, [4]Biomembrane Signaling Laboratory, Tokyo Metropolitan Institute of Medical Science, Japan

CAPN3 (also called p94 or calpain-3) is an intracellular cysteine protease predominantly expressed in skeletal muscles. *CAPN3*/*Capn3* are responsible genes for limb-girdle muscular dystrophy type 2A (LGMD2A). Our previous studies demonstrated that dysfunction of CAPN3 protease activity caused muscular dystrophy using “knock-in” (referred to as *Capn3*$^{CS/CS}$) mice, in which the endogenous CAPN3 was replaced with a mutant CAPN3:C129S, that was proteolytically inactive but structurally intact CAPN3 (*K. Ojima, et al.* (2010) *J. Clin. Invest.* 120, 2672-2683). Dystrophic symptoms of *Capn3*$^{CS/CS}$ mice, however, was milder than those of

Capn3 null (*Capn3*$^{-/-}$) mice. This suggests that CAPN3 also has a non-proteolytic function. Here, we showed that CAPN3 functions as a structural element rather than as a protease in the sarcoplasmic reticulum (SR). Immunoblot and pull-down assays revealed that CAPN3 was a component of the SR. Although CAPN3 interacted with the SR components, CAPN3 did not proteolyze typical SR components including ryanodine receptor. Furthermore, *Capn3*$^{CS/CS}$ mice showed that CAPN3 molecule(s) was required for proper Ca^{2+} efflux from the SR to cytosol during contraction of skeletal muscles. Taken together, our results indicate that CAPN3 plays a role of non-enzymatic element for the Ca^{2+} efflux machinery in the SR. Thus, defects of the non-enzymatic function of CAPN3 as well as protease dysfunction of CAPN3 lead to LGMD2A.

724

Arbekacin as a therapeutic readthrough inducer for treatment of nonsense mutation-mediated *Duchenne* muscular dystrophy.

M. Shiozuka[1], A. Nishida[2], M. Matsuo[2,3], M. Yoshida[4], Y. Nonomura[1], R. Matsuda[1]; [1]Univ Tokyo, Tokyo, Japan, [2]Kobe Univ, [3]Kobegakuin Univ

Translational readthrough of a premature termination codon is a promising therapeutic method in more than 2,400 distinctly inherited human diseases. We previously reported that negamycin, a dipeptide antibiotic, that binds to the ribosomal decoding site and alters translational accuracy, successfully restored dystrophin expression with less toxicity than gentamicin in *mdx* mouse, which carries a premature termination codon in the dystrophin gene. In order to measure translational readthrough activity with quantitative accuracy, we established a novel transgenic mouse strain, named READ (Readthrough Evaluation and Assessment by Dual reporter). We found that arbekacin induced the in vivo nonsense suppression in READ mice dose-dependently, and promotes the accumulation of dystrophin, reduction of serum creatine kinase activity and improvement of contractile function in *mdx* mice. Moreover, arbekacin exhibits restoration of dystrophin expression on muscle cell obtained by biopsies from *Duchenne* muscular dystrophy patients caused by nonsense mutations. We have validated the efficacy of arbekacin on dystrophin-deficient muscle that we ultimately wish to treat. Arbekacin is a brekthrough readthrough-inducing drug for muscular dystrophy patients harboring nonsense mutations. This work was supported in part by The Ichiro Kanehara Foundation (to MS), Fugaku Foundation (to MS), Health and Labour Sciences Research Grant for Research on Psychiatric and Neurological Diseases and Mental Health (19A-020; to RM), Comprehensive Research on Disability Health and Welfare (H22-ShinkeiKin-Ippan-016; to RM), Nervous and Mental Disorders (20B-13; to RM) from the Ministry of Health, Labour and Welfare, Japan.

725

Effects of Dietary Phosphate on Ectopic Calcification and Muscle Function in mdx Mice.

E. Wada[1], M. Yoshida[2], M. Date[3], T. Higashi[4], R. Matsuda[2]; [1]The University of Tokyo, Meguro, Tokyo, Japan, [2]The University of Tokyo, [3]Rion, [4]Hitachi Aloka Medical

Duchenne muscular dystrophy (DMD) is a severe muscular disorder affected about one in 3,500 boys. Lacking of dystrophin, a large cytoskeletal protein playing as a stabilizer of muscle fiber membrane, is the main cause of this disease. Patients of DMD show significant muscle weakness and wasting beginning at early childhood. They then complicate cardiac or respiration failure causing the early death by age 30.
Ectopic calcification in skeletal muscle has been reported in dystrophin-deficient mdx mice. We previously reported that the calcification was a form of hydroxyapatite, a deposition of calcium phosphate. Also C2C12 cells cultured in a high-phosphate medium expressed osteogenic markers and down-regulated myogenic pathway. Mdx mice had significantly higher serum

phosphate levels than the control mice while no significant difference in serum calcium levels (Kikkawa et al., 2009). When the kidneys are either mechanically or functionally disordered, phosphate metabolism is imbalanced. Abnormalities of phosphate metabolism related to kidney malfunction may play a central role in the deposition of calcium and phosphate in extra-skeletal tissues.
The aim of this study was to clarify the effects of dietary phosphate (Pi) on calcium deposits and muscle function in mdx mice. Mdx mice and the control mice (B10) were divided into three different diet groups (low-Pi, mid-Pi, and high-Pi) from weaning. Severe muscle necrosis and calcinosis were observed in 90-day-old mdx mice fed a high-Pi diet and serum phosphate levels were significantly rose. Few cases of calcium deposits were also observed in kidneys and the heart. These results indicated that high-Pi fed mdx mice were associated with hyperphosphatemia and suspected kidney dysfunction. In contrast, ectopic calcification was rarely seen in mdx mice under low-Pi diet.
We also compared muscle forces of B10 and mdx mice. While B10 mice fed any of the three Pi diets did not have significant differences, mdx mice fed a high-Pi diet had significantly lower maximal twitch and tetanic forces than those of mdx mice fed a mid-Pi diet. In contrast, both of the forces were significantly greater in mdx mice fed a low-Pi diet compared with a mid-Pi diet.
Noninvasive whole-body images of mdx mice taken by a CT scanning revealed that mice fed a high-Pi diet displayed an increased volume of ectopic calcification from 60 to 90 days of age, whereas mdx mice fed a low¬-Pi diet had a reduced. Our results indicated that lowering phosphate intake can be a complementary therapy for muscular dystrophy.

726

Alterations in NF-κB signaling in dystrophic muscle.

C. Carlson[1,2], C. Stefanski[1], D. Bayless[1], A. Adams[1], E. Cottey[1], M. Carr[1], C. Warnars[1];
[1]Physiology, AT Still University, Kirksville, MO, [2]Physiology, Midwestern University Glendale, Glendale, AZ

An examination of the levels of expression for several NF-κB signaling components indicated enhanced nuclear activation of p65 in the presence of elevated levels of cytosolic IκB-α in untreated adult dystrophic costal diaphragm suggesting that both elevated IκB-α kinase (IKK) activity and elevated p65 expression contribute to enhanced nuclear p65 activation in dystrophic muscle (Singh et al., J. of Neurological Sciences, 285, 159-171, 2009). To assess the role of constitutive factors in enhancing NF-κB signaling in dystrophic muscle, primary cultures of wild type (C57Bl10SnJ) and dystrophic (C57Bl10-mdx) myotubes were obtained and the distribution and expression of p65 was determined using confocal immunofluorescence techniques. The myotubes were examined at approximately 10 to 15 days after plating at a time when protein expression is high and the myotubes are spontaneously active. Untreated wild type and mdx myotubes exhibited no differences in either the proportion of nuclear p65 or the concentration of cytosolic p65, suggesting that the alterations in p65 distribution and expression observed in adult dystrophic muscle are not constitutive. To examine whether alterations in the rate of p65 degradation may influence p65 expression in adult dystrophic muscle, adult nondystrophic and mdx costal diaphragms were exposed to the proteasomal inhibitor MG132 for a period of 6 hours. This treatment produced a significantly larger increase in whole cell p65 expression in nondystrophic costal diaphragms, suggesting that the basal rate of ubiquitination and proteasomal degradation of p65 may be reduced in adult mdx muscle. Consistent with this conclusion, mdx costal diaphragms exhibited a slight but significantly reduced expression of the p65 ubiquitin E3 ligase, PDLIM2 (Tanaka et al., Nature Immunol., 8, 584, 2007). Whole cell expression of p65 was increased by about 12% in the mdx fibers, a value lower than that previously observed (Singh et al., 2009). These results suggest that dystrophic alterations in p65 signaling initially arise from extracellular mediators, and that prolonged exposure to these

mediators may produce secondary reductions in p65 degradation and corresponding increases in whole cell p65 expression (supported by AFM#13980 and NIHR15AR055360-01A2 to CGC).

Three-dimensional microcirculatory measurements and the protective effects of endurance exercise on its complications in non-obese type 2 diabetic muscle.

H. Kondo[1], H. Fujino[2], S. Murakami[2], F. Nagatomo[3], N. Fujita[2], A. Ishihara[3]; [1]Food Science & Nutrition, Nagoya Women's University, Nagoya, Japan, [2]Rehabilitation Science, Kobe University, Kobe, Japan, [3]Neurochemistry, Kyoto University

Purpose: Diabetes is closely linked to the risk of microcirculatory complications in tissues. Previous studies were based on two-dimensional capillary staining of muscle cross-sections, and the three-dimensional (3-D) microcirculatory networks and their relationships have rarely been studied in skeletal muscle. We visualized 3-D microcirculatory networks because of the recognition of the complexity and functional importance of skeletal muscle with type 2 diabetes (T2DM). The aim of the present study was to explore metabolic and microcirculatory changes in the skeletal muscle following endurance exercise training.
Methods: Male Goto-Kakizaki (GK) spontaneously non-obese T2DM rats were used in this study. Three groups of rats were studied: sedentary diabetic GK, exercised diabetic (GK+Ex), and sedentary non-diabetic Wistar (Con). The rats in the GK+Ex run at a low-intensity (15 m/min, serum lactate < 2 mmol/l) on a treadmill for 3 wks (60 min/day, 5 times/wk). The microcirculatory network of the soleus muscle was visualized using confocal laser microscopy. Plasma glucose and insulin levels, fiber oxidative enzyme activity, and the expressions of angiogenic and metabolic factors in the soleus muscle were examined after endurance exercise training for 3 wks.
Results: The levels of plasma glucose in diabetic GK and GK+Ex were higher than that of age-matched Con. The levels of plasma insulin in GK and GK+Ex were lower than that of Con. Although the oxidative enzyme activity of muscle fiber in the GK was lower than in the Con, that in the GK+Ex was greater than that in the Con and GK. The 3-D microcirculatory network of the soleus muscle regressed in GK group, whereas that in GK+Ex increased. Additionally, the capillary volume in GK was lower than that in Con, and the exercised muscle microcirculatory network was attenuated toward to the level of Con. Thus, endurance training could bring about the protective effect on the microcirculatory network in T2DM muscle. The expressions of angiogenic and metabolic factors were lower in GK than in the Con muscle. However, those in GK+Ex muscle were attenuated.
Conclusion: These data suggest that endurance exercise training may be an effective countermeasure to the detrimental effects of non-obese T2DM on skeletal muscles.

728

Analysis of Expression of WWP1 protein in Mouse Normal Tissues.

M. Imamura[1], S. Takeda[1]; [1]Department of Molecular Therapy, National Institute of Neuroscience, NCNP, Tokyo, Japan

The *WWP1* gene was recently identified as a candidate responsible for chicken muscular dystrophy by genetic linkage analysis. This gene encodes a HECT-type E3 ubiquitin protein ligase (922 amino acids) that is composed of three functional domains: an N-terminal C2 domain for calcium-dependent phospholipid binding, a central region containing four WW domains recognize substrates with PY motifs, and a C-terminal HECT catalytic domain for ubiquitin transfer from E2 to substrates. Since oncogenic role of WWP1 has been suggested in prostate and breast tumors, many studies have been carried out using primary tumor cells and tumor cell lines. However, especially at protein levels, little is known about WWP1 expression in

normal tissues and organs. Thus, in this study, we have newly generated polyclonal antibody against a recombinant WWP1 fragment and have examined the expression of WWP1 in mice. Immunoblot analysis of various mouse tissues, i.e., brain, lung, heart, skeletal muscle, liver, spleen, kidney, intestine and testis, has detected a major protein band at approximately 120 kDa in all the tissue homogenates, revealing widely expression of WWP1 in a variety of tissues. This signal has been relatively abundant in lung and brain, but the lowest in heart. In addition to this, a relative weak 110 kDa signal has been also detected in all tissues except for heart and skeletal muscle. However, in these striated muscle tissues, an 85 kDa protein band has been detected instead of the 110 kDa band. Several alternative splice isoforms were reported in WWP1 expression. These multiple bands detected in the analysis would be protein products of the splice isofroms.

729

Three-dimensional visualization of capillary and prevention of capillary regression by antioxidant supplementation in disused skeletal muscle.

H. Fujino[1], M. Kanazashi[1], H. Kondo[2], S. Murakami[1], F. Nagatomo[3], N. Fujita[1], A. Ishihara[3]; [1]Rehabilitation Sci, Kobe Univ Grad Sch Hlth Scis, Kobe, Japan, [2]Food Sci and Nutr, Nagoya Women's Univ, [3]Cell Biology and Life Sci, Kyoto Univ

Purpose: Exposure to reduced activity induces a disuse atrophy of postural muscles. Disuse results in a decrease in muscle volume, strength and capillary regression. Oxidative stress might contribute to muscle atrophy and capillary regression, and this form of muscle atrophy could be retarded by the delivery of antioxidant supplementation. This study was designed to test two hypotheses in rats. First, we visualized the 3-D capillary because of the recognition of the complexity and functional importance of skeletal muscle with disuse atrophy. Secondly, antioxidant supplementation, i.e., astaxanthin (ASX), would regulate genes involved in capillary regression.
Methods: Male Wistar rats were used in this study. Four groups of rats were studied: control (Con), control with ASX(Con+ASX), hindlimb unloading (HU), hindlimb unloading with astaxanthin (HU+ASX) groups. In the Con+ASX and HU+ASX groups, astaxanthin (Fuji chemical industry, Japan) was orally administered twice in a day for seven consecutive days. The dose of ASX was based on 50mg/kg body weight, and interval of six hours was kept between first and second administrations in a day. Hindlimb unloading was applied to animals by suspending their tails for seven days and induced muscle atrophy. The three-dimensional (3-D) capillary of the soleus muscle was visualized using confocal laser microscopy. The expression levels of superoxide dismutase (SOD-1), VEGF, its receptors, angiopoietins and metabolic factors were measured in soleus muscle.
Results: Hindlimb unloading resulted in a decrease of the number of capillaries, capillary volume, and capillary luminal diameter. The 3-D capillary network of the soleus muscle regressed in HU. Additionally, HU caused the overexpression of SOD-1 and decreased the expression level of VEGF. However, the 3-D visualized capillary network of the soleus muscle prevented disuse-induced capillary regression in HU+ASX. Furthermore, ASX supplementation abolished the unloading-induced increase in SOD-1 and attenuated decrease in VEGF, and other angiogenic factors. Additionally, the expression levels of PGC1α and HIF1α in HU+ASX were maintained at Con level although those in HU decreased.
Conclusion: These results revealed that astaxanthin is effective to attenuate the development of oxidative stress and maintain the architecture of capillary network in disused skeletal muscle.

730

Using Xenopus laevis to elucidate the roles of thin filament regulatory proteins: Leiomodin 3 and Tropomodulin 4 are important for skeletal muscle thin filament assembly.

C. U. Nworu[1], D. C. Schnurr[1], C. C. Gregorio[1], P. A. Krieg[1]; [1]Department of Cellular and Molecular Medicine, College of Medicine, The University of Arizona, Tucson, AZ, Tucson, AZ

To generate optimal force for efficient contraction, actin-thin filament lengths must be closely regulated. Capping proteins contribute to thin filament length uniformity by regulating both elongation and depolymerization of the filaments at their ends. The Leiomodins (Lmod1-3), are structurally related to Tropomodulin (Tmod) proteins and are reported to localize to the pointed end of actin filaments and to contribute to thin filament length regulation.

This study aims to determine the role of Tmod4 and Lmod3 during de novo skeletal myofibrillogenesis in Xenopus laevis embryos. Developmental in situ hybridization studies show that Lmod3 and Tmod4 transcripts are expressed at high levels from the earliest stages of skeletal muscle development, suggesting that both molecules contribute to myofibril assembly and maintenance. Reducing the protein levels of Tmod4 or Lmod3 via morpholino technology compromised sarcomere development, thin filament assembly and the embryo's ability to swim. Double knockdown of Tmod4 and Lmod3 resulted in a more severe sarcomere assembly phenotype compared with single protein knockdowns. Our results suggest that Lmod3 and Tmod4 cooperatively regulate thin filament dynamics. Furthermore, we show that mis-regulation of actin filament assembly results in disruption of myofibrillogenesis in Xenopus skeletal muscle.

731

Desmoplakin and Talin2 Are Novel mRNA Targets of Fragile X Related Protein-1 in Cardiac Muscle.

L. Yu[1], S. A. Whitman[1], C. Cover[1], D. Zarnescu[2], C. C. Gregorio[1]; [1]Cellular and Molecular Medicine, University of Arizona, Tucson, AZ, [2]Molecular and Cellular Biology, University of Arizona, Tucson, AZ

RNA binding proteins are important players in the post-transcriptional regulation of mRNA transcripts. In cardiac muscle, where the precise assembly and interactions of numerous cytoskeletal and regulatory proteins are necessary for proper contraction and force transmission, RNA binding proteins must also play a key role in the assembly and maintenance of these specialized cardiac structures. The objective of this study is to investigate the molecular mechanisms and targets of muscle-specific Fragile X mental retardation, autosomal homolog 1 (FXR1), whose loss leads to perinatal lethality in mice and cardiomyopathy in zebrafish. Through immunoprecipitation, we found that desmoplakin and talin2 mRNAs associate with FXR1 in a complex. In vitro assays indicate that FXR1 binds these mRNA targets directly and represses their translation. Fxr1 KO hearts exhibit an up-regulation of desmoplakin and talin2 proteins, which is accompanied by severe disruption of desmosome as well as costamere architecture and composition in the heart, as determined by electron microscopy and deconvolution immunofluorescence analysis. Fluorescent in situ hybridization in combination with immunofluorescence staining further shows that FXR1 does not exert localization control over desmoplakin and talin2 transcripts. Our findings reveal the first direct mRNA targets of FXR1 in striated muscle and support translational repression as a novel mechanism for regulating heart muscle development and function, in particular the assembly of specialized cytoskeletal structures.

Immune System

732

Electron tomographic studies of HIV in the gut.

M. S. Ladinsky[1], D. Kwon[2], C. D. Kieffer[1], B. D. Walker[2], P. J. Bjorkman[1]; [1]Biology, California Institute of Technology, Pasadena, CA, [2]Ragon Institute of MGH, MIT and Harvard, Charlestown, MA

The human digestive system is one of the first lines of defense against infection and is home to almost half of the body's immune cells. As such, in HIV-positive patients the gut harbors large populations of the virus, especially at early stages of infection. At later stages, following depletion of T-cells, the virus may remain in regions of the gut where it is inaccessible to anti-retroviral drug therapy. We are using high-resolution electron tomography and immuno-EM to study HIV-infected gut tissue from humanized mouse models and biopsies from HIV-positive human patients. Our goal is to study early and late events of HIV infection in situ, identify the cells that harbor the virus at specific locations within the gut and determine where and how the virus may "hide" from HAART therapy. Both mature and immature (budding/recently-budded) virions can be identified by distinct structural features and by immunolabeling with antibodies against specific HIV antigens. Pools of mature HIV are often found in the intercellular spaces of the Crypts of Lieberkühn and viral budding profiles are detected on a subset of mucosal and Crypt-associated cells. The specific cell type (T-cell, macrophage or dendritic cell) can be determined by immunoEM. The nature and location of these virus pools gives us insight to how the virus may evade HAART and may suggest new therapies directed to these specific structures.

733

Estradiol Differentially Regulates Calreticulin: A Potential Link with Abnormal Calcium Signaling in Systemic Lupus Erythematosus T Cells?

J. Ward[1], V. Rider[1], N. Abdou[2], B. Kimler[3]; [1]Biology, Pittsburg State University, Pittsburg, KS, [2]Center of Rheumatic Diseases, St. Luke's Hospital, Kansas City, MO, [3]Radiation Oncology, University of Kansas Medical Center, Kansas City, KS

Systemic lupus erythematosus (SLE) is an autoimmune disease that affects women nine times more often than men. Calcium signal transduction is altered in response to estradiol in SLE T cells but not in normal T cells. Microarray analysis suggested a key player in the calcium signaling pathway, calreticulin, is differentially regulated by estradiol in SLE T cells. To gain insight into the differential control of calreticulin, human T cells were purified from blood samples obtained from control females (n = 15) and SLE patients (n = 12). The T cells were cultured for 18 h without and with estradiol 17-β (10^{-7} M). Some samples were activated further by addition of phorbol 12 myristate 13-acetate (PMA, 10 ng/ml) and ionomycin (0.5 μg/ml) for 4h. Calreticulin expression was quantified in resting and activated T cells by real time polymerase chain amplification. Plasma estradiol at the time of blood draw was measured by ELISA. To assess whether calreticulin could affect estrogen receptor location and turnover, calreticulin was immunoprecipitated from nuclear and cytosolic compartments of T47D breast cancer cells and human T cells. The immunoprecipitates were analyzed by Western blotting using an estrogen receptor-α antibody. Estradiol stimulated (p= 0.034) calreticulin expression in activated control T cells. Calreticulin expression was not significantly different in either resting or activated SLE T cell samples in response to estradiol. Mean plasma estradiol concentrations were similar among SLE patients and controls. Calreticulin associated with estrogen receptor-α in the nucleus of resting cells. The results indicate that estradiol controls calreticulin expression in normal T cells

but not in SLE T cells. The results suggest shuttling of estrogen receptors from nucleus to cytosol, via a calreticulin mediated mechanism, could alter estrogen receptor turnover, calreticulin expression and calcium signaling in SLE T cells.

734

Indeterminate Third-Generation Hepatitis C Recombinant Immunoblot Assay and HCV RNA Analysis: c22p-4+ Pattern Associated with Viremia in Immunosupressed Patients.

F. Leite[1,2], A. Leite[3], J. Coutinho[1]; [1]Clinical Haematology Dept-, Santo António's Hospital- CHP, Porto, Portugal, [2]Biochemistry, Faculty of Medicine- University of Porto, Porto, Portugal, [3]IBMC-Institute for Molecular and Cell Biology-Porto

Background: the aim of our work was to study the meaning of Indeterminate Hepatitis C Virus (HCV) Third Generation Recombinant Assay (RIBA®3.0 Ortho Diagnostics Systems) in donor (D) and patient (P) populations.
Methods: we retrospectively looked for individuals with Indeterminate RIBA®HCV 3.0 Pattern (IRP) between November 2001 and June 2011. D and P were screened with Abbott Prism® HCV and/or Vitros Eci Anti-HCV. HCV RNA was detected by bDNA, PCR and/or a NAT test: Procleix® Ultrio™ Assay, being excluded HBV and HIV infections when this method was performed. We followed the manufacturer's instructions for the assay protocol and results interpretation. We determined the patient´s diagnosis. Individuals not tested for HCV RNA were excluded for the IRP study. Data statistical analysis was performed with SPSS program (version 16.0) and *P* value.< 0.05 was regarded significant.
Results: we found 334 individuals with IRP, 74 D and 260 P; HCV RNA was not determined (ND) in 58 patients. The RIBA -3 indeterminate donors showed a significantly lower S/CO ratio distribution than patients (2.28 vs. 9.96 p.=.000). None of donors had positive HCV RNA; 31% of P were immunosupressed patients (IP) and 71% of these were HIV-1 infected (57). IP showed a higher S/CO compared to P not IP (13.90 vs 8.31; p.=.000). We found a significant positive relationship between S/CO value and HCV RNA (p.=.000) with a positive predictive value for the HCV infection when S/CO>5 (p.=.000). ND patients presented an average S/CO of 8.66. The patterns c100p and NS5 were associated with no viremia and c22p-4+, c33c-4+ and c33c-3+ showed association with the presence of HCV RNA (p.=.000). The c33c-2+ was the most frequent IRP associated with no viremia and the higher relation between IRP and the presence of RNA HCV was verified with c22p-4+ pattern. c22p-4+ was the IRP more frequent in the IP and the c33c-2+ was the most prevalent pattern in donors (p.=.000).
Conclusions: The prevalence of the disease on the population, the S/CO value, the RIBA indeterminate pattern including the type and the strength of the band are predictive for the presence of HCV infection. We found a high prevalence of IRP in immunosuppressed patients, namely in HIV-1 co-infected. We found a significant relationship between the S/CO of the screening tests and the presence of viremia. S/CO superior to 5 is predictive of infection and we failed to diagnose HCV infection in those individuals without determination of HCV RNA with an average S/CO of 8.66. There is a significant relationship between the IRP and HCV viremia. The IRP are significantly different in donor and patient populations. In immunosupressed patients c22p-4+ associated with a high S/CO ratio is predictive for HCV infection. Immunosuppressed patients with high S/CO and IRP should have HCV RNA periodic determinations since a negative viremia has not the meaning of no infection considering the natural course of Hepatitis C disease.

735

Differential regulation of IL-1 receptor antagonist in human fibroblasts and fibrocytes by thyrotropin: A heretofore unrecognized link between the thyroid axis and inflammation.

B. Li[1], T. Smith[1]; [1]Departments of Ophthalmology and Visual Sciences and Internal Medicine, University of Michigan Medical School, Ann Arbor, MI

Interleukin-1(IL-1) is an important mediator of inflammation that has been implicated in many autoimmune diseases. As an endogenous IL-1 inhibitor, IL-1 receptor antagonist (IL-1RA) competitively binds IL-1 receptor (IL-1R), blocking its downstream signaling. The balance between IL-1 and IL-1RA determines the characteristics of chronic inflammation. Graves' disease and its orbital manifestation, thyroid-associated opthalmopathy (TAO) represents a systemic autoimmune process characterized by high levels of agonist antibodies against thyrotropin receptor (TSHR). Orbital fibroblasts in TAO represent important targets of inflammatory cytokines. Here we examined the effects of IL-1â and TSH on IL-1RA expression in orbital fibroblasts and bone marrow derived fibrocytes, which we believe replace orbital fibroblasts in TAO. Using real-time RT-PCR, flow cytometry, ELISA, and Western blot, we demonstrate differential induction by TSH and IL-1â of icIL-1RA and sIL-1RA in these cell types. These effects are mediated through TSHR and IL-1R, respectively, . The up-regulation results from modest increases in the activities of the two gene promoters but dramatic enhancement of mRNA stability, both occurring in a cell-specific manner. These findings further our understanding of fibroblasts heterogeneity and shed light on the mechanisms by which the TSH/TSHR pathway might modulate inflammation in GD and TAO.

736

PEDF promotes tumor cell death by inducing macrophage membrane trail.

Y-P. Tsao[1]; [1]Mackay Meml Hosp, Taipei, Taiwan

Pigment epithelial-derived factor (PEDF) is an intrinsic anti-angiogenic factor and a potential anti-tumor agent. The tumoricidal mechanism of PEDF, however, has not been fully elucidated. Here we report that PEDF induces the apoptosis of TC-1 and SK-Hep-1 tumor cells when they are cocultured with bone marrow-derived macrophages (BMDMs). This macrophage-mediated tumor killing is prevented by blockage of TNF-related apoptosis-inducing ligand (TRAIL) following treatment with the soluble TRAIL receptor. PEDF also increases the amount of membrane-bound TRAIL on cultured mouse BMDMs and on macrophages surrounding subcutaneous tumors. PEDF-induced tumor killing and TRAIL induction is abrogated by peroxisome proliferator-activated receptor gamma (PPARγ) antagonists or small interfering RNAs targeting PPARγ. PEDF also induces PPARγ in BMDMs. Furthermore, the activity of the *TRAIL* promoter in human macrophages is increased by PEDF stimulation. Chromatin immunoprecipitation and DNA pull-down assays confirmed that endogenous PPARγ binds to a functional PPAR-response element (PPRE) in the *TRAIL* promoter, and mutation of this PPRE abolishes the binding of the PPARγ/RXRα heterodimer. Also, PPARγ-dependent transactivation and PPARγ/RXRα binding to this PPRE are prevented by PPARγ antagonists. Our results provide a novel mechanism for the tumoricidal activity of PEDF, which involves tumor cell killing via PPARγ–mediated TRAIL induction in macrophages.

737

***Tsukushi* differentially modulates TLR2- and TLR4-mediated signaling in murine macrophages.**

K. Watanabe[1,2], T. Shuto[1,2], M. Sato[1,2], K. Onuki[1,2], M. Suico[1,2], K. Ohta[2,3] H. Kai[1,2]; [1]Department of Molecular Medicine, Graduate School of Pharmaceutical Sciences, Kumamoto University, Kumamoto, Japan, [2]Global COE "Cell Fate Regulation Research and Education Unit",

Kumamoto University, Kuamoto, Japan, [3]Department of Developmental Neurobiology, Graduate School of Medical Sciences, Kumamoto University

Tsukushi (*Tsk*), a member of the secreted small leucine-rich repeat proteoglycan (SLRP) family, has been recognized as a key molecule during developmental stages. However, its biological role in the innate immune regulation has not been elucidated. Here, we identify *Tsk* as modulators of downstream signaling of pattern recognition receptors toll-like receptor-2 (TLR2) and TLR4. Primary peritoneal macrophages from *Tsk*-deficient mice overproduced TNFα and KC mRNA expression in response to bacterial cell wall component peptidoglycan (PGN), a TLR2 ligand, suggesting the role of *Tsk* in the negative regulation of PGN-TLR2 signaling. On the other hand, *Tsk* (-/-) peritoneal macrophages exhibited reduced expression of TNFα, IL-6, KC and IFNβ mRNA after challenge with lipopolysaccharide (LPS), a TLR4 ligand derived from Gram-negative bacteria. Both overexpression and knockdown studies in LPS-treated RAW264.7 macrophage cell line further suggested the role of *Tsk* in the positive regulation of LPS-TLR4 signaling. Since deletion of *Tsk* did not affect gene expression of hes-1/hey-1 and Id1/Id2, downstream markers of Notch- and BMP/TGFβ-mediated signaling, respectively, in peritoneal macrophages, mechanisms underlying *Tsk*-dependent modulation of TLR2/4 signaling may be different from those in described in previous studies on developmental stages. Finally, *in vivo* experiments with mice revealed that *Tsk*-deficient mice are more susceptible to PGN-induced lethality, while more resistant to LPS-induced lethality, compared to their wild-type littermate mice, which are consistent with *in vitro* findings. Overall, our data reveal differential roles of *Tsk* in regulating TLR2- and TLR4- mediated signaling in murine macrophages.

738

The effect of sTLT-1 on bateriaactivated neutrophils.

M. E. Martinez[1], A. V. Washington[2], M. Fernandez[2]; [1]Biology, University of Puerto Rico Mayaguez Campus, Rincon, Puerto Rico, [2]University of Puerto Rico Mayaguez Campus

It is well known that platelets regulate blood coagulation, however, recently they have been shown to play a major role in immune regulation. TLT-1 (Triggering Receptor Expressed in Myeloid (TREM)–like transcript-(TLT)-1 is a receptor found in the a-granules of platelets. Characterization of the treml1-/-mouse has shown that they bleed after an immune challenge. These results suggest that TLT-1 may be an important link between the inflammatory and coagulatory compartments thru the regulation of innate immune function. Moreover, recent publications demonstrate that activated platelets release large amounts of the soluble form of TLT-1 (sTLT-1) into the blood, although sTLT-1's role in coagulation or inflammation is not understood. Determination of sTLT-1 function is critical for a better understanding of the link between hemostasis and inflammation. As a preliminary step to this understanding, we devised a in vitro system using flow cytometry to measure neutrophil activation. Neutrophils were isolated thru density gradient centrifugation and incubated with E.Coli in the presence or absence of sTLT-1. Neutrophils activation was measured at 2 hours using degranulation (CD66b and CD35) and adhesion (CD 11b) markers by flow cytometry. Our results demonstrate a down-regulation of the expression of CD66b and CD35 on activated neutrophils. There was no apparent regulation of any sort in the expression of CD11b. These results suggest that sTLT-1 has an inhibitory effect on the degranulation of bacteria-activated neutrophils, which may provide insight into the immune bleeding phenotype of the treml1-/- mouse. Our studies suggest that TLT-1 may preemptively regulate neutrophil function as a mechanism to control bleeding. Further studies of the interaction between the sTLT-1 and neutrophils will allow us a broader understating of the physiological processes occurring in the hemostatic and immunological systems of a patient during sepsis.

How Does SHP-1 Inhibition Improve Effectiveness of DC-Based Prostate Cancer Vaccines?

D. M. Peterson[1,2], I. Ramachandran[2], J. Levitt[2]; [1]Biology, Prairie View A&M university, Prairie View, TX, [2]Immunology and Pathology, Baylor College of Medicine, Houston, TX

A relatively new approach to prostate cancer immunotherapy is the use of Dendritic Cell (DC) based vaccines. These vaccines manipulate the immune system to thwart off prostate cancer using DCs and prostate cancer specific antigen. The most important cells in initiating an immune response are DCs. These cells are antigen presenting cells that engulf and process antigen in the periphery. From the periphery they migrate to the lymph nodes and interact with cytotoxic T lymphocytes (CTLs). This interaction causes CTL proliferation and cytotoxicity responses to the presented antigen. Src homology domain 2-containing protein tyrosine phosphatase-1 (SHP-1) is a naturally occurring intrinsic regulator of DCs that inhibits DC activation, migration, survival, cytokine production, and moreover, inhibits DC stimulation of CTLs. It is known that inhibition of SHP-1 in DCs improves efficacy of DC based prostate cancer vaccines, although a proper understanding of how this occurs is relatively unknown. Our objective is to explore SHP-1's function and mechanism of action in DCs, as well as, observe SHP-1 knockdown DCs effect on immune system development. We hypothesize SHP-1 knockdown DCs will have a developmental effect on the immune system. In addition, we believe that SHP-1 interacts with Interleukin-1-receptor-associated kinase 4 (IRAK-4), an important kinase molecule found in the Toll Like Receptor-4 (TLR-4) pathway. Lastly, we identify novel binding target candidates for SHP-1 in the TLR-4 pathway in DCs. We show DC specific SHP-1 deficiency affects system development of the spleen, an important immune system organ. We show spleen enlargement or splenomegaly in DC specific SHP-1 deficient mice. Upon cellular examination of these spleens we observed a significant decrease in splenic T-cell and B-cells, but a significant increase in splenic DCs. Molecularly in our DCs we show SHP-1 interacts IRAK-4, an important kinase molecule found in the TLR-4 pathway. The TLR-4 pathway activates Nuclear Factor-KappaB (NfkB), which allows for transcription of immune response genes necessary for DC activation, migration, survival, cytokine production, and DC stimulation of CTLs. In addition, we discovered a number of novel binding target candidates for SHP-1 in the TLR-4 pathway in DCs. Elucidating SHP-1 and its mechanism of action in DCs potentially could lead to novel DC regulation approaches. This can translate to new and improved DC based immunotherapeutics for prostate cancer and countless other diseases.

The Role of Microvesicle Encapsulated RNA in Autoimmune Disorders.

D. L. Quarles[1], R. Bonegio[2]; [1]Biology, Morehouse College, Atlanta, GA, [2]Nephrology, Boston University School of Medicine, Boston, Massachesetts

Previous work performed in our lab causes us to suspect that Toll-Like Receptors (TLRÕs),Ða specific class of pattern recognition receptors that play a key role in the innate mammalian immune response, are indicated in various autoimmune disorders including systemic lupus erythmatosus-induced glomerular nephritis. In our study, live podocyte cells were stimulated in cell culture using Nephrotoxic Serum (NTS) and a solution containing an array of complement proteins. Upon binding, this immunoglobulin-complement complex underwent a series of recruitment steps to form the membrane attack complex (MAC), which disrupted the membrane of the podocytes via penetration allowing intracellular components to flow into the cellular medium.
The contents of this intracellular medium is of specific interest because podocytes have a large and highly developed vesicular network that include a special class of endosomes called

microvesicles. Some of these microvesicles are thought to contain RNA that activates Toll-Like Receptor 7 (TLR7), causing the release of cytokines that induce inflammation and cellular pathology within the kidney. We exposed the podocytes to various concentrations of NTS (2%, 1%, and 0.5% utilizing 0% as a Control) and complement (3%, 2%, and 1%- Heat inactivated serum control) and collected the medium at various time points (1, 2, and 3 days). Utilizing a Quant-ITª RNA Assay, we quantified the RNA in the various medium aliquots and found that significant RNA release did occur in the cells exposed to a NTS concentration above 0.5% compared to the control and that there was an inverse dose-dependent response for the concentration of complement in the 2% NTS samples.

741

Identifiying the anti-TR antigen in paraneoplastic cerebellar degeneration.

E. De Graaff[1,2], P. Maat[2], E. Hulsenboom[2], R. van den Berg[1], M. van den Bent[2], J. Demmers[3], C. C. Hoogenraad[1], P. Sillevis Smitt[2]; [1]Dept of Biology, Div Cell Biology, Utrecht University, Utrecht, Netherlands, [2]Dept of Neurology, ErasmusMC, Rotterdam, Netherlands, [3]Dept of Biochemistry, ErasmusMC, Rotterdam, Netherlands

Paraneoplastic cerebellar degeneration (PCD) is characterized by subacute cerebellar ataxia which coincides with the presence of specific tumour types and antineuronal antibodies. One particular form of PCD is associated with Hodgkin Lymphoma (HL) and the presence of antibodies against cerebellar Purkinje cells in several of these patients' sera. These later called anti-Tr antibodies recognize a specific punctuate immunoreactivity in the large dendritic tree as well as the soma of the Purkinje cells, but not in the axons. Although this characteristic immunoreactive pattern is considered to be a good hallmark for the presence of anti-Tr antibodies, further diagnosis is elaborate. In order to aid this diagnosis, and to understand the pathogenic nature of the PCD we aimed to identify the antigen recognized by anti-Tr antibodies.
Objective:
We aimed to identify the long sought antigen recognized by anti-Tr antibodies.
Methods: To identify the antigen we performed immunoprecipitation using four anti-Tr positive sera on total rat brain extract followed by mass spectrometry. By Western blotting and cell-based assays we subsequently determined the region of the epitope recognized by the anti-Tr antibodies. Deletion and mutant constructs were generated to further map the antigenic region.
Results: We identified Delta/Notch-like epidermal growth factor (EGF)-related Receptor (DNER) as the Tr antigen. In a cell-based screening assay 191 control samples were negative, whereas all of the 12 anti-Tr positive sera stained HA-tagged-DNER expressing cells. Using deletion constructs we pinpointed the main epitope to the extracellular domain. Glycosylation inhibitor tunicamycin and N-glycosylation mutations in DNER abolished the anti-Tr staining, indicating that DNER must be glycosylated to be recognized by anti-Tr antibodies.
Conclusion: Anti-Tr positive sera recognize DNER. Using the cell based assay, presence of anti-Tr antibodies in patients with PCD and HL can now be screened both quickly and reliably.

742

Anti-P Autoantibodies Enhance Cytosolic Calcium and Neurotransmission in Hippocampal Neurons by Cross-Reacting with Cell Surface NSPA.

F. Segovia-Miranda[1,2], J. Parodi[1], F. Serrano[1], N. Escobedo[1], M. Bravo-Zehnder[1,2], J. Larrain[1], L. Massardo[2], D. Valenzuela[3], P. Zamorano[4], N. Inestrosa[1], A. Gonzalez[1,2]; [1]Centro de Envejecimiento y Regeneración (CARE), Fac. Ciencias Biológicas. Pontificia Universidad Católica de Chile, Santiago, Chile, [2]Depto. Inmunología Clínica y Reumatología, Fac. Medicina. Pontificia Universidad Católica de Chile, Santiago, Chile, [3]Regeneron Pharmaceuticals, Inc., [4]Depto. Biomédico. Universidad de Antofagasta

Autoantibodies against the carboxyterminal region of three ribosomal phosphorylated proteins (anti-P) have been associated with psychosis and depression in systemic lupus erythematosus (SLE). We recently showed that anti-P antibodies induce calcium influx followed by apoptosis in cortical neurons and gave evidence of cross-reaction with a high molecular mass protein of unknown function, called NSPA (Neuronal Surface P Antigen) (Matus et al. J Exp Med, 2007). To test more directly the role of NSPA as an anti-P target we cloned the NSPA cDNA linked to GFP at its N-terminal region to transfect HEK293 cells, and also produced an NSPA-null/LacZ knock-in mice. Cell surface immunocapture, and biotinylation assays in Hek293 cells expressing NSPA-GFP point to NSPA as anti-P cell surface target. Beta-Gal staining in NSPA-null/LacZ knock-in mice shows a expression pattern mostly colocalized with that previously reported by immunohistochemistry, though encompassing additional brain regions. Because hippocampal neurons display the highest expression levels, we tested the effects of anti-P on these neurons. Anti-P autoantibodies increase cytosolic calcium levels in hippocampal neurons in primary culture and neurotransmission assessed by field excitatory postsynaptic potential in hippocampus slices, but only from wild type and not from NSPA-null mice. These results provide evidence that NSPA, and not other antigens, display a P epitope at the cell surface and may mediate deleterious effects of anti-P in brain neurons (Financed by CONICYT grant# PFB12/2007, grant# AT24100147 and FONDECYT grant# 1110849).

Elucidating formation of the catalytically-competent V(D)J recombinase complex.

S. Zhao[1], N. S. Rahman[1], W. Rodgers[2], K. K. Rodgers[1]; [1]Biochemistry & Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK, [2]Cardiovascular Biology Research Program, Oklahoma Medical Research Foundation

The adaptive immune system is driven by the ability of T cell receptors and immunoglobulins to recognize invading pathogens. The intact functional genes encoding these antigen receptors are assembled during lymphocyte development through a process known as V(D)J recombination. The V(D)J recombinase, consisting of the RAG1 and RAG2 proteins, is essential for the first DNA cleavage steps in this process. However, the characteristics of the complex formed between the RAG proteins, and how each protein contributes to the overall catalytic activity is not yet well understood. Using a limited proteolysis approach, we identified regions in RAG1 that appear to be sequestered in the interface of the RAG1-RAG2 complex. From these results, we developed a model for how proper assembly of the V(D)J recombinase leads to a catalytically-competent complex. To test this model, we used fluorescence microscopy to compare the cellular co-localization properties of RAG2 with wild type and with mutant forms of RAG1. The microscopy results are consistent with our above model in that mutations in the putative RAG2-interacting regions of RAG1 resulted in partial defects in cellular co-localization of the RAG proteins. Moreover, defective co-localization properties correlated with reductions in cellular V(D)J recombination activity. One of the RAG1 mutants studied, E767K, leads to an immunodeficiency disease known as Ommenn syndrome, which is characterized by only limited

production of mature lymphocytes. Based on our results from limited proteolysis and cellular co-localization studies, we propose that the E767K mutation results in a partial disruption of the interface in the V(D)J recombinase, thereby leading to a catalytically-incompetent complex. We conclude that although the V(D)J recombinase interface is extensive, single point mutations can lead to subtle defects in how the complex assembles, with corresponding reductions in catalytic activity. The combined methods used here illustrate that RAG2 acts as a scaffold to orient multiple regions of RAG1 in formation of the RAG1 DNA cleavage active site.

Immune responses in alcohol-induced pancreatic injury are associated with CCN2 expression and action in acinar cells.

A. Charrier[1], D. Brigstock[2,3]; [1]The Ohio State University, Columbus, OH, [2]Department of Surgery The Ohio State University, [3]Nationwide Childrens Hospital Research Institute

Introduction: Alcoholic chronic pancreatitis (ACP) is characterized by pancreatic necrosis, inflammation, and scarring, the latter of which is due to excessive collagen deposition by activated pancreatic stellate cells (PSC). We have have previously shown that in a novel model of ACP in mice (a species that is usually resistant to the toxic effects of alcohol), PSC are principally responsible for the production of connective tissue growth factor (CCN2) which is correlated spatially and temporally with sites of collagen production (Charrier & Brigstock; Lab Invest, 2010). This is consistent with our earlier in vitro data showing that PSC produce collagen in response to ethanol via the production of CCN2 (Lawrencia et al; Growth Factors, 2009).

During the course of the in vivo studies, we observed that, prior to the fibrotic phase (>Day 20), the combination of ethanol and cerulein caused a transient increase in CCN2 production in acinar cells, even though these cells are not collagenic. Thus we adopted in vivo and in vitro approaches to investigate this finding further

Methods: C57/Bl 6 mice received ethanol injections for 6-16 days against a background of cerulein-induced acute pancreatitis. Pancreata from mice that were treated with cerulein plus 33% ethanol were examined at Days 6, 9, 13, and 16 for the presence of CCN2 and its relationship to inflammatory responses. Additionally, the rat acinar cell line, AR42J, was grown in culture and treated with ethanol and both CCN2 and Interleukin-1 beta (Il-1 beta) mRNA levels were evaluated by qRT-PCR. AR42J cells transfected with pcDNA3.1 plasmid containing a CMV promoter and the entire human CCN2 gene were analyzed by an RT2 Profiler Inflammatory Cytokines and Receptors Array for downstream effects of CTGF expression.

Results: In the in vivo model, there was strong immunofluorescent signal for CCN2 in acinar cells by Day 16 of treatment with ethanol + cerulein and this was not co-localized to á-SMA-postive smooth muscle cells of the vasculature. This pattern of CCN2 staining was not apparent in pancreata of mice receiving water + saline. F4/80 immunofluorescence showed some macrophage infiltration of pancreatic tissue at days 6 and 9, but this was substantially increased on Day 16 and thus correlated with CCN2 production by acinar cells. Immunofluorescence staining further demonstrated that the increase in acinar CCN2 by ethanol + cerulein was spatially and temporally correlated with that of IL-1 beta.
In vitro studies showed that after treatment of rat AR42J cells with 6.25-100mM ethanol for 24 or 48 hours, the pattern of CCN2 mRNA induction was correlated with that of IL-1 beta expression. IL-1 beta expression was not affected by an increase in CCN2 expression, however, expression of chemokine (C-C motif) ligand 20 (CCL20) and C-C chemokine receptor type 6 (CCR6) were significantly increased.

Conclusions: Unrelated to its pro-fibrotic role in PSC, CCN2 is robustly expressed in mouse acinar cells during chronic pancreatic injury, the timing corresponds to increased infiltration of activated macrophages as well as of acinar IL-1 beta expression. Cultured rat acinar cells demonstrate co-expresison of CCN2 and IL-1 beta in response to ethanol. Although IL-1â was not CCN2 dependent it is also known to increase levels of CCL20 and CCR6 suggesting a possible upstream role of IL-1 beta in CCN2 signaling during the classic inflammatory cascade. Taken together, these data support a role for acinar cell-derived CCN2 as a modulator of the immune response. We conclude that CCN2 regulates components of the immune response during pancreatic injury prior to exerting its fibrotic role.

PGF2alpha Stimulates the Expression IL8 and other Chemokines: A Potential Role in Corpus Luteum Regression Through Recruitment of Neutrophils.

H. Talbott[1], X. Hou[1], J. Li[1], P. Zhang[1], R. A. Cushman[2], A. S. Cupp[3], J. S. Davis[1,4]; [1]Obstetrics and Gynecology, University of Nebraska Medical Center, Omaha, NE, [2]ARS U.S. Meat Animal Research Center, Clay Center, NE, [3]Department of Animal Science, University of Nebraska-Lincoln, Lincoln, NE, [4]VA Medical Center, Omaha, NE

Early pregnancy is maintained by progesterone produced by the ovarian corpus luteum (CL). In unfertile reproductive cycles and at the end of pregnancy the uterus produces prostaglandin F2 alpha (PGF), which causes regression of the CL in ruminants and other species, including humans. PGF receptors are GPCRs that couple to Gq and provoke calcium, PKC and ERK signaling in steroidogenic cells. Recent studies suggest chemokines and cytokines may contribute to the process of luteal regression. Our objective was to identify chemokines induced by PGF in vivo and to determine their effect on specific luteal cell types in vitro. Mid-luteal phase cows were injected with saline or a luteolytic dose of PGF and ovaries containing CL were removed after 0.5, 1, 2 or 4 hours. Tissue was processed for protein or RNA isolation. Gene expression was analyzed using Affymetrix bovine WT microarrays and validated by quantitative real time PCR. Purified steroidogenic cells, endothelial cells and fibroblasts were prepared for analysis of signaling molecules by western blot and progesterone production was determined by radioimmunoassay. Bovine neutrophils were purified from peripheral blood and were analyzed for activation and migration. Analysis of gene array data by Ingenuity Pathway Analysis indicated patterns of genes associated with the inflammatory response and cell-to-cell signaling. PGF treatment in vivo rapidly increased the expression of the chemokines IL8, CXCL2, CCL2, and CCL8. Four hours after treatment CXCL2 had increased 7-fold, CCL2 increased 12-fold, and CCL8 increased 30-fold. IL8 expression increased 10-fold within an hour and 35-fold after 4 hours. Expression of IL8 mRNA in steroidogenic luteal cells was also stimulated following in vitro PGF treatment. IL8 rapidly activated the ERK and NFkB signaling pathways in neutrophils, but did not activate either signaling pathway in steroidogenic cells, endothelial cells or fibroblasts. IL8 significantly induced neutrophil migration and degranulation. In conclusion, PGF rapidly induced chemokine expression in vivo and in vitro. IL8 stimulated migration and degranulation of neutrophils. The rapid induction of chemokines by PGF suggests that the process of luteolysis may be a controlled inflammatory response. Support: VA, NIFA 2011-67015-20076.

Central obesity is associated with a lower β2-adrenoceptor expression in peripheral blood mononuclear cells.

F. Leite[1,2], A. Santos[2], M. Lima[2], M. Cosentino[3], L. Ribeiro; [1]Department of Biochemistry, Faculty of Medicine, University of Porto, Portugal, [2]Department of Clinical Haematology, St. Antonio Hospital, Porto, Portugal, [3]Department of Clinical Medicine Section of Experimental and Clinical Pharmacology, University of Insubria, Varese, Italy

Background and aim: Sympathetic nervous activation plays a major role in the onset and development of obesity and cardiovascular comorbidities. A large part of the sympathetic nervous system-mediated energy expenditure occurs via coupling of adrenaline (AD) and noradrenaline (NA) with β2-adrenoceptors (β2-AR) [1]. Central fat–related activation of the innate immune system [2] and insulin resistance are implicated in the pathogenesis of cardiovascular diseases. The recent finding that immune cells and adipocytes are catecholamine-producing cells prompt us to investigate the association between central obesity (CO) and β2-AR expression in peripheral blood mononuclear cells (PBMCs) and innate inflammatory markers in a blood donor population.
Methods: We have studied 60 blood donors (33 men and 27 women) aged 20 to 63 years (mean 39) considering waist circumference (WC), inflammatory markers, namely plasma ultrasensitive PCR (usPCR) and monocyte subpopulations (CD14+ CD16− or CD14+ CD16+) and β2-AR expression in PBMCs. The latter was investigated by quantitative real-time PCR and monocyte subsets staining for CD14, CD16, CD36 and CD11b by flow cytometry analysis. CO was defined following IDF criteria by using WC measurement (≥80 cm for women and ≥ 94 cm for men) [3]. Student-t test was used to assess differences between groups ($p < 0.05$).
Results: Seventy-three percent of blood donors were centrally obese. CO was associated with a more proinflammatory monocyte pattern: less intensity of CD36 (0.4504 ± 0.001 vs. 0.549 ± 0.001) and CD14 (0.393 ± 0.024 vs. 0.536 ± 0.054) and lower side scatter signal (0.843 ± 0.010 vs. 0.881 ± 0.020), $p < 0.05$. Centrally obese subjects showed lower β2-AR expression in PBMCs (1.4 x 10-5 ± 6 x 10-6 vs. 6.5 x 10-5 ± 2.5 x 10-5; $p = 0.007$) and higher plasmatic levels of usPCR (2.5 ± 0.5 vs1.0 ± 0.3; $p = 0.049$), comparing with those without CO. Using regression analysis, we have found that in men β2-AR expression was negatively correlated with NA and usPCR plasmatic levels. However, none of these correlations were found for women.

Conclusion: In our population, waist circumference, a marker of central obesity, is associated not only with higher systemic levels of markers of innate immune activation, but also with β2-adrenoceptor expression in peripheral blood mononuclear cells. The pathophysiological relevance of this finding needs clarification, since lower β2-adrenoceptor expression might be associated with a higher cardiovascular risk, especially in men.

Membrane Trafficking at the Synapse

747

Synaptic activity stabilizes the post-synaptic density scaffold proteins SAP97 and AKAP79 in the neuronal dendritic spine.

J. A. Gorski[1], J. L. Sanderson[1], M. D. Pink[1], M. L. Dell'Acqua[1,2]; [1]Pharmacology, University of Colorado Denver, Aurora, CO, [2]Neuroscience, University of Colorado Denver

Scaffold and anchoring proteins play critical roles in regulating spatial and temporal regulation of signaling cascades. In excitatory neurons, regulation of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors is central to the regulation of glutamatergic synaptic activity. Activity-dependent changes in AMPA receptors are initiated by regulation of lateral diffusion, endocytosis, recycling, and post-translational modifications. These events are controlled by a rich array of scaffold proteins expressed in the postsynaptic density (PSD), of which SAP97 and AKAP79 are the focus of this study. Using Fluorescence Recovery After Photobleaching (FRAP), we investigated how the mobility of these two scaffold proteins in postsynaptic dendritic spines is influenced by neuronal activity and cytoskeletal actin remodeling. We demonstrated that increasing neuronal activity by activating NMDA-type glutamate receptors or stabilizing the actin cytoskeleton with Jasplakinolide reduces the mobile fraction of SAP97 and AKAP79 in spines. The ratio of SAP97 and AKAP79 in spines versus dendritic shafts was greater after these treatments indicating that synaptic activity or a stabilized actin cytoskeleton reduced the net movement of SAP97 and AKAP79 out of spines. In particular, stabilization of AKAP79 in spines with increased synaptic activity required an internal domain that binds to SAP97 and the related scaffold protein PSD-95 as well as palmityolation of the AKAP N-terminal targeting domain that binds membranes and F-actin. Thus, activity-dependent stabilization AKAP79 may depend on coordinated regulation of AKAP interactions with the postsynaptic membrane cytoskeleton and other PSD scaffolds.

748

MAP1A supports NMDA-receptor transport for synaptic plasticity.

Y. Takei[1], Y. Kikkawa[1], N. Atapour[2], T. Hensch[2], N. Hirokawa[1]; [1]Dept Anatomy and Cell Biology, Tokyo University, Tokyo, Japan, [2]Laboratory for Neuronal Circuit Development, RIKEN BSI

Microtubule-associated protein 1A (MAP1A) is one of the major components of the neuronal cytoskeleton. To examine the role of MAP1A, we generated mutant mice lacking MAP1A. Through analysis of their phenotypes, we found that MAP1A knockout mice exhibited severe memory disturbances. The MAP1A-knockout neurons revealed reduced surface expression of NMDA-receptors concomitant with a decrease in NMDA-dependent postsynaptic current and long-term potentiation (LTP). Reduced NMDA receptor transport underlay the altered receptor function. These results suggest that MAP1A supports the transport of NMDA-receptors and synaptic plasticity in neuronal dendrites(Y.T. and Y.K. contributed equally to this work).

Soluble oligomeric amyloid-beta peptide causes defects on vesicle traffickings.

J. PARK[1], Y. KIM[1], S. LEE[1], S. CHANG[1]; [1]Biomedical science, Seoul National University, Seoul, Korea

Soluble oligomeric form of amyloid beta (oAbeta) has been linked to memory and cognitive deficits in Alzheimer disease (AD). The oAbeta is believed to be a key cytotoxic agent in AD, although correlation with disease progression and soluble Abeta levels is still controversial.

Recent growing evidences support the link between Abeta oligomers and synaptic function, while a direct role of oAbeta in presynaptic functions has not been established. Here we found that acute treatment of nanomolar concentration of oAbeta affects multiple steps of synaptic vesicle traffickings including exo-endocytosis and repriming. All of effects were recovered to the control levels with pretreatment of a specific antibody to Abeta. Our results suggest that oAbeta causes defects in the synaptic vesicle traffickings, which could affect to synaptic dysfunction associated with AD. More experiments to pinpoint the site of action are on the way.

750

Chondroitin sulfate proteoglycans target TrkB to downregulate spine formation in the cortical neurons.

D. Kurihara[1,2], T. Yamashita[1,2]; [1]Department of Molecular Neuroscience, Graduate School of Medicine, Osaka University, Suita, Japan, [2]Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Agency (JST), Tokyo, Japan

Chondroitin sulfate proteoglycans (CSPGs) are components of the extracellular matrix inhibitory for axonal sprouting and experience-dependent plasticity. CSPGs are required for closure of the critical period in the visual cortex, whereas the molecular mechanism underlying the limitation of neuronal plasticity by CSPGs remained poorly understood. In addition, although Protein Tyrosine Phosphatase σ (PTPσ) was proven to be a receptor for CSPGs, its downstream signals remained elucidated. Here we show that CSPGs target and dephosphorylate tropomyosin-related kinase B (TrkB), the receptor of brain-derived neurotrophic factor (BDNF), via PTPσ in the embryonic cortical neurons in vitro. PTPσ interacted with TrkB in the neurons. Although BDNF promoted dendritic spine formation of the embryonic cortical neurons, CSPGs abolished the effects of BDNF and even eliminated dendritic spines. The latter effect was dependent on the p75 receptor, suggesting that BDNF binding to the p75 receptor elicits elimination of dendritic spines. These results highlight the counteracting effects of CSPGs against neurotrophins at the receptor level on the formation of dendritic spines.

751

Regulation of AMPA receptor-mediated transmission by the Arf6-GEF BRAG1

K. R. Myers[1], G. Wang[2], J. J. Zhu[2], J. E. Casanova[1]; [1]Cell Biology, University of Virginia, Charlottesville, VA, [2]Pharmacology, University of Virginia, Charlottesville, VA

Activity-dependent modifications of excitatory synapses contribute to synaptic strength and maturation, and are critical for learning and memory. Consequently, impairments in synapse formation or synaptic transmission are thought to contribute to several types of mental disability. BRAG1 is a guanine nucleotide exchange factor (GEF) for the small GTP-binding protein Arf6 and localizes to the postsynaptic density of excitatory synapses. Mutations in BRAG1 have been identified in 4 separate families with X-linked intellectual disability (XLID). These mutations mapped to either the catalytic domain or a precicted calmodulin-binding IQ-like motif, however the pathophysiological basis of these mutations remains unknown. Here, we show that the BRAG1 IQ motif binds to apo-calmodulin, and that calcium-induced calmodulin release triggers a reversible conformational change in BRAG1. We demonstrate that BRAG1 activity, stimulated by activation of NMDA-sensitive glutamate receptors, acts to depress AMPA receptor-mediated transmission. Importantly, a BRAG1 mutant that fails to activate Arf6 also fails to depress AMPA-R signaling, indicating that Arf6 activity is necessary to this process. Conversely, mutation of the BRAG1 IQ-like motif impairs calmodulin binding and results in constitutive, NMDA-R-independent depression of AMPA-R activity. Together these findings suggest that BRAG1 GEF activity is critical for synaptic transmission, and is regulated by its interaction with calmodulin downstream of NMDA receptor activation. Our findings reveal a role for BRAG1 in

response to neuronal activity with possible clinical relevance to nonsyndromic X-linked intellectual disability.

752

VAC14, a Protein that Regulates the Phosphoinositide PI(3,5)P2, Localizes to Synapses and Regulates Synaptic Function.

Y. Zhang[1], A. McCartney[2], S. Zolov[1], C. Ferguson[3], M. Meisler[3], M. Sutton[2], L. Weisman[1]; [1]Life Science Institute, University of Michigan, Ann Arbor, MI, [2]Department of Molecular and Integrative Physiology, University of Michigan, [3]Department of Human Genetics, University of Michigan

The signaling lipid, phosphatidylinositol 3,5-bisphosphate (PI(3,5)P_2), is regulated by a protein complex composed of FAB1/PIKfyve, VAC14, and FIG4. Mice hypomorphic for VAC14 and FIG4 exhibit degeneration in the central and peripheral nervous systems. Moreover, mutations in human *FIG4* are associated with Charcot-Marie-Tooth syndrome and Amyotrophic Lateral Sclerosis. How the nervous system is susceptible to loss of PI(3,5)P_2 was not clear. Here we use cultured hippocampal neurons and show that endogenous VAC14 partially overlaps with early and late endocytic markers in both the soma and neurites. Unexpectedly, a significant fraction of VAC14 localizes to synapses, suggesting a role in regulating synaptic function. Indeed, the amplitude of miniature excitatory synaptic currents is enhanced in *Vac14*$^{-/-}$ neurons. This defect is rescued by overexpression of VAC14 in the postsynaptic neuron. Consistent with this finding, surface GluA2, a glutamate receptor subunit, is elevated in *Vac14*$^{-/-}$ neuron. Thus, VAC14 plays a role in controlling postsynaptic function, possibly through regulation of glutamate receptor internalization or recycling.

753

Local palmitoyltransferase activity induces nucleation of postsynaptic protein assembly.

M. Fukata[1], A. Dimitrov[2], J. Noritake[1], O. Vielemeyer[2], F. Perez[2], Y. Fukata[1]; [1]National Institute for Physiological Sciences, Okazaki, Japan, [2]Institut Curie Centre de Recherche

Palmitoylated PSD-95, a representative postsynaptic scaffold protein, clusters at specialized postsynaptic membranes and plays a critical role in synaptogenesis and synaptic plasticity. However, how the position of PSD-95 clusters is determined in polarized neurons and what triggers their formation are not completely understood. To investigate this process, we selected a recombinant antibody that specifically recognizes the palmitoylated conformation of PSD-95. Its use as a GFP-tagged intrabody in live imaging allowed spatiotemporal visualization of palmitoylation state of endogenous PSD-95. We discovered previously unidentified postsynaptic structures: multiple submicron clusters of PSD-95 in a dendritic spine. These submicron clusters were colocalized with AMPA-type glutamate receptors and plasma membrane-inserted PSD-95 palmitoyltransferase, DHHC2. Knockdown of DHHC2 blocked multicluster formation while forced accumulation of DHHC2 on the dendritic membrane generated PSD-95 clusters. Thus, highly localized palmitoylating activity at the plasma membrane directly nucleates protein assembly to organize postsynaptic protein assembly.

754

Palmitoylation of an AKAP Scaffold Protein Regulates Dendritic Endosomal Targeting and Synaptic Plasticity Mechanisms.

D. Keith[1], J. Sanderson[2], E. Gibson[2], H. Robertson[2], K. Woolfrey[2], K. Olszewski[2], R. Kang[1], M. Dell'Acqua[2]; [1]Psychiatry, Univ of British Columbia, Vancouver, BC, Canada, [2]Pharmacology, Univ Colorado School of Medicine, Aurora, CO

LTP and LTD regulate AMPA receptor (AMPAR) phosphorylation and postsynaptic localization to control synaptic strength during learning and memory. The A-kinase anchoring protein (AKAP) 79/150 signaling scaffold regulates AMPAR phosphorylation and trafficking during LTP/LTD. AKAP79/150 is targeted to dendritic spine plasma membranes by an N-terminal domain that binds phospholipids, actin, and cadherins. However, we do not understand how regulation of AKAP targeting controls AMPAR endosomal trafficking. Here we report that palmitoylation of the AKAP N-terminal domain targets it to endosomes and is regulated by LTP/LTD and seizure activity. With chemical LTP induction we observe palmitoylation-dependent AKAP spine recruitment that requires Rab11-regulated endosome trafficking coincident with spine enlargement and AMPAR surface delivery. Importantly, expression of an AKAP palmitoylation-deficient mutant prevents spine enlargement, AMPAR surface delivery, and synaptic potentiation. These findings emphasize the emerging importance of palmitoylation in controlling synaptic function and reveal novel roles for the AKAP79/150 signaling complex in endosomes.

"Journey to the Center of Translation: In Situ Visualization and Characterization of Compartmentalized Protein Synthesis in Cells and Tissues."

A. David[1], B. Dolan[1], H. Hickman[1], M. Seedhom[1], J. Bennink[1], J. Yewdell[1]; [1]LVD, NIH/NIAID, Bethesda, MD,

Protein translation is a central cellular function considered for decades as the domain of hardcore biochemists. Recently, translation has attracted attention from cell biologists integrating gene product-specific information into a systems view of cellular function. Protein synthesis is a highly varied process with global adaptations for varied circumstances, including distinct modifications tailored for environmental and infectious stressors and differentiation states. Recent studies imply that translation is compartmentalized to allow for local expression of specific mRNAs in order to optimize processes such as cell migration, embryogenesis, neuronal synapse formation, and viral infection. To study translational compartmentalization, we developed the RiboPuromyclation Method (RPM), which visualizes translating ribosomes in cells by standard immunofluorescence. RPM is based on ribosome-catalyzed puromycylation of nascent chains immobilized on ribosomes by chain elongation inhibitors and detection of the puromycylated nascent chains with a puromycin-specific mAb. Ribosome catalyzed puromycylation occurs in live and digitonin permeabilized cells and cell extracts. Due to its high sensitivity, RPM enabled us to visualize translation sites and distinguish protein synthesis sub-compartments based on their localization and their composition. We corroborated the significance of local protein synthesis in several key cellular mechanisms including activation, differentiation, stress, antigen presentation and viral infection. Applying RPM *in vivo*, we demonstrated that protein synthesis is anatomically regulated in lymphoid organs -and even more strikingly in specific cell subsets- following viral infection.

Overall this study demonstrates the remarkable and tremendously intricate organization of the protein synthesis machinery. In addition, it clearly illustrates the strength of RPM as a unique and powerful tool for **visualizing and characterizing** translation sites that will facilitate understanding of translation compartmentalization across many disciplines in biological research, including eukaryotic and simple prokaryotic cell biology.

756

Phagosome volumes similar to infection by L. amazonensis, altered the production of IL-12 via ER-Golgi in phagocytosis of latex particles, and also could be secreted by endocytic pathway.

A. P. Rojas[1], M. Camacho[2,3]; [1]Grupo Biofísica y Biología de Membranas, Doctorado en Química, Departamento de Farmacia, Universidad Nacional de Colombia., Bogota, D.C., Colombia, [2]Departamento de Biología, Facultad de Ciencias, Universidad Nacional de Colombia, Sede Bogotá, Centro Internacional de Física, Bogotá, Colombia., Bogota, D.C., Colombia, [3]Bogota, D.C., UNiversida Nacional de Colombia, Bogota, D.C., Colombia

The intracellular pathway to secrete immune effectors from macrophages and its relationship with vesicular trafficking are poorly described. The objective of this work was to study the effect of phagosomes of different volumes in the intracellular route and trafficking of interleukin 12 (IL-12). J774A.1 macrophage-like cells were infected with L. amazonensis or exposed to latex beads of different diameter and at different proportions to generate phagosomes of different sizes. Then J774.A1 were exposed to interferon gamma (INF-g) and lipopolysaccharide (LPS) to induce classical activation. IL-12 expression was determined by real time PCR, its intracellular location by confocal microscopy and its secretion by flow cytometry. Co-labeling of components of the endocytic pathway or classical secretion was also done.
There was not constitutive secretion of IL-12 but it was induced after exposure to INF-g and LPS. Secretion was dose dependent and biphasic with a first peak at two hours and second pick at six hours post-activation. IL-12 was detected early after activation and co-localized with Calnexin indicating a endoplasmic reticulum (ER) localization. By four hours IL-12 co-localized with ICAM-1 to the plasma membrane. Neither infection nor phagocytosis induced per se IL-12 secretion. However there was detection at ER of IL-12 after L. amazonensis infection. At phagosome volumes above 160 mm3 the quantity of IL-12 detected was less compared to activated macrophages, despite the nature of the phagocytic load. Not only, the amount of IL-12 varied, this interleukin co-localized in these groups with GM-130 suggesting retention at Golgi.
These results suggest that large phagocitic volumes, alter intracellular IL-12 route by the classical secretion pathway via RE-Golgi, compromising its secretion. IL-12 is secreted in vesicles t-SNAREs containing SNAP-23 in the Leishmania infection and alternative RE-Golgi routes for IL-12 secretion may be used by the macrophage.

757

GPI PbPga1p of P. brasiliensis is a surface antigen that binds to extracellular matrix components and activates murine macrophages releasing TNF-α and NO.

C. X. Valim[1], P. S. Coelho[1], T. F. dos Reis[2], F. B. Almeida[1], L. R. Basso Junior[1], L. K. Arruda[1], M. C. Jamur[1]; [1]FMRP-USP, Ribeirão Preto, Brazil, [2]FFCL-USP

Paracoccidioides brasiliensis, a dimorphic fungi, is the etiologic agent of paracoccidioidomycosis (PCM), one of the most prevalent mycosis in Latin America. *P. brasiliensis* cell wall components interact with host cells and can influence the pathogenesis of PCM. In *P. brasiliensis* and other fungi, most of the proteins that compose the cell wall are GPI anchored. These proteins are involved in cell-cell adhesion and cell-tissue adhesion, and have a key role in the interaction between fungal cells and host cells. The protein PbPga1 is a GPI

anchored protein from P*. brasiliensis* whose function is unknown. In the present study, we examined the gene expression of PbPga1 by RT-PCR and observed that PbPga1p is up-regulated in the yeast pathogenic form. A recombinant protein rPbPga1p was then produced in *Pichia pastoris,* purified on a NI-NTA column and an antibody anti-rPbPga1p was produced in chickens. The ability of rPbPga1p to bind to extracellular matrix components and to activate murine macrophages was also examined. rPbPga1p was able to bind to laminin, fibronectin, collagen type I and type IV in a dose-dependent manner. These results suggest that PbPga1 can facilitate the adhesion of *P. brasiliensis* to host tissues, which is one of the crucial steps in the pathogenic process and a pre-requisite for host colonization. Interestingly, rPgPga1p induced mouse peritoneal macrophages to release high levels of TNF-α and nitric oxide (NO) *in vitro*. Moreover, anti-rPbPga1p was able to recognize a protein located on the yeast cell surface at the neck between the mother cell and the bud, covering the surface of the new buds. Taken together these results indicate that PbPga1 is a surface antigen that may play an important role in PCM pathogenesis.

Bacillus anthracis Stimulates the Formation of Neutrophil Extracellular Traps.

S. E. Szarowicz[1], A. Friedlander[2]; [1]Bacteriology, USAMRIID (ORISE), Fort Detrick, MD, [2]Bacteriology, USAMRIID, Fort Detrick, MD

Bacillus anthracis Stimulates the Formation of Neutrophil Extracellular Traps
Clinical findings from the 2001 bioterrorist attacks revealed normal or minimally elevated peripheral polymorphonuclear neutrophils (PMN) counts at time of hospital admission, despite high-levels of bacteremia. PMNs are the first cells recruited to sites of infections, yet surprisingly little is known about their role in anthrax pathogenesis. The poly-γ-D-glutamic acid capsule of *B. anthracis* serves as a virulence factor that inhibits phagocytosis by PMNs allowing anthrax to grow unimpeded. In addition to phagocytosis, activated PMNs release extracellular traps (NETs) that contribute to resistance by degrading virulence factors and killing bacteria. NETs provide high local concentrations of antimicrobial proteins to bind, disarm, and kill microbes extracellularly, independent of phagocytic uptake. OBJECTIVE: We sought to determine if *B. anthracis* stimulates NET production and if NETs are able to efficiently capture and kill both the spore and vegetative forms of *B. anthracis*. METHODS: In this study we infected PMNs with spores or vegetative bacilli of a fully virulent encapsulated or nonvirulent unencapsulated *B. anthracis* strain. We used methods that facilitate the visualization and measurement of NETs using different *in vitro* cell culture techniques and functional assays. RESULTS: We were able to show for the first time that both spores and vegetative bacilli are able to stimulate the induction of NETs. After blocking phagocytosis with cytochalasin D, an inhibitor of actin polymerization, we found an extracellular mechanism of killing. Unencapsulated bacilli but not encapsulated bacilli were killed through entrapment of bacilli in NETs and the antimicrobial activity of histones located on the NETs. Interestingly, both NET and phagocytosis-mediated killing occurred independent of reactive oxygen species. Virulent encapsulated bacilli, although trapped in NETs were resistant to killing. Spores from either strain were not readily captured by the NETs even though they stimulate NET production. CONCLUSIONS: We showed, for the first time, that PMNs are able to readily form NETs in response to *B. anthracis* infection. Unencapsulated bacilli are killed by entrapment in NETs and the antimicrobial activity of histones. The poly-γ-D-glutamic acid capsule appears to protect *B. anthracis* from PMN-mediated NET killing, and we are presently exploring the mechanism of action. These results suggest a significant role for NETs in neutrophil-mediated innate immunity.

Yeast Entry into Host Cells: Studying Cryptococcus neoformans-macrophage Interaction.

C. R. Guerra[1], W. de Souza[1], S. Rozental[1]; [1]Biophysics Institute, Federal University of Rio De Janeiro (UFRJ), RIO DE JANEIRO, Brazil

Cryptococcus neoformans is an encapsulated yeast that causes disease in immunocompromised and, less commonly, immunocompetent patients. Cryptococcosis is considered an AIDS-defining condition, and it is the third most frequent neurological complication in AIDS patients. During the last decade, studies have focused on how this yeast can survive and proliferate within macrophages. However, no studies have been made to better understand which mechanisms the yeast uses upon entering host cells. Therefore, we have started our studies observing C. neoformans interactions with peritoneal macrophages using scanning electron microscopy (SEM) and fluorescence microscopy.

C. neoformans strains ATCC28957 and ATCC52817 (CAP67 – acapsular mutant) were put to interact with peritoneal macrophages, previously adhered on glass cover slips, in a ratio of 25:1 (yeast:host cell) for 2, 4 and 6 hours. The cells were then processed for SEM or fluorescence microscopy, where actin was fluorescently labeled with AlexaFluor 488 phalloidin and a-tubulin was imunnolabeled with anti-a-tubulin AlexaFluor 546 conjugate.

In order to better understand the morphology of the phagocytic uptake structures involved in C. neoformans-macrophage interactions, we used SEM. Macrophages represent the first line of defense for the immune system, and the phagocytic uptake of invading microorganisms is a prerequisite for their efficient elimination. Different structures were observed during interaction with both strains, such as ruffle-like uptake structures and zipper-like internalization processes in infected macrophages. These findings suggest that macrophages can engage different mechanisms to engulf C. neoformans yeasts and the presence or absence of capsule does not seem to influence these uptake structures. Analyzing how the cytoskeleton is involved in this internalization process, a-tubulin was observed surrounding endossomes containing yeasts, whereas actin did not appear to be recruited after yeast internalization. Together, these results contribute to an early understanding on how C. neoformans-macrophage interaction occurs. Further studies are ongoing and will aid on the unraveling of this opportunistic yeast's survival in host.

Host-specific Cell Surface Proteomes of African Trypanosomes.

M. M. Shimogawa[1], M. Oberholzer[1], Z. P. Kabututu[1,2], A. A. Vashisht[3], J. A. Wohlschlegel[3], K. L. Hill[1]; [1]Department of Microbiology, Immunology and Molecular Genetics, University of California, Los Angeles, Los Angeles, CA, [2]Current address: Department of Biological Sciences, National University of Singapore, Singapore, [3]Department of Biological Chemistry, University of California, Los Angeles

The African trypanosome, *Trypanosoma brucei*, is a protozoan parasite that causes sleeping sickness in humans and related debilitating diseases in animals. Sleeping sickness is fatal if untreated, yet current treatments are old, toxic and difficult to administer. Thus, there is a pressing need to better understand these parasites and facilitate development of new therapeutic interventions. *T. brucei* alternates between mammalian and tsetse fly hosts and must integrate signals from diverse external environments for survival, development and pathogenesis. Parasite surface proteins protect against host immune defenses, allow acquisition of nutrients and provide sensory and signaling functions important for host-parasite

interactions and pathogenesis. Cell surface proteins are thus critical for the parasitic lifestyle of *T. brucei* and make attractive targets for therapeutic intervention in sleeping sickness. The flagellar membrane in particular, is a sub-domain of the cell surface specialized for host-parasite interaction in *T. brucei* and important for signaling in a wide variety of other organisms. We recently published a flagellum surface proteome from bloodstream form parasites obtained by combining affinity purification of surface-exposed proteins with state-of-the-art proteomics, however no systematic study of the entire parasite surface has been conducted and only a few key surface-exposed proteins have been characterized. This represents a major gap in our understanding of trypanosome biology and the host-parasite interface. We have now capitalized on our proteomics approach to define the cell surface proteomes of *T. brucei* from insect and mammalian bloodstream form parasites. From these data, we have identified life cycle stage-specific cell surface proteins that may provide host-specific adaptations, including several life cycle stage-specific adenylate cyclases. Ongoing experiments will test the impact of host-specific proteins on infection of the mammalian host and address whether protein diversity on the cell surface is concentrated within the flagellum membrane. Together, the proposed experiments will increase understanding of the role of trypanosome surface proteins during infection and advance efforts to understand and exploit the flagellum as a key host-parasite interface. While our focus is on the host-parasite interface of *T. brucei*, we expect our results to be of wide interest for the community studying fundamental biology and pathogenesis of parasitic protozoa.

761

A putative ion channel is required for flagellum attachment in Trypanosoma brucei.

G. Langousis[1], M. Oberholzer[1], K. Hill[1,2]; [1]Microbiology, Immunology and Molecular Genetics, University of California, Los Angeles, Los Angeles, CA, [2]Molecular Biology Institute, University of California Los Angeles

Trypanosoma brucei is the etiological agent of sleeping sickness, which causes significant human mortality and limits economic development in sub-Saharan Africa. Critical to trypanosome development and disease pathogenesis is the parasite’s single flagellum which drives cell motility and participates in host-pathogen interactions, immune evasion and cell morphogenesis. A unique and defining feature of T. brucei cell architecture is the flagellum attachment zone (FAZ), a region of membrane-cytoskeleton linkages that provide for lateral attachment of the flagellum to the cell. Disruption of the FAZ results in flagellum detachment and is lethal. Only a handful of proteins have been localized to the FAZ, some of which function in maintenance of attachment and others that participate in surface remodeling. However, the nature of the attachment architecture and the involved components remain enigmatic.

We discovered that Goldengate, a putative calcium channel, localizes to the FAZ region and is required for flagellum attachment. Goldengate is a massive 304 kDa multi-spanning membrane protein with orthologs in many eukaryotes. We in situ tagged Goldengate in both procyclic and bloodstream form parasites and showed FAZ localization and membrane partitioning by immuno-fluorescence and biochemical fractionation respectively. Flagellum-detachment experiments suggested that Goldengate resides on the flagellar side of the FAZ. Surprisingly, RNA-interference knockdown of Goldengate results in flagellar detachment and is lethal in both life stages. Precise localization of Goldengate by immuno-electron microscopy and structure-function experiments are underway to distinguish between ion channel functions and structural functions in flagellum attachment.

The gen LbrM01_V2.0210 of Leishmania braziliensis codifies for a chloride channel.

Y. Y. Lozano Jimenez[1,2], M. E. Forero[2], M. Carreño[1], N. Quintero[1,2], O. Parada[1], C. Dorado[1], M. L. Posada[3], M. Camacho[1,2]; [1]Universidad Nacional de Colombia, Bogota, Colombia, [2]Centro Internacional de Física, Bogotá, Colombia, [3]Universidad del Rosario

Leishmaniasis is a complex of diseases of high relevance, caused by protozoan parasites of the genus *Leishmania*. To complete its life cycle *Leishmania* is exposed to different temperature, osmolarity, ion concentration and pH conditions. As a promastigote, extracellular stage inside the gut of a sand fly vector, the parasite is at 28°C, ~300 mOsm and pH of 7,0-8,0, but, as an amastigote, the intracellular stage, the environment is at 35°C, ~150–250 mOsm and pH 4,5-5,5 inside the parasitophorous vacuole. Parasite adaptation to this pH gradient and osmolarity changes while, securing nutrient transport depends on P-type H^+-ATPases function, coupled to anionic transport. We recorded voltage-dependent chloride currents in *Xenopus laevis* oocytes after injection of *Leishmania* mRNA. A group of four putative sequences for chloride channels is reported in the *Leishmania braziliensis* genome. In this work we present evidence of expression of these sequences in *Leishmania* promastigotes and recorded chloride currents from HEK 293 cells transfected with *LbrM01_V2.0210.*
Specific primers were designed to amplify partial and total coding regions of the genes *LbrM01_V2.0210, LbrM04_V2.1010, LbrM32_V2.3670* (GeneBank and GeneDB). Total RNA was extracted from various *Leishmania* species and different parasite stages with and cDNA obtained, that was used as template for PCR. The *LbrM01_V2.0210* PCR product was purified, cloned into the mammalian expression vector pcDNA3.1/CT-GFP-TOPO, and verified by sequencing (Macrogen USA), before transfection into HEK 293 cells. Chloride channel activity was recorded by patch clamp.
Products of the expected molecular weight were detected for *LbrM33_V2.1260, LbrM01_V2.0210, LbrM04_V2.1010, LbrM32_V2.3670* in stationary promastigotes of *L. braziliensis, L. amazonensis, L. panamensis* and *L. major.* Partial sequence showed high similarity to those reported in GeneDB. Expression of *LbrM33_V2.1260, LbrM01_V2.0210* was also found in *L. braziliensis* amastigotes. Bioinformatic analysis of these genes reported homology to mammalian intracellular ClC channels, particularly ClC3 and ClC6. Promastigote labeling with anti-ClC3 antibodies shows fluorescence in the parasite plasma membrane and flagellar pocket. Whole cell recordings of HEK 293 cells transiently transfected with *LbrM01_V2.0210* showed outwardly rectifying voltage currents. The amplitude of these currents was modulated by hipotonicity and low pH. Inhibitors of anionic channels block the current by 50-70%. These electrophysiological properties are consistent with a chloride channel type ClC that may support pH and osmolarity regulation in *Leishmania*.

763

Host cell egress by intracellular protozoan parasites.

L. M. Garcia[1,2], M. D. Quintana[1,2], M. Camacho[1,2]; [1]Universidad Nacional de Colombia, Bogota, D.C., Colombia, [2]Centro Internacional de Física, Bogotá, Colombia

Leishmania sp. and Plasmodium falciparum are obligatory intracellular parasites, responsible of major tropical diseases. Their life cycle include a stage in a vertebrate host, within which they localized intracellularly, confined into a parasitophorus vacuole (PV). In the PV, these parasites divide and are released in order to infect new cells. The egress model has not been fully established, but two basic mechanisms are proposed: (1) egress by lysis of the parasitophorous vacuole membrane (PVM) and the host cell plasma membrane (HCPM) or (2) egress by fusion of the PVM and the HCPM. We explore both mechanisms in these two models.

Monitoring infection by light microscopy indicates that parasite exit occurs between 72-78 hours post-infection (hpi) for Leishmania and at 48 hpi for Plasmodium. The period measure for Leishmania coincides with an increase in macrophage's capacitance, suggesting incorporation of membrane to the HCPM, which could come from PVM fusion. Lactate dehydrogenase (LDH) activity, distribution of the fluorescent probe Calcein AM and FM464 and FM143 labeling were carried out to infer the egress mechanism. During parasite exit, LDH activity was detected in culture supernatants but it was of less magnitude to that of total HCPM lysis. Calcein was partially distributed to supernatants with an important amount left in host cells. The evidence indicates that these parasites might use both mechanisms as has been shown for Chlamydia.

764

Stereoscopic transmission electron microscopy of Maurer′s Clefts in ″unroofed″ specimens of *Plasmodium falciparum*-infected erythrocytes.

E. H. Hayakawa[1], F. Tokumasu[2], J. Usukura[3], T. Tuboi[4], H. Matsuoka[1], T. E. Wellems[2]; [1]Lab of Medical Zoology and Parasitology, Department of Infection and Immunity, Jichi Medical University, Shimotsuke, Japan, [2]Laboratory of Malaria and Vector Research, National Institute of Allergy and Infectious Diseases, NIH, Bethesda, MD, [3]Division of Integrated Project, EcoTopia Science Institute, Nagoya University, Nagoya, Japan, [4]Malaria Research Unit, Cell-Free Science and Technology Research Center, Ehime University, Matsuyama, Japan

Intraerythrocytic stages of human malaria parasite, *Plasmodium falciparum* (*Pf*), modify and remodel their host cell environment in numerous ways. Among these modifications are Maurer′s Clefts (MCs), which develop in erythrocyte cytoplasm and promote the trafficking of parasite proteins including Pf erythrocyte membrane protein 1 (PfEMP1). The fine structure of MCs and their relationships with the erythrocyte membrane are still poorly understood. In this study, we investigated the structure of MCs by stereoscopic transmission electron microscopy (TEM) of snap frozen and ″unroofed″ specimens of parasitized erythrocytes. Our images show that MCs have spherical/oval bodies with sizes of approximately 200 nm to 500 nm in width and 300 to 700 nm in length. These shapes are consistent with a previously proposed 3D model reconstructed from TEM section images. In addition, we observe tethers/strings which interconnect adjacent MCs and connect to the erythrocyte membrane skeleton. The presence of these previously unobserved extensions and tethers in our images demonstrates the value of unroofing techniques and their ability to provide new information on the structural modifications of parasitized erythrocytes.

765

PfEXP-250, a Novel P. falciparum-exported Protein, Associated with the Maurers clefts is Expressed in the Exoerythrocytic Stages.

G. Mayer[1], S. Jean[1], O. Akande[1]; [1]Virginia Commonwealth University, Richmond, VA

After invading a host erythrocyte, *Plasmodium falciparum* induces extensive modification of the host erythrocyte. Thus far, the expression and localization of *Plasmodium*-exported has only been studied in the erythrocytic stage. Very little is known about the *Plasmodium* proteins exported during the liver stage. We have previously characterized PfEXP-250, a unique *P. falciparum*-exported protein containing a PEXEL motif located at the carboxy-terminus of the protein. PfEXP-250 is highly conserved and has paralogues in *P. vivax*, *P. yoelii* and *P. berghei*. We have found PfEXP-250 to be exported to the erythrocyte cytosol and to be associated with Maurer's cleft resident proteins. Surprisingly, we have also found EXP-250 to be expressed in sporozoites and in the exo-erythrocytic forms of *P. berghei*. However, EXP-250 does not appear to be exported in the sporozoite and exo-erythrocytic forms. We have examined the expression of skeleton-binding protein 1 (SBP-1) and ring-exported protein 1 (REX-1) in *P. berghei* and

found both not to be expressed in the liver stage. These data suggest that PfEXP-250 may be playing a unique role in the parasite. Its mechanism of export is currently under investigation

766

The Adaptor Protein MyD88 is Essential For Development of Murine Placental Malaria.

R. Barboza[1], L. G. Silva[1], D. D. Leite[1], K. R. Pereira[1], S. Epiphanio[2], C. R. Marinho[1];
[1]ICB/Parasitology, University of Sao Paulo, Sao Paulo, Brazil, [2]Federal University of Sao Paulo, Brazil

Placental malaria (PM) is associated with a panel of complications affecting both mother and fetus. Many of the injuries induced by the infection during pregnancy are related with the accumulation of infected red blood (iRBC) cells in the placenta and the interaction between parasite and host cells. It has been described that members of the Toll Like Receptors (TLR) family, recognize components of Plasmodium sp. and affect the host immune response. In common, TLR signal through MyD88, which leads to induction of NF-kB-dependent inflammatory cytokine production. The objective of this study was to evaluate the effect TLR activation by iRBC in the placenta. Initially, to ascertain if TLR could recognize P. berghei NK65 iRBC, human embryonic kidney epithelial (HEK) cells were cotransfected with mouse CD14 and TLR2 or TLR4, or transfected with TLR9. For luciferase reporter assay, cells were also cotransfected with ELAM-1-firefly luciferase and beta-actin-Renilla luciferase plasmids. Our results shown that iRBC were able to activate TLR9 and with less intensity activate TLR4-CD14, but not TLR2-CD14 transfected cells. To verify the effects of TLR activation, we infected pregnant MyD88 knockout and C57BL/6 mice with P. berghei NK65 on the 13th gestational day. Histopathological analysis of the placentas shows a decrease of vascular spaces in C57BL/6 infected mice when compared with placentas from non-infected mice (38% vs. 48% of vascular space). On the other hand, placentas from infected and non-infected MyD88 did not presented differences. Moreover, we evaluate the placental expression of pro-inflammatory cytokines IL-1β and IL-6 mRNA. Our results show that only C57BL/6 infected mice present an increase in the expression of both cytokines. Placental inflammation is correlated with abortions and preterm delivery, in fact in our results, C57BL/6 infected mice presented an increased number of abortions when compared with non-infected animals (1.8 vs. 0.2 abortions/female) whereas in MyD88KO mice no abortions were observed. In summary, this study illustrates the importance of a severe inflammatory response in the development of PM pathogenesis and, additionally, indicates the adaptor protein MyD88 as potential targets for therapeutics intervention.

A Live-Cell Approach to Investigating the Microsporidia-Host Interface.

M. Santiana[1], A. Cali[1], P. M. Takvorian[1], N. Altan-Bonnet[1]; [1]Biology, Rutgers University, Newark, NJ

The Microsporidium, *Anncaliia algerae (Brachiola algerae),* is an obligate eukaryotic intracellular parasite and an opportunistic human pathogen that can cause morbidity and mortality among immune-compromised individuals including patients with AIDS and those undergoing chemotherapy. There is little known about the Microsporidia-host cell interface in living host cells, due to current approaches being limited by the lack of fluorescent reporters for detecting the parasite lifecycle. Here we have developed and applied novel fluorescent parasite labeling methodologies in conjunction with fluorescent protein-tagged reporters to be able to track simultaneously the dynamics of both parasite and host cell specific components, including the secretory and endocytic trafficking pathways, during the entire infection time period. We have found dramatic changes in the dynamics of host secretory trafficking organelles during the course of infection. The Golgi compartment is gradually disassembled and regenerated adjacent

to Endoplasmic Reticulum exit sites. Importantly we find that individual microsporidial progeny are each associated with these *de novo* formed mini-Golgi structures. These host structures appear to create a membrane bound niche environment for parasite development. Our studies presented here are an important first step in understanding the biology of Microsporidial parasites in the living host.

768

Essential Roles for Soluble Virion-Associated Heparan Sulfonated Proteoglycans and Growth Factors in Human Papillomavirus Infections.

Z. Surviladze[1], A. Dziduszko[1], M. A. Ozbun[1]; [1]Molecular Genetics & Microbiology, University of New Mexico School of Medicine, Albuquerque, NM

A subset of human papillomavirus (HPV) infections is causally related to the development of human epithelial tumors and cancers. Like a number of viruses, HPV entry into target cells is initiated by first binding to heparan sulfonated proteoglycan (HSPG) cell surface attachment factors. The virus must then move to distinct secondary receptors, which are responsible for particle internalization. Despite intensive investigation, the mechanism of HPV movement to and the nature of the secondary receptors have been unclear. We report that HPV16 particles are not liberated from bound HSPG attachment factors by dissociation, but rather are released by a previously unobserved process for pathogens. Virus particles reside in infectious soluble high molecular weight complexes with HSPG, including syndecan-1 and bioactive compounds, including growth factors. MMP inhibitors that block HSPG and virus release from cells interfere with virus infection. Using a co-culture assay, we demonstrate HPV associated with soluble HSPG-growth factor complexes can infect cells lacking HSPG. Interaction of HPV-HSPG-growth factor complexes with growth factor receptors leads to rapid activation of signaling pathways important for infection, whereas a variety of growth factor receptor inhibitors impede virus-induced signaling and infection. Depletion of syndecan-1 and removal of serum factors reduce infection, while replenishment of growth factors restores infection. Our findings support an infection model whereby HPV usurps normal host mechanisms for presenting growth factors to cells via soluble HSPG complexes as a novel method for interacting with entry receptors independent of direct virus-cell receptor interactions.

769

Purified the Human T-Cell Leukemia Virus Type 1 via Centrifugation.

C. Nwankwo[1], A. Fuksz[1], T. Gibson, Ph.D. [1]; [1]Biology, University of Texas of the Permian Basin, Odessa, TX

Human T-Cell Leukemia Virus Type 1 (HTLV-1) is a human retrovirus. It is the cause of two types of human diseases: adult T-cell leukemia (ATL) and tropical spastic paraparesis/HTLV-1 associated myelopathy (TSP/HAM). Currently, there are no therapeutic agents for HTLV-1 infection. Our hypothesis is that there are cellular factors packaged within HTLV-1 virion, which are important for successful viral replication. In order to investigate this, purified virus must be used. Therefore, we have performed tripartite transfection to produce VSV-G[HTLV-1] virions. HEK 293T-cells were transfected with three plasmids, which contain the necessary viral genes to produce VSV-G[HTLV-1]. Next, western blots have been performed, which confirm that VSV-G[HTLV] virions were produced and processed correctly. We have developed a purification method involving dialysis and centrifugation to purify the viruses from producer cells. As a control MT-2 cells, which are chronically infected with HTLV-1, have been used. Currently, we are using microscopy and western blotting techniques to identify cellular proteins that are packaged inside of the VSV[HTLV-1].

770

PI4P/Cholesterol enriched Membrane Platforms are required for viral RNA synthesis.

O. Ilnytska[1], N. Altan-Bonnet[1]; [1]Biological Sciences, Rutgers University, Newark, NJ

Many RNA virus infections induce complex subcellular membrane structures, on which they assemble their replication enzymes and synthesize viral RNA. These replication membrane platforms are unique in protein and lipid composition from that of host membranes. Previously we had demonstrated that enteroviruses and flaviviruses hijack host phosphatidylinositol-4-kinase III beta (PI4KIIIb) enzymes to generate replication platforms enriched in phosphatidylinositol-4-phosphate (PI4P) lipids, which in turn facilitated viral RNA synthesis. In this study we demonstrate that in addition to PI4P lipids, the sterol cholesterol also plays an important role in generating the viral replication platforms. We show that in the early stages of infection viral RNA enzymes are assembled on pre-existing membrane domains of the TGN that are enriched in both PI4P and cholesterol. The replication organelles that are generated later during peak replication kinetics also continue to be enriched in both PI4P and cholesterol. We show that the cholesterol at these membrane sites is trafficked from the plasma membrane via Rab8 and Rab11 dependent endocytic pathways. Furthermore the presence of cholesterol binding proteins such as Caveolin, OSBP and CERT can compete and interfere with the assembly of viral replication complexes on these platforms. Taken together, these findings indicate that PI4P/cholesterol platforms can facilitate viral RNA synthesis and these domains may be critical for helping assemble the viral replication machinery components in the early stages of infection when they are in low abundance in the cell.

771

Interaction of soluble S proteins of *transmissible gastroenteritis coronavirus* (TGEV) with its receptor pAPN and sialic acids.

K. Shahwan[1], G. Herrler[1]; [1]Institute of Virology, University of Veterinary Medicine Hannover, Hannover, Germany

Transmissible gastroenteritis virus (TGEV) is a porcine coronavirus that infects the epithelium of the intestinal tract leading to gastroenteritis. It affects pigs of all ages and the cellular receptor - the porcine aminopeptidase N (pAPN) - is required to initiate the infection of target cells. Binding to pAPN is mediated through the spike glycoprotein (S) of TGEV. The S protein also possesses a sialic acid binding activity which is connected with the enterotropism of TGEV. It has been shown in previous studies that TGEV recognizes a mucin-type glycoprotein in a sialic acid-dependent fashion.

To analyze the binding activity - to both the cellular receptor pAPN and the high molecular weight sialoglycoprotein - we generated a soluble S proteins comprising the S ectodomain connected either to the human Fc backbone or to the trimerization domain derived from the GCN4 leucine zipper. The soluble proteins were expressed by baby hamster kidney cells (BHK-21) or human embryonic kidney cells (293T). These S proteins bound to BHK cells transiently expressing pAPN as shown by indirect immunofluorescence and FACS analysis. The binding to porcine cell lines originating from testis (ST) or gut epithelium (IPI-2I) was also demonstrated. Pretreatment of the cells with neuraminidase (from Clostridium perfringens) showed a significant increase in binding of the soluble S proteins. Furthermore, we used swine erythrocytes for an erythrocyte pull-down assay to demonstrate the pull-down of soluble S proteins after incubation with erythrocytes. As shown by Western blot analysis, the pull-down-assay did not provide evidence for interaction of sol S proteins with sialic acids of erythrocytes.
Thus, the soluble S protein provides an interesting tool to investigate the interaction of TGEV with porcine aminopeptidase N.

772

Live imaging of membrane compartments interacting with herpes simplex virus during viral production: Evidence for HSV1- recruitment of fast vesicular transport machinery.

P. Ferland[1,2], K. Kilpatrick[2], E. L. Bearer[2]; [1]Pathology, Brown University, [2]Pathology, University of New Mexico, Albuquerque, NM

A major controversy exists as to the molecular mechanism(s) of outbound transport of nascent herpes simplex virus after replication in the nucleus. Infectious herpes simplex virus type 1 (HSV1) particles have four concentric compartments: a double-stranded DNA core within a proteinaceous capsid, encased in tegument proteins and enveloped in a glycoprotein-rich lipid membrane. Whether virus assembles before, during or after transport is not understood. To address this question, we performed live confocal time-lapse imaging of HSV1 packaging and transport in cells synchronously infected over a one-hour window. By labeling cellular membrane systems with lipid dyes, DiI, DiO and DiD, transfecting cells with cellular membrane proteins labeled with fluorescent proteins, and infecting with HSV1-VP26GFP that carries GFP label on capsids, we directly witness the dynamic interplay between cellular membranes and nascent virus. These studies show that at early time points, most viral capsids assemble with membranes in the perinuclear region (71%) and then travel together with membranes to the periphery, with multiple reversals and zig-zags. A few capsids also travel at fast transport rates independent of detectible membranes or cellular membrane proteins. At later time points when the Golgi has fragmented and drifted towards the cell periphery, more capsids travel outwards for longer distances without membranes. We conclude that viral transport is most often but not necessarily coupled with secondary envelopment, that the stage of infection influences transport mechanisms, and that HSV1 thus may use multiple redundant mechanisms to attract cellular motors mediating its exit from cells. NS062184; RO1 NS046810 and P5OGM08273.

773

Intranuclear Pathways Targeted by Influenza Virus.

P-L. Tsai[1], C. V. Forst[2], A. Garcia-Sastre[3], B. M. Fontoura[1]; [1]Department of Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX, [2]Department of Clinical Sciences, University of Texas Southwestern Medical Center, Dallas, TX, [3]Department of Microbiology, Mount Sinai School of Medicine, New York, NY

Influenza A viruses are negative-sense, segmented RNA viruses, which cause about 500,000 deaths worldwide per year. Genomic studies have shown that the non-structural protein (NS1) of influenza A virus is a major virulence factor that is essential for pathogenesis. NS1 is a multifunctional protein localized in the nucleus and in the cytoplasm. In the cytoplasm, NS1 inhibits host signaling pathways that result in down-regulation of interferon expression and innate immune response. In the nucleus, NS1 represses host gene expression by down-regulating mRNA processing and export. We showed that NS1 binds the mRNA complex constituted of NXF1/TAP, NXT/p15, Rae1, and E1B-AP5, which are key components of the mRNA export machinery. By targeting this complex, NS1 blocks host mRNA export, and cells become highly permissive to virus replication. Another intranuclear pool of NS1 was found to interact with a host protein termed NS1-BP (NS1-Binding Protein), which has been suggested to play a role in pre-mRNA splicing. However, the functions and mechanisms involving NS1-BP and their impact in the host and for the influenza virus life cycle remained to be elucidated. To investigate the function of NS1-BP, we first identified its binding partners by immunoprecipitation followed by mass spectrometry. We then functionally validated these interactions and showed that NS1-BP has roles in transcription and mRNA processing. These functions direct impact both virus replication and host intranuclear functions that regulate host mRNA levels. Thus, we identified here NS1-BP as a regulator of virus replication and as a host factor that is required for

proper expression of specific subsets of host mRNAs. These functions regulate both the virus life cycle and the host immune response.

774

Enhanced invertase activities in the callus-like structures induced by BSCTV infection on Arabidopsis.

J. Park[1], Y. Jung[1], E-J. Kil[1], J-D. Kim[1], S. Kang[1], S. Cho[1], J. Chae[1], J-H. Park[1], S-H. Cho[1], S. Lee[1]; [1]Dept. of Genetic Engineering, Sungkyunkwan University, Suwon, Korea

Geminiviruses are single-stranded DNA viruses that infect a number of monocotyledonous and dicotyledonous plants. *Arabidopsis* is susceptible to infection with the *Curtovirus* group of geminiviruses including *Beet severe curly top geminivirus* (BSCTV). *Arabidopsis* infected with BSCTV exhibits systemic symptoms such as stunting of plant growth, callus induction on shoot tips, and curling of leaves and shoot tips. The regulation of sucrose metabolism is essential for obtaining the energy required for the process of viral replication and the development of symptoms in BSCTV-infected *Arabidopsis*. We evaluated the enhanced transcript level and enzyme activity of invertases in the inflorescence stems of BSCTV-infected *Arabidopsis*. These results were consistent with the increased pattern of ribulose-1,5-bisphosphate carboxylase/oxygenase activity and photosynthetic pigment concentration in virus-infected plants to supply more energy for BSCTV multiplication. The altered gene expression of invertases during symptom development was functionally correlated with the differential expression patterns of D-type cyclins, E2F isoforms, sucrose metabolism-related genes, and auxin-associated genes. Taken together, our results indicate that sucrose sensing by BSCTV infection may regulate the expression of sucrose metabolism and result in the subsequent development of viral symptoms in relation with the activation of cell cycle regulation.

Automated Correlation of Fluorescent and Electron Micrographs of Astrocyte Cells.

C. Mathisen[1], C. Loussert[2], B. Lich[1]; [1]FEI Co, Eindhoven, Netherlands, [2]Plateforme de microscopie électronique, University of Lausanne, Lausanne, Switzerland

The accurate correlation of fluorescent and electron data is becoming increasingly popular among cell biologists but is often impeded by the lack of automation and certainty in their correlative approach. Our work focused on the automatic correlation of images taken with a fluorescent light microscope (FLM) and scanning transmission electron microscope (STEM). Astrocyte cells expressing enhanced green fluorescent protein (EGPF) collected from the hippocampus of transgenic mice were used for this experiment. The cells were also immunolabeled for EGFP with nano gold particles. Although EGFP expression was apparent in the light micrographs, images of the ultrastructure were also needed to confirm EGFP expression was confined to astrocyte cells. With the aid of newly designed software, images acquired from the FLM and an overview image from the STEM were accurately aligned. This subsequently allowed for automatic acquisition of higher resolution STEM images in selected EGFP expressing areas. Using this method it was possible to accurately locate the electron dense tags in the cellular ultrastructure and determine that the expression of EGFP was confined to only astrocyte cells.

776

Advances in serial block face DualBeam electron microscopy for the exploration of cardiovascular and muscular tissues.

B. Humbel[1], W. Voorhout[2], R. Snyder[3], D. Wall[2], T. Wohlfarth[2], M. de Winter[4], C. Schneijdenberg[4], J. Post[4], B. Lich[2]; [1]Electron Microsopy Centre, University Lausanne, Lausanne, Switzerland, [2]FEI Company, Eindhoven, Netherlands, [3]FEI Company, Hillsboro, OR, [4]Cellular Architecture and Dynamics, University of Utrecht, Utrecht, Netherlands

Traditionally serial section transmission electron microscopy has been the only method available in which images are acquired from sections that are cut and mounted on grids. These image representing a 3D volume can be used to reconstruct and analyze the structure of the elements within. This method is very labor intensive, requiring a greater deal of manual dexterity, and when small mistakes occur, a continuous dataset is lost.

Recent studies have explored an alternative method for serial image acquisition in which the block face of resin-embedded neural tissue was imaged within a FEG SEM [1]. Sections were removed from the imaged face in the microscope using an ultra microtome and then immediately imaged by the SEM. This provides a series of aligned images of the tissue in the block face and has the clear advantage that image acquisition can be fully automated. However the quality of the sectioning is critically dependent on homogenous resin hardness which is difficult to maintain when the electron beam is being used at higher resolution and part of the block suffers from the differential heating effects.

We have continued [2] to explore an alternative approach that is seemingly unaffected by variations in resin quality that uses a focused ion beam directed perpendicular to the block face. This is used to mill the surface of the resin from which serial images can be acquired in either an arbitrary location or in a selected area of specific interest.

We have used automated repetitive cutting and imaging on the DualBeam (Slice and View) with consistent sectioning intervals to as low as 5 nm. I two separate experiments we used en EPON embedded vascular sample with an endothelial cell layer with an atherosclerotic plaque and block of heart muscle tissue to demonstrate the specific site 3D analysis (plaque region) as well as a bulk 3D analysis for the muscular tissue.

Results show that this focused ion beam technique is capable of reliably sectioning tissue, and using the back scattered electrons we were able to visualize the detailed ultrastructure. Organelles like ER, mitochondria, myosin are clearly visible. In a fully automated mode we were able to collect serial images that allowed us to make detailed morphological analyses of the cellular architecture in 3D.

Spatio-temporal control of intracellular ROS concentration in PDGF signaling revealed by single Eu^{3+}-doped nanoparticle imaging.

C. Bouzigues[1], T-L. Nguyen[1], R. Ramodiharilafy[1], P-L. Tharaux[2], A. Alexandrou[1]; [1]Laboratoire Optique et Biosciences, Ecole Polytechnique, Palaiseau, France, [2]PARCC, HEGP, Paris, France

For many cell functions, notably those requiring an asymmetric response, such as directed migration, spatio-temporal organization of signaling pathways is important for the cell response regulation. PDGF (Platelet Derived Growth Factor) induces migration in numerous contexts, such as reparation of vascular lesions or metastasis formation, inducing ROS (Reactive Oxygen Species) production as second messenger. The potential lethality of concentrated ROS and the importance of intracellular organization for migration require a tight control of their concentration. However, the dynamics of ROS production and organization is so far mostly unknown. By imaging single Eu^{3+}-doped nanoparticles[1], we probed the intracellular ROS response with high temporal and spatial resolution. We thus measured the absolute ROS concentration in normal or tumoral cells and revealed specific temporal patterns of ROS production under PDGF stimulation. We measured an integration time of several minutes required for the ROS response formation. This response formation is shorter for tumoral cells. We satisfyingly explained this fact by modeling the diffusion-limited dimerization of PDGFRs. This may constitute a temporal filtering mechanism for preventing cell responses to transient signals and its impairment in tumoral cells could be of great physiological relevance for the metastatic transition. We moreover quantitatively measured a transactivation of EGFR by PDGF stimulation and revealed its role in the dynamics of the cell response. By using a microfluidic system, we furthermore apply spatially controlled PDGF stimulation and displayed the maintenance of asymmetric ROS concentration in the cell under a PDGF gradient. This likely relies on a balance between ROS diffusion and degradation. This balance controls the local ROS concentration and thus the cell response. Altogether, our results reveal the tight regulation of the ROS spatio-temporal organization by the cell, which illustrates how the spatio-temporal control of transduction pathways is crucial for the buildup of the cell response.

The Living Cell Perceives the Difference between Magnetic and Nonmagnetic Isotopes of Magnesium.

V. Koltover[1], Y. Kutlakhmedov[2], D. Grodzinsky[2]; [1]Bio-Reliability Group, Institute of Problems of Chemical Physics, Russian Academy of Sciences, Chernogolovka, Moscow Region, Russia, Chernogolovka, Moscow Region, Russia, [2]Department of Radiation Biology, Institute of Cell Biology and Genetic Engineering, National Academy of Sciences of Ukraine, Kyiv, Ukraine, Kyiv, Ukraine

Some chemical elements have two kinds of stable isotopes, magnetic and non-magnetic ones. The question arises of whether the living cell can perceive the difference between magnetic and non-magnetic nuclei of the same element? Among three stable magnesium isotopes, ^{24}Mg, ^{25}Mg and ^{26}Mg with natural abundance about 79, 10 and 11%, only ^{25}Mg has nuclear spin and, hence, nuclear magnetic field. We revealed the isotope difference in parameters of growth of *E. coli* on different isotopes of magnesium. The adaptation period of the cells to the liquid media supplied with magnetic ^{25}Mg was found to be shorter than the adaptation period to the media supplied with nonmagnetic ^{24}Mg or ^{26}Mg. The cells enriched with ^{25}Mg demonstrate less activity of superoxide dismutase (SOD) when compared to the cells enriched with the nonmagnetic

isotope. Since the SOD level is adjusted to the level of superoxide radicals ($O_2^{\bullet-}$), it can be considered as evidence for the lower production of $O_2^{\bullet-}$ as by-product of respiration. On the solid nutrient media, the cells that were previously grown on ^{25}Mg demonstrate essentially higher viability (determined by counting CFU) than the cells grown on the nonmagnetic isotopes (Koltover et al., 2011). Furthermore, in experiments with *S. cerevisiae* we revealed the isotope difference in parameters of recovery of yeast cells after UV irradiation. The rate of post-radiation recovery was found to be twice higher for the cells enriched with ^{25}Mg as compared to the cells enriched with the nonmagnetic isotope (Grodzinsky et al., 2011). Magnetic isotope effects are known in chemistry (Buchachenko et al., 2008). We have uncovered, for the first time, the magnetic isotope effects *in vivo*. These results demonstrate the feasibility of new antistress therapy including radio-protectors based on the stable magnetic isotopes. Fibroblasts in Unloaded Tendon Tissue In Vitro Have Warmer (Mid-Infrared) Cytoplasm Than Nucleus.

B. Johnson-Wint[1]; [1]Department of Biological Sciences, Northern Illinois Univ, De Kalb, IL

Fibrillar extracellular type I collagen of dense connective tissue and osteoid is the main structural element bearing the load of tissue and organism weight in gravity. Fibroblasts and osteocytes in these tissues produce, degrade, organize and maintain type I collagen. Fibroblasts and osteocytes breakdown native type I collagen with a specific collagenase, matrix metalloproteinase I. I asked if fibroblasts and osteocytes also use thermal energy to denature adjacent collagen to gelatin and control very localized collagen breakdown through general proteolysis? In the present preliminary study tendon tissue was imaged in vitro to evaluate the distribution of 3-5 µm thermal energy in the extracellular matrix (ECM) and cells. Freshly isolated adult rat tail tendon was placed unloaded in an uncovered petri dish on top of a gauze pad containing complete culture medium. The tendon was barely covered on top by a thin layer of culture medium between it and the camera but was able to absorb nutrients from the culture medium below. This set up was placed on a heating plate set at 37° C. A FLIR mid-wavelength (3-5 um) infrared camera, SC7650E with 1X and 3X close-up lenses, was used to image the tendon. Images were captured with FLIR ExaminIR software and analyzed using Image J. The temperature range across the thickness of the tendon went from 32.25 °C to 34.5° C. Fibroblasts could be distinguished from the surrounding ECM of the tendon. In all regions of the tendon the cells were 0.2° C cooler than the adjacent ECM. In addition, the center of the fibroblasts were 0.1° C cooler than their periphery. Cell processes connecting fibroblasts in the tendon tissue could not be distinguished at 1X or 3X. These results suggest that the ECM of tendon is 0.2° C warmer than the fibroblasts in the tissue. However, since tendon is a bright white tissue, it is likely that ECM is reflecting IR which leaves unresolved evaluation of its temperature. The results also show that the periphery of the fibroblasts where the cytoplasm, cytoskeleton and organelles reside is 0.1°C warmer than the center of the cells where the nucleus is. This may reflect increased heat production in the periphery of the fibroblast due to metabolic processes and cytoskeletal force generation. And finally, these results show that imaging finer details of the fibroblasts will require greater than 3X magnification.

Metabolic labeling of newly synthesized proteins and their post translational modification reveals differential involvement of cellular degradative pathways.

N. Dolman[1], K. Chambers[2], B. Mandavilli[2], R. Batchelor[2], M. Janes[2]; [1]Cellular Imaging, Molecular Probes, Life Technologies, Eugene, OR, [2]Molecular Probes, Life Technologies

After translation by the ribosome cellular proteins have a finite lifespan. This lifespan is governed by one of two major degradative pathways: the ubiquitin-proteasome system (UPS) and the autophagy-lysosome pathway (ALP). Deficits in either pathway alter protein homeostasis and can cause proteins to build up in the cytoplasm, which can be detrimental to the cell. In an extreme case these proteins form aggregates and these have been associated with cellular pathologies including neurodegenerative disorders. Here we report the metabolic labeling of proteins with a methionine analog in conjunction with tagging of post-translation modification with mannosamine analogs. Using metabolic labeling of proteins we show the lifetime of metabolically labeled proteins in HeLa and A549 cells. We also quantify the relative contribution of the UPS and ALP to protein clearance and show that under regular growth conditions the UPS is the predominant route for protein clearance. Finally we use this approach to demonstrate the accumulation of ubiquitin-positive protein aggregates in the cytoplasm of cells treated with inhibitors of the UPS and ALP. We also show the accumulation of post-translation products upon inhibition of either the UPS or ALP, thereby highlighting the role of these two pathways in recycling moieties attached to proteins following translation.

Microfluidic devices for live imaging of gently immobilized C.elegans and for high-resolution imaging of early embryos during acute drug treatment.

E. Gutierrez[1], R. Green[2], A. Carvalho[2], S. Olson[2], K. Oegema[2], A. Groisman[3]; [1]Department of Physics, University of California-San Diego, La Jolla, CA, [2]Ludwig Institute for Cancer Research, Dept. of Cellular and Molecular Medicine, University of California-San Diego, [3]Physics, University of California-San Diego

A major challenge for studying dynamic developmental processes in C. *elegans* has been difficulties associated with long-term high-resolution imaging of worms. We use a micro-machined elastomer chip that is pushed against a thin layer of a silicone gel on a glass coverslip by the application of vacuum to trap worms between the elastomer and gel. Loading the device is simple and minimizes the loss of worms. The device is compatible with short working distance microscope objectives and has an array of continuously perfused compartments with individual worms sequestered in them. The pushing force is widely adjustable by varying the level of vacuum, making the device suitable for a variety of worm sizes and enabling a user-defined degree of immobilization. Upon reduction of the vacuum, the worms recover their normal behavior, while staying confined in their compartments. Worms can be easily recovered from the device into a minimal volume of buffer for further propagation, by separating the elastomer chip from the gel substrate. In pilot experiments, we have successfully used this device to completely immobilize and image worms at different developmental stages without loss of viability. Specifically, we have imaged individual neurons and the developmental time course of the gonad region, using DIC and two-color fluorescence confocal microscopy.
Small molecule inhibitors are a valuable tool for the analysis of fundamental cellular functions and an entry point for the development of therapeutic agents. In C. *elegans* embryos the use of small molecule inhibitors has been limited by eggshell impermeability. We identified a gene whose inhibition renders the eggshell permeable without disrupting events during the early embryonic division and built a specialized microdevice for in situ worm dissection and high resolution imaging of embryos. The microdevice has a rectangular well with an array of

microwells at the bottom and an integrated dissection board nearby. Worms are placed on the board, cut with a scalpel and the fragile embryos are gently swept towards the microwell array. Embryos settle onto the bottom of the microwells, where they rest on a coverslip, being protected from flow by the microwell walls. Permeable embryos are acutely exposed to drugs after the medium in the microwells is exchanged by aspiration of the existing medium and dispensing of a medium with the drug into the well with a pipette. The technique was tested with 4 common inhibitors: the microtubule inhibitor nocodazole, actin inhibitor latrunculin A, myosin inhibitor blebbistatin, and proteasome inhibitor c-lactocystin-β-lactone. All 4 inhibitors had the expected effects on permeable embryos and no effect on control impermeable embryos.

782

Label-free imaging of the trabecular meshwork of the eye using Coherent Anti-Stokes Raman Scattering (CARS) microscopy.

T. Lei[1], D. Ammar[2], O. Masihzadeh[3], E. Gibson[3], M. Kahook[2]; [1]Electrical Engineering, University of Colorado Denver, Denver, CO, [2]Ophthalmology, University of Colorado Denver, [3]Bioengineering, University of Colorado Denver

Objective: Dysfunction of fluid outflow through the trabecular meshwork (TM) region of the eye is the primary cause of glaucoma. Our objective was to image the human TM using a non-invasive, non-destructive technique without the application of exogenous label.
Methods: Flat-mounted trabecular meshwork samples from a human cadaver eye were imaged using two non-linear optical techniques: coherent anti-Stokes Raman scattering (CARS) and two-photon autofluorescence (TPAF). In TPAF, two optical photons are simultaneously absorbed by autofluorescence molecules such as collagen and elastin. The CARS technique uses two laser frequencies to specifically excite carbon-hydrogen bonds, allowing the visualization of lipid-rich cell membranes. Multiple images were taken along an axis perpendicular to the surface of the TM for subsequent analysis.
Results: Analysis of multiple TPAF images of the TM reveals the characteristic overlapping bundles of collagen of various sizes. Simultaneous CARS imaging revealed elliptical structures of ~7x10 µm in diameter populating the meshwork which were consistent with TM cells. Irregularly shaped objects of ~4 µm diameter appeared in both the TPAF and CARS channels, and are consistent with melanin granules.
Conclusions: CARS techniques were successful in imaging live TM cells in freshly isolated human TM samples. Similar images have been obtained with standard histological techniques, however the method described here has the advantage of being performed on unprocessed, unfixed tissue free from the potential distortions of the fine tissue morphology that can occur due to infusion of fixatives and treatment with alcohols. CARS imaging of the TM represents a new avenue for exploring details of aqueous outflow and TM cell physiology.

Real-time hyperspectral fluorescence imaging of β-cell insulin-secreting dynamics with Image Mapping Spectrometer (IMS).

L. Gao[1], A. D. Elliott[2], N. Bedard[3], A. Ustione[4], N. Hagen[3], R. Kester[3,5], D. Piston[2], T. S. Tkaczyk[6,7]; [1]Rice Quantum Inst, Rice University, Houston, TX, [2]Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN, [3]Bioengineering, Rice University, [4]Department of Molecular Physiology and Biophysics, Vanderbilt University, [5]Rebellion Photonics Inc, Houston, TX, [6]Bioengineering, Rice University, Houston, TX, [7]Electrical and Computer Engineering, Rice University, Houston, TX

Ca2+ and cAMP are important second messengers that are involved in the regulation of insulin secretion [1]. Although previous studies have suggested that Ca2+ signal pathway directly

interacts with cAMP production, the underlying mechanisms remain unresolved, especially regarding the role of Ca2+ in regulating the cAMP oscillation following both glucose and hormone secretion. Recently, a range of fluorescent-Protein (FP)-based biosensors have been developed [2], which allows the dynamics of cAMP to be imaged in living cells. However, since most FP-based biosensors spectrally overlaps with Ca2+ indicator – Fluo4, it is difficult for traditional cameras to image FP-based biosensor and Ca2+ indicator Fluo4 simultaneously.
In our study, a novel hyperspectral imaging device – Image Mapping Spectrometer (IMS) has been utilized to monitor insulin-secreting cellular dynamics. The IMS is a widefield method acquiring full spectral information simultaneously from every pixel in the field-of-view [3]. It works by spatially distributing (i.e. mapping) neighboring image zones to create space between them. A spectrally dispersive element then spreads the wavelength content from each zone into this space which is recorded by a CCD detector. Since no scanning is employed in the IMS, The IMS system offers significant advantages in spectral imaging speed (currently up to 7.2 fps) and signal collection (~ 85% optical throughput) [4].
To demonstrate the capabilities of the IMS in cellular applications, we measured the drug response of cAMP production (indicated by a FP-based biosensor - Epac) and Ca2+ flow (indicated by Fluo4 dye) in living MIN6 ß-cells. Then, the cAMP oscillations in the islet and their relation to Ca2+ oscillations have been investigated as a function of glucose and other perturbative factors in the insulin secretion pathway. Our data indicate that, upon initialization of cAMP production, the signaling cascades between Ca2+ oscillations and cAMP oscillations are interconnected at the time scale of a sec. These findings prove that significant progress in elucidating the roles of Ca2+ and cAMP in ß-cell function is possible with the simultaneous monitoring provided by the IMS system.

High-speed quantum dots tracking reveals small-scale short-term compartmentalized diffusion in plasma membranes.

M. P. Clausen[1], B. C. Lagerholm[1]; [1]MEMPHYS - Center for Biomembrane Physics, University of Southern Denmark, Odense M, Denmark

In this work, we show that tracking of single quantum dots (QDs) is possible at image acquisition rates up to ~2,000 Hz. We image with a spatial precision of ~40 nm for several seconds (9,000 frames) at this high-speed imaging rate using a standard wide-field fluorescence microscope and an EMCCD camera.
Using this system, we show that membrane proteins and lipids, which have been exogenously labeled with functionalized QDs display three types of motion in the plasma membrane of live cells; free diffusion, confined diffusion, and compartmentalized diffusion where the molecules moves between compartments of ~100 nm in diameter within a lifescale of ~100-200 ms (also termed hop-diffusion). We further investigate the cholesterol dependence of the compartmentalized diffusion.
Such observed dynamic features will always be dependent on three parameters; the diffusion rate of the investigated molecule, the compartment size, and the image acquisition rate. If not imaged at sufficient speed, compartmentalized diffusion will appear either as free or confined diffusion but at a slower diffusion rate. Therefore, we compare our experimental result with

computer simulations to find the relation between the diffusion rate, the compartment size and the image acquisition frequency.
The QDs used in this imaging system has a signal brightness and stability advantage as compared to conventional fluorophores allowing for long-term fast imaging, and a size advantage to gold particles used for high-speed single particle tracking.

785

Polarized TIR-FM of sub-resolution membrane curvature during endocytosis and viral budding.

J. G. Kerkvliet[1], E. D. Swanson[2], A. D. Hoppe[2]; [1]Chemistry and Biochemistry, South Dakota State University, Brookings, SD

Induction of membrane curvature is an essential step in the formation of endocytic vesicles and viral particles. Electron microscopy can be used to visualize membrane curvature in fixed cells, however, these techniques cannot be used to visualize the dynamics of the biochemical events influencing bilayer structure. Axelrod and co-workers have shown that certain fluorescent dye molecules can orient in the lipid bilayer and can be selectively excited by polarized light thereby enabling detection of membrane curvature in a fluorescence microscope. Therefore, we investigated whether polarized Total Internal Reflection Fluorescence Microscopy (TIR-FM) could be used to visualize endocytosis and viral budding in cells labeled with the lipophilic fluorophore DiI. s-pol and p-pol TIRF fields were created by positioning a beam laser at distinct azimuthal positions in the back focal plane using a commercial two-dimensional scan head. s-pol images preferentially excited DiI molecules in membrane parallel to the coverglass and p-pol preferentially excited DiI molecules orthogonal to the coverglass. Ratios of p/s were calculated to generate images of membrane curvature and images of p+2s allowed visualization of total membrane. Images of clathrin-YFP and HIV Gag-YFP were collected simultaneously to visualize sites of endocytosis and viral assembly.

786

***In vivo* Imaging of Plasmid DNA Reporters in Skeletal Muscle.**

M. G. Guess[1], K. Bjorkman[2]; [1]University of Colorado, Boulder, CO, [2]MCDB, Boulder, CO

To date, skeletal muscle differentiation and development has been heavily researched and intense focus has been placed on understanding these processes as they relate to disease. While recent advances have yielded many insights into the transcriptional and post-transcriptional mechanisms that control these processes, the difficulty of mammalian *in vivo* experiments has limited many of these findings to *in vitro* models. A system which would allow the real-time measurement of transcriptional and post-transcriptional regulation events both spatially and temporally, in living animals, would greatly augment our current cellular and molecular understanding of skeletal muscle. In an attempt to achieve this we have developed a novel system to visualize reporter activity in skeletal muscle myofibers. Using hydrodynamic limb vein injection (HLV) of plasmid DNA, combined with *in vivo* fluorescent and bioluminescent imaging, we can monitor the activity of reporters and quantify the signal using Region of Interest (ROI) analysis. This allows measurement of promoter regions temporally during regeneration in C57BL/6 mice and also in the mdx4cv muscular dystrophy model. There is also an interest in understanding the pathophysiological role that microRNAs play in skeletal muscle disorders, and in muscle regeneration following injury. Here we show that this technique can also be used to monitor in real time the activity level of endogenous microRNAs by using complementary microRNA sequences inserted into the firefly luciferase 3’-UTR.

787

Quantification of homo and hetero oligomerization between paralogous proteins in Saccharomyces cerevisiae.

G. Lopez[1], M. Duhne[1], A. Gonzalez Manjarrez[1]; [1]IFC UNAM, Mexico City, Mexico

Introduction

A trascendental aspect related to the quaternary organization of paralogous proteins is the study of the transition from homomeric to heteromeric structures and the importance of this transition in the appearance of new functions. Such functional versatility may imply a mayor stability of the complexes, the acquisition of different kinetic properties or changes in the interaction networks with other proteins. The simultaneous existence of different isoforms between products of duplicated genes, their impact in the physiology and biochemistry of *Saccharomyces cerevisiae* were assessed in this study.

Methodology

Saccharomyces cerevisiae strains Y8205 MATα y BY4741 MATa were used in this study. The analysis of the different interactions between paralogous proteins was assessed by BiFC. This technique consists in the phusion of complementary half's of GFP to the paralogous proteins. If there is an interaction between these proteins, the GFP is reconstituted producing a fluorescence signal which can be quantified by confocal microscopy and flow cytometry.

Results

The pertinent constructions to determine the formation of oligomers of the following paralogous proteins pairs: *ENO1, ENO2, GDH1, GDH3, HXK1, HXK2, LEU4, LEU9, LYS20, LYS21, PYC1, PYC2, TDH1, TDH2, TDH3, URA7, URA8* were made. Using flow cytometry the dynamic fluctuations of the formation of different isoforms (homo- and hetero-oligomers) was evaluated for the first time.

Conclusions

A very important aspect in the study of protein-protein interactions is the quantitative analysis to determine the frequency of homomeric and heteromeric interactions. Recently the dynamic of the protein associations in *S. cerevisiae* was assessed by BiFC quantifying the product of this interaction with flow cytometry which allows to:

Identify that the hetero-oligomerization between products of duplicated genes in *S. cerevisiae* occurs frequently.
Describe the simultaneous existance and the relative prevalence of the different oligomeric states between paralogous proteins.
For certain paralogous proteins the hetero-oligomeric form predominates in at least one metabolic condition.

PhenoRipper: A Novel Platform For Rapid Image Analysis.

S. Rajaram[1,2], B. Pavie[1,2], L. Wu[1,2], S. Altschuler[1,2]; [1]Pharmacology, UT Southwestern Medical Center, Dallas, TX, [2]Green Comprehensive Center for Computational and Systems Biology, UT Southwestern Medical Center, Dallas, TX

Fluorescence microscopy provides a high-content molecular profiling platform to investigate the relationship between complex cellular phenotypic states of biomarkers with quantities of biological and clinical interest, such as tumor type or disease progression. Automated analysis of microscopy images has the potential to act as a standardized aid for tumor classification and

biomarker discovery, particularly for subtle or uncharacterized phenotypes. While many computational tools exist to characterize cellular phenotypes, they require significant sample dependent fine tuning. In particular, cellular segmentation, a prerequisite for most analysis schemes, remains a challenging problem in general, and is often intractable on tumor samples. Thus without dedicated image-analysis experts, there is a significant barrier to automated image analysis by life scientists.
Here we present PhenoRipper, an easy to use, image analysis software package that enables rapid exploration and interpretation of microscopy data. PhenoRipper requires minimal user input or training, effectively making it a turnkey solution for the comparison and classification of microscopy images. Users can also correlate PhenoRipper results with image phenotypes and any metadata provided by the user.
In tissue samples, we show that PhenoRipper can distinguish tumors from non-tumor regions. In HeLa culture, we show that different groups of perturbations can be grouped together: drugs with similar mechanism of action cluster and knockdowns of related genes are found to have similar phenotypic effects in a siRNA screen. Despite requiring virtually no tuning of algorithmic parameters, the classification performance of PhenoRipper rivals that of established methods, while taking an order of magnitude less computational time. Additionally, PhenoRipper provided insights into the presence of subpopulations and their fractional changes across conditions.
PhenoRipper is an unsupervised, exploratory tool for analysis of high-content images which will enable bench-scientists to perform rapid exploratory analysis of their data soon after acquisition. We believe that the rapid turn-around between analyses and imaging made possible by PhenoRipper will make it a useful tool during assay development and for bio-marker selection while PhenoRipper's simplicity will encourage automated quantification of samples whose complexity has so far limited such analysis.

789

Quantitation of collagen alignment: tools for characterizing cancer progression and invasion.

C. Pehlke[1], J. Doot[2], K. Sung[3], K. Riching[3], R. Nowak[2], D. Beebe[3], P. Keely[4], K. Eliceiri[1];
[1]Laboratory for Optical and Computational Instrumentation, University of Wisconsin at Madison, Madison, WI, [2]Electrical and Computer Engineering, University of Wisconsin at Madison, Madison, WI, [3]Biomedical Engineering, University of Wisconsin at Madison, Madison, WI, [4]Molecular Biology, University of Wisconsin at Madison, Madison, WI

Collagens are the most abundant proteins in mammalian bodies and a major protein constituent of the extracellular matrix (ECM), which principally maintains shape and structural integrity for cells and tissues, and plays an important role in wound healing, tissue repair and morphogenesis. Of particular interest is the involvement of stromal ECM in the formation, growth and progression of tumors. It has been shown that the physical characteristics of stromal collagen influence and are influenced by tumor initiation and local invasion into the stroma. An important facet of this relationship is the local reorganization of collagen fibers at the tumor-stroma boundary that facilitates invasion of transformed epithelial cells into the surrounding ECM, with tumor cells migrating directly along collagen fibers. Using the nonlinear optical imaging techniques of multiphoton laser-scanning microscopy (MPLSM) and second harmonic generation (SHG) imaging, specific and consistent changes in stromal collagen organization at various stages of breast cancer progression have been detected. Of particular relevance, two of these signatures differentiate non-invasive from invasive characteristics of the primary tumor and, as such, correlate with metastatic potential. Specifically, non-invasive regions are contained by collagen fibers oriented parallel to the tumor boundary while regions of local invasion possess areas where collagen has been realigned perpendicular to the tumor boundary to facilitated local invasion. Therefore, it has been hypothesized that the angle of

collagen fibers relative to the tumor boundary may be used as a predictor of imminent invasion and metastasis. Hence, the ability to quickly and accurately quantify both fiber angle and any related structural changes of the collagen matrix, in conjunction with cellular morphology and concurrent molecular events, could result in an effective experimental and diagnostic tool. To this end, we have developed two semiautomated tools based on the Fast Discrete Curvelet Transform (FDCT) for detecting the orientation of collagen fibers in biological Issues.

790

Minimizing Detection Errors in Single Molecule Localization Microscopy.

G. M. Hagen[1], I. Raska[2], P. Krizek[2]; [1]Charles University in Prague, Prague, Czech Republic

Fluorescence microscopy using single molecule imaging and localization (PALM, STORM, and similar approaches) has quickly been adopted as a convenient method for obtaining multicolor, 3D superresolution images of biological samples. Using an approach based on extensive Monte Carlo simulations, we examined the performance of various noise reducing filters required for the detection of candidate molecules. We determined the best noise reduction method among those tested, and derived an optimal, nonlinear threshold which minimizes detection errors introduced by conventional algorithms. We also present a new technique for visualization of single molecule localization microscopy data based on adaptively jittered 2D histograms. We used our new methods to image both Atto565-phalloidin labeled actin in fibroblast cells, and mCitrine-erbB3 expressed in A431 cells. The enhanced methods developed were crucial in processing the data we obtained from these samples, as the overall signal to noise ratio was quite low. Low SNRs in SMLM data can result in significant numbers of missed molecules, and worse, an unacceptably high rate of false positive detections. Systematic analysis of the algorithms used for the detection of candidate molecules can significantly reduce the problem. Our results also suggest the use of a nonlinear threshold boundary on the measured data, combining both the signal to noise ratio and the imaged sizes of the detected objects. This approach minimizes detection errors in an automated and unbiased way.

P. Křížek, I. Raška, and G. M. Hagen, 2011, "Minimizing detection errors in single molecule localization microscopy," *Optics Express*, 19, p. 3226.

791

Functional and molecular diversification of the endocytic pathways and their cell-to-cell variability.

P. Liberali[1], B. Snijder[1], Y. Heer[1], L. Pelkmans[1]; [1]IMLS, University of Zurich, Zurich, Switzerland

Endocytosis has evolved from a simple pathway in single-cell eukaryotes into a highly complex network of uptake mechanisms and intracellular trafficking routes in mammalian cells. We currently do not have a systematic functional genomics view of this complexity and how it has emerged. We conducted parallel RNAi screens targeting 1,183 genes on the endocytosis of Transferrin, Cholera Toxin B, Low Density Lipoprotein, Epidermal Growth Factor, GPI-anchored GFP, Dextran via fluid phase endocytosis, and Dextran via EGF-induced macropinocytosis in human tissue culture cells. This was complemented with screens on subcellular patterns of molecular markers of early endosomes, late endosomes, the Golgi complex, and caveolae. Using automated image analysis of app. 10^6 single cells per screen, combined with novel multivariate statistics incorporating population context-determined cell-to-cell variability, we uncover that endocytosis routes have different, mutually exclusive patterns of cell-to-cell variability. By accounting for this cell-to-cell variability, we reveal a first unbiased quantitative molecular classification of the endocytic pathways. From the classification tree, we identified 200 genes determining the core diversification machinery. Evolutionary analysis of these genes

in 18 genomes covering most branches of the tree of life, revealed hierarchical organization of conserved endocytic modules. Besides the core machinery of diversification that acts in all cells, we also reveal a regulatory machinery, enriched in protein kinases and regulators of GTPases, which controls endocytic pathways in subsets of cells as a function of population context, coordinating the establishment of mutually exclusive patterns of cell-to-cell variability of endocytosis routes.

Actin and Actin-Associated Proteins II

792

The small GTPase Rif triggers formation of actin stress fibre in epithelial cells.

L. Fan[1], H. Mellor[1]; [1]Biochemistry, University of Bristol, Bristol, United Kingdom

The Rho family of small GTPases is the critical regulators of the actin cytoskeleton. We found that small Rho GTPase Rif triggers formation of one kind of key element of the actin cytoskeleton; actin stress fibres. Actin stress fibres are composed of bundles of actin filaments, which allow the cell to apply contractile force to its body. It is widely accepted that stress fibre formation is controlled by the small GTPase RhoA and two highly related proteins, RhoB and RhoC, representing the canonical stress fibre formation pathway. The work we have done showed that Rif GTPase triggers the stress-fibre formation in epithelial cells in an alternative pathway. Rif is distantly related to RhoA; however, we show that the two proteins share a common downstream partner in stress-fiber formation - the Diaphanous-related formin mDia1. Rif-induced stress fibers also depend on the activity of the ROCK protein kinase. This study establishes Rif as a general regulator of Diaphanous-related formins and shows how non-classical Rho family members can access classical Rho pathways to create new signaling interfaces in cytoskeletal regulation.

793

Differential regulation of actin microfilaments by human MICAL proteins.

S. Panapakkam Giridharan[1], J. Rohn[2], N. Naslavsky[1], S. Caplan[1]; [1]Department of Biochemistry and molecular biology, University of Nebraska Medical Center, Omaha, NE, [2]MRC Laboratory for Molecular Cell Biology, University College London, London, United Kingdom

The Drosophila melanogaster MICAL (D-MICAL) protein is essential for the neuronal growth cone machinery that functions through plexin- and semaphorin-mediated axonal signaling. D-MICAL is also involved in regulating myofilament organization and synaptic structures, and serves as an actin disassembly factor downstream of plexin-mediated axonal repulsion. In mammalian cells there are three known isoforms: MICAL1, MICAL2 and MICAL3, as well as the MICAL-like proteins MICAL-L1 and MICAL-L2, but little is known of their function, and information comes almost exclusively from neural cells. In this study we show that in non-neural cells human MICALs are required for normal actin organization, and all three MICALs regulate actin stress fibers. Moreover, we provide evidence that the generation of reactive oxygen species by MICAL proteins is critical for their actin-regulatory function. However, while MICAL1 is auto-inhibited by its C-terminal coiled-coil region, MICAL2 remains constitutively active and affects stress fibers. These data suggest differential but complementary roles for MICAL1 and MICAL2 in actin microfilament regulation.

794

Filamin CH domains bind to F-actin in an open conformation.

A. A. Orlova[1], V. E. Galkin[1], F. Nakamura[2], E. H. Egelman[1]; [1]Dept.of Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA, [2]Dept.of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA

Filamin is a large non-muscle protein participating in numerous cellular processes which lead to reorganization of the actin cytoskeleton. This protein crosslinks actin filaments into bundles or a

three-dimensional gel. The protein contains an N-terminal F-actin-binding domain (ABD) and an elongated flexible segment with numerous immunoglobulin-like repeats. The ABD contains two calponin homology (CH) domains similar to those in α-actinin. Like α-actinin, filamin forms a homodimer.
We used electron microscopy and three-dimensional reconstruction to study the complex of F-actin with the filamin ABD. The reconstruction shows that the filamin tandem CH domains bind to F-actin in open conformation, where only one CH domain is bound while the other is disordered. This is very similar to what we observed with the tandem CH domains of α-actinin when bound to F-actin (Galkin *et al.*, Nature Struct. Biol. **17**, 614-616, 2010). This result confirms our earlier suggestion that the opening of these domains when binding to F-actin may be one of the main regulatory mechanisms for actin-binding proteins containing tandem CH domains.

795

Profilin I and II are both influencing SRF-dependent signalling in B16 melanoma cells and loss of Profilin I interferes with cell migration.

S. Sadi[1], A-K. Johnsson[1], R. Karlsson[1]; [1]Stockholm University, Dept. of Cell Biology, Stockholm, Sweden

Cellular functions such as migration, adhesion, endo/exocytosis, intracellular trafficking and the maintenance of cell shape and polarity are all dependent on the actin microfilament system - its dynamic remodelling and force-generation.

Profilin is a key regulator of actin polymerization. It binds to actin monomers and forms the profilin:actin (P:A) complex, which delivers actin monomers to growing filament (+)-ends in a process that is enhanced by nucleation and elongation promoting factors like Ena/Vasp and the formins. Profilin binds a number of other proteins and also lipids of the phosphatidylinositol family. It has been reported that both actin and profilin are present in the nucleus, however it is less clear to what extent the P:A complex is formed and functions in the nucleus.

Actin is coupled to gene expression control through the serum response factor (SRF)-pathway. SRF is a transcription factor which controls a large number of genes, including many encoding microfilament associated proteins like actin itself and profilin. It 'senses' cytoplasmic changes in actin dynamics through its co-activator megakaryocytic acute leukemia (MAL), which is an actin monomer binding protein that rapidly shuttles to the nucleus when dissociated from the actin. It competes with profilin for actin binding and upon serum stimulation and dissociation from actin, it accumulates in the nucleus where it cooperates with SRF to induce gene expression.

In this study we report on the connection between SRF/MAL and actin dynamics with respect to the role of profilin (isoforms I and II); we have observed that down-regulation of profilin I expression using siRNA interferes with the nuclear accumulation of MAL fused to GFP. Furthermore, siRNA-depletion of profilin I and II represses SRF/MAL-controlled transcription as seen using a SRF reporter system. Migration of profilin-depleted cells was slightly reduced.

796

The Forked Proteins of Drosophila and Their Relationship to the Espin Actin-Bundling Proteins of Vertebrates.

D. Beeler[1], L. Zheng[1], J. Bartles[1]; [1]Cell and Molecular Biology, Northwestern University Feinberg School of Medicine, Chicago, IL

The forked proteins are required to assemble large parallel actin bundles in the developing neurosensory bristles of *Drosophila* pupae. Although the forked proteins are putative orthologs of the espin actin-bundling proteins of vertebrates, relatively little is known about their activities. Espins, which are present in a variety of parallel actin bundle-containing structures (hair cell stereocilia, microvilli, and Sertoli cell junctions), cross-link F-actin into parallel actin bundles and are the target of the jerker deafness mutation, which causes espin deficiency and results in abnormally thin, unstable stereociliary actin bundles in mice. Here, we uncover some activities of the forked proteins and clarify their relationship to the espins. When expressed in transfected LLC-PK1-CL4 epithelial cells the major forked isoform, forked A, was targeted to the nucleus and assembled large nuclear actin bundles. This unexpected result was also observed in Cos-7 cells and *Drosophila* S2 cells. Untagged forked A also formed nuclear actin bundles. An examination of forked A fragments revealed that the protein is composed of two major functional domains: an N-terminal domain that targets the nucleus, owing to a previously unrecognized nuclear localization signal, and a C-terminal domain that targets microvillar actin bundles (LLC-PK1-CL4) or stress fiber-like actin bundles (Cos-7), by analogy to espins. Accordingly, the purified recombinant C-terminal domain of forked A bound and bundled F-actin in vitro similarly to espin constructs. The identification of the forked peptides and amino acids required revealed a degree of homology to espins greater than that appreciated previously. Since certain espin isoforms contain functional nuclear localization signals, we suggest that the forked and espin proteins constitute a family of evolutionarily related actin-bundling proteins that can transit between cytoplasmic actin bundles and the nucleus (NIH DC004314 to JRB).

Cortactin knockdown reduces tubulobulbar complex length.

J. S. Young[1], M. De Asis[1], J. A. Guttman[2], A. W. Vogl[1]; [1]Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada, [2]Biological Sciences, Simon Fraser University, Burnaby, BC, Canada

Tubulobulbar complexes are podosome-like double membrane structures that internalize intercellular junctions in the seminiferous epithelium of mammalian testis. These actin-based projections possess a similar protein network to podosomes that includes N-WASp, Arp2/3, cortactin and dynamin. Cortactin depletion by RNA interference results in a loss of podosomes in osteoclasts. Here, we test the prediction that knockdown of cortactin in the seminiferous epithelium will cause a similar loss of tubulobulbar complex formation. To target cortactin, we used an *in vivo* knockdown strategy using SD strain rats. In each animal, one testis was surgically exposed and injected with RNAi reagents. The other testis served as a control by receiving the same treatment with a non-targeting reagent. After three days and in each experiment, control and experimental testis were removed and prepared for analysis by electron microscopy, immunofluorescence and immunoblotting. Two animals were used for each analysis. Immunofluoresence microscopy revealed a remarkable phenotype in RNAi-treated testis in comparison to control testes. Rather than a complete loss of tubulobulbar complexes, the complexes appeared shorter. Immunoblots confirmed that cortactin expression was less in experimental testes in comparison to control testes. To be certain that the phenotype was caused by siRNA, we repeated the experiment with a dye modification on one of the four targeting siRNA sequences. On cryosections of seminiferous epithelium, dye clusters could be detected in Sertoli cells confirming that reagents entered the cells. Our results indicate that normal levels of cortactin are essential for tubulobulbar complexes to acquire or maintain their normal length. Supported by an NSERC Discovery grant to AWV.

798

The prognostic role of fascin-1 in cancer progression-Insights from epidemiology and cell biology.

V. Y. Tan[1,2], R. M. Martin[2], J. C. Adams[1]; [1]Department of Biochemistry, University of Bristol, Bristol, United Kingdom, [2]Department of Social and Community Medicine, University of Bristol, Bristol, United Kingdom

Fascin-1 is a 55-kDa actin-bundling protein that functions in forming parallel actin bundles in cell protrusions. Fascin-1 is low or absent in most normal adult epithelia, yet its expression in carcinomas from many tissues correlates clinically with aggressive disease and reduced patient survival. This has raised interest in fascin-1 as a novel biomarker and potential therapeutic target for aggressive, metastatic carcinomas. However, many clinical studies have been based on relatively small numbers of samples. The carcinoma types in which fascin-1 might be of most relevance remain unclear. We are therefore taking combined epidemiological and cell biology approaches to analyse the role and regulation of fascin-1 in carcinomas. A systematic review and meta-analysis of the association of fascin-1 expression with cancer-specific survival in breast, colorectal and oesophageal cancer has identified that up-regulation of fascin-1 protein is associated with increased risk of cancer-specific mortality in breast, colorectal and oesophageal cancer patients. In parallel, we are studying molecular mechanisms of *FSCN1* transcription. CREB and AhR are major, specific regulators of FSCN-1 promoter activity in human breast and colon carcinoma cells [Hashimoto et al. PLoS One 2009. **4**: e5130]. We have extended analysis to androgen responsive and non-responsive prostate carcinoma cells as new early biomarkers for aggressive disease are urgently needed in prostate cancer. With luciferase promoter reporter assays, we demonstrate that the *FSCN1* promoter region -219/+1 is active in androgen responsive PC3 and DU-145 cells and non-responsive LNCaP cells. The conserved CREB and AhR binding motifs within this promoter region are required for promoter activity in prostate carcinoma cells. These results suggest that regulation of FSCN1 promoter activity in different carcinomas occurs by common transcriptional regulatory pathway mechanisms which depends on CREB and AhR. The meta-analysis results highlight the potential value of fascin-1 as a novel biomarker and therapeutic target and the need for more clinical studies to elucidate role of fascin-1 in progression of breast and prostate carcinomas. *Supported by the Wellcome Trust.*

CARMIL Removes Capping Protein from the Barbed End by an Allosteric Mechanism.

D. Sept[1], T. Kim[2], J. A. Cooper[2]; [1]University of Michigan, Ann Arbor, MI, [2]Washington University, St. Louis, MO

Regulation of capping protein (CP) is important for controlling polymerization at free barbed ends of actin filaments. In lamellipodia of migrating cells, CP bound to F-actin dissociates quite rapidly, suggesting the possibility of uncapping. A CP-interacting motif (CPI) capable of inhibiting capping and promoting uncapping is found in a set of otherwise unrelated proteins. The protein CARMIL contains a CPI motif plus another CP-binding motif specific to CARMIL, termed CSI (CARMIL-specific interacting). In vitro, a 115-aa CP-binding region (CBR) of CARMIL, which contains the CPI and CSI motifs, binds to CP with high affinity, inhibits capping, and promotes uncapping. We asked how CARMIL binding to CP inhibits capping and promotes uncapping. Structural and biochemical studies have shown that the actin-binding surface of CP is located on the top of the mushroom-shaped molecule, and that the CPI and CSI motifs both

bind to the under surface of the mushroom cap. Here, we used a collection of mutants affecting the actin-binding surface of CP to test the possibility of a steric-blocking model, which had remained open because a region of CBR between the CPI and CSI is unresolved in the CBR / CP co-crystal structure. The CP actin-binding surface mutants bound CBR normally, arguing against a steric-blocking model. In addition, a mutant form of CBR in which all the amino acids of the unresolved region had been changed showed nearly normal binding to CP, also arguing against steric blocking. To test the possibility of an allosteric model, we used molecular dynamics and principle component analysis on free CP as well as CP bound to actin and bound to CBR. We conclude that the CBR of CARMIL promotes uncapping by binding to a freely accessible site on CP bound to a filament barbed end and inducing a change in the conformation of the actin-binding surface of CP. This biochemical process has physiological relevance for actin assembly in migrating cells.

800

N-WASP independent role of CR16 in the formation of filopodia through IRSp53.

S. Bhattacharyya[1], T. Thanabalu[2]; [1]NTU, Singapore

The Neural Wiskott Aldrich syndrome protein (N-WASP) belongs to the WASP/WAVE family of proteins and is a key regulator of actin dynamics, which is critical for many cellular processes such as cell migration and cell adhesion. The mammalian verprolins are known regulate the actin cytoskeleton through WASP dependent and WASP independent pathways. The primary objective was to identify the role of corticoid regulated (CR16) protein in remodeling the actin cytoskeleton, in an N-WASP independent manner. CR16 is a proline rich protein which interacts with N-WASP through the C-terminal WBD (WASP binding domain). In order to identify other binding partners of CR16 we performed a yeast two-hybrid screen using CR16, as bait. Using this screen, we identified IRSp53 as one of the interactors of CR16. The activity of CR16 was characterized by expressing CR16 together with IRSp53 in N-WASP-/- mouse embryonic fibroblasts (MEFs), which showed that CR16-IRSp53 complex, caused a significant increase in filopodia induction. IRSp53 is an adaptor protein with an IMD (IRSp53 and MIM (missing in metastases) homology Domain) located at the N-terminus, a GTPase Binding Domain (GBD) and a SH3 domain. IRSp53 mutants with mutations in the IMD domain (IRSp534A), the CRIB domain (IRSp53I267N) and the SH3 domain (IRSp532A) were further transfected along with CR16 and a reduction in the filopodia induction was observed. The interaction between CR16 and IRSp53 is regulated by Cdc42 (member of Rho family of GTPase) as expression of CR16 and IRSp53 with constitutively active form of Cdc42 (cdc42G12V) resulted in membrane localization however when expressed in conjunction with dominant negative mutant of Cdc42 (Cdc42T17N) a loss of localization was observed. In conclusion, CR16 interacts with IRSp53 in concert with Cdc42 and induces filopodia formation independent of N-WASP.

801

Identification and characterization of a unique region of WASP in Jurkat T-cells chemotaxis.

N. JAIN[1], T. Thanabalu[1]; [1]School of Biological Science, Nanyang Technological University, Singapore, Singapore

Wiskott-Aldrich syndrome protein (WASP) and its homologue Neural-WASP (N-WASP) are the members of WASP family of proteins which act as nucleation promoting factors and integrate receptor signalling with actin cytoskeleton reorganization. WASP is expressed predominantly in hematopoietic cells compared to N-WASP which is expressed ubiquitously and absence of WASP expression in hematopoietic system leads to Wiskott-Aldrich syndrome (WAS). WASP and N-WASP share more than 50% sequence homology, having similar binding partners and

basic functions. Although WASP and N-WASP both are expressed in hematopoietic system, N-WASP can only partially compensate for the loss of WASP in WASP knockout hematopoietic cells suggesting that WASP may have some unique functions compared to N-WASP or their activity may be regulated by different mechanism. Here we have identified a unique region of WASP which is rich in proline residues. Using yeast two hybrid system, we have found that this region of WASP interacts with 8 SH3 domain containing proteins out of 17 known WASP Proline Rich Region interacting proteins tested. In resting state, WASP has been shown to adopt a closed conformation in which an auto-inhibitory loop is formed through the binding of the VCA domain to the upstream GTPase binding domain (GBD). Using Bi-molecular Fluorescence Complementation (BiFC) assay; we found that deletion of this region of WASP relieved WASP from its closed conformation even in the presence of WIP. We further identified the role of this region of WASP in WASP knockdown human Jurkat T-cells. Knockdown of WASP expression in Jurkat T-cells does not affect the expression of N-WASP. We tested the chemotactic response of WT and WASP knockdown Jurkat T-cells in response to chemokine SDF-1á using Dunn chamber and found to be impaired in WASP knockdown Jurkat T-cells which were rescued by expression of WT WASP. We will use the WASP knockdown Jurkat T-cells to determine the the role of the unique region in chemotaxis and T-cell activation.

802

Cooperative binding of drebrin to actin filaments.

E. E. Grintsevich[1], S. Sharma[1], J. K. Gimzewski[1], E. Reisler[1]; [1]University of California, Los Angeles, Los Angeles, CA

Drebrin A is a major brain-specific actin-binding protein localized in dendritic spines – the dynamic, actin-rich dendrite-specific structures that participate in signal transmission to the cell body of neurons. Reduced drebrin levels have been reported in patients with Alzheimer’s disease and Down syndrome. This study tested the possible cooperativity of drebrin interaction with F-actin on a single filament level. Atomic force microscopy (AFM) experiments revealed that N-terminal drebrin construct (sequence 1-300, Drb1-300) causes the same morphological changes in actin filaments as the full length drebrin A. This result is in a good agreement with our previously reported solution binding data and makes Drb1-300 a suitable tool to investigate the effects of drebrin on F-actin morphology and dynamics. High resolution AFM imaging showed that under sub-saturating conditions Drb1-300 exhibits a cluster-like decoration of actin filaments, revealing positive binding cooperativity. Moreover, we observed the propagation of the drebrin-induced conformational changes on the neighboring ‘bare’ actin regions. Binding cooperativity was farther confirmed in a two-color TIRF experiments with Drb1-300KCK construct labeled by Cy3 fluorescent dye and then visualized on Alexa 488 palloidin-stabilized actin filaments. Cluster-like F-actin decoration was observed upon rapid complex dilution into F-buffer followed by its immobilization on polylysine coated coverslips. Our results provide evidence for cooperative binding of drebrin to actin filaments. Possible mechanisms and biological implications will be discussed.

803

Drebrin Induces Stabilization of Actin Filaments.

M. A. Mikati[1], E. E. Grintsevich[1], E. Reisler[1]; [1]Chemistry and Biochemistry, UCLA, Los Angeles, CA

Drebrin is a mammalian neuronal protein that binds to and organizes filamentous actin (F-actin) in dendritic spines, the receptive regions of most excitatory synapses whose morphology was shown to play a crucial role in higher brain functions. Here, structural effects of drebrin on F-actin were examined in solution. Depolymerization and differential scanning calorimetry (DSC)

assays show that F-actin is stabilized upon decoration by drebrin. Along with full length drebrin, C-terminal truncated constructs of the protein were employed to clarify the domain requirements for the observed stabilization effects. Drebrin inhibits depolymerization at both barbed ends and pointed ends of a filament and increases thermal stability of F-actin by 0.5^{o}C. Because previous Atomic Force Microscopy (AFM) analysis showed that drebrin-A induced an increase in the helical pitch and stiffness of F-actin, we explored the molecular details of the observed changes by probing the effects of drebrin on lateral and longitudinal contacts in actin filaments. We have found that drebrin binding rescues the polymerization of V266G/L267G, a hydrophobic loop (H-loop) yeast actin mutant with an impaired lateral interface. In good agreement with these findings, Drebrin actin binding domain ($DrbABD_{233-300}$) increases the inter-strand disulfide cross-linking between Cys265 (H-loop) and Cys374 (C-terminal) in yeast S265C mutant F-actin. To probe the longitudinal interface, we use assembly incompetent tetramethyl rhodamine (TMR) labeled-actin, T203C/C374S yeast actin mutant and ECP cleaved actin (specifically cleaves the DNaseI-binding loop between Gly42 and Val43). Our results show drebrin rescues the polymerization of the ECP cleaved actin. Our data suggest that drebrin stabilizes actin filament through its effect on the inter-strand and intra-strand contacts in F-actin.

804

Role of the formin FMNL3 in filopodia assembly and cell-cell adhesion.

T. J. Gauvin[1], H. N. Higgs[1]; [1]Biochemistry, Dartmouth Med School, Hanover, NH

Formins are actin assembly proteins that can nucleate actin filaments as well as control filament elongation. Mammals possess 15 formin proteins, and the cellular functions of many formin isoforms are poorly understood. FMNL3 (also called FRL2) belongs to a sub-family of formins that can bundle actin filaments in vitro, in addition to its effects on nucleation and elongation. We have previously shown that over-expression of constitutively active FMNL3 constructs causes a dramatic increase in filopodia assembly in a variety of cell types (Harris et al (2010) Cytoskeleton). In this poster, we show that endogenous FMNL3 enriches strongly at the leading edge plasma membrane in NIH 3T3 cells, with particular enrichment at filopodia tips. The most dramatic enrichment in FMNL3 occurs in filopodia that are making contact with a neighboring cell. Live-cell microscopy shows that FMNL3-GFP-containing filopodia at the leading edge are are highly dynamic, growing and retracting on a timescale of minutes. In contrast, filopodia in contact with another cell are not dynamic, maintaining constant length for minutes. Following up on these observations, we are currently studying the role of FMNL3 in cell migration and cell-cell adhesion.

805

Investigating the Mechanism of INF2-mediated Actin Filament Severing and Depolymerization.

P. S. Gurel[1,] H. N. Higgs[2]; [1]Dartmouth College, Hanover, NH, [2]Biochemistry Department, Dartmouth Medical School, Hanover, NH

Formins are a class of proteins that accelerate actin nucleation, then influence actin filament elongation rate by remaining at the barbed end. INF2 is a biochemically unique mammalian formin in that it accelerates both actin polymerization and depolymerization. Importantly, mutations in INF2 lead to the kidney disease focal and segmental glomerulosclerosis (FSGS). I am elucidating the molecular mechanism of INF2’s unique depolymerization activity, using TIRF microscopy and other biochemical assays of actin dynamics. Prior work in our lab has shown that depolymerization requires both the FH2 and WH2/DAD sequences, and occurs in two steps: a) a severing step, which requires phosphate release from the actin subunits; and b) a depolymerization step, which requires the WH2/DAD. I used two INF2 constructs to test this

mechanism further: the FH1FH2C construct (containing the WH2/DAD); and the FH1FH2 construct (without the WH2/DAD). Using TIRF microscopy, I find that severing occurs throughout the length of the filament, and that the individually severed filaments depolymerize rapidly thereafter. This result suggests that INF2 binds filament sides prior to severing, and is supported by direct binding assays. INF2 can bind filament sides that are both phosphate-bound and phosphate-free, suggesting that phosphate release is not required for side binding but is required for subsequent severing. The FH1FH2 construct alone has depolymerization activity, albeit at much reduced levels compared to the FH1FH2C construct. I postulate that filament side binding by the FH2 domain changes the twist of the filament, which promotes severing and changes monomer dynamics at filament ends. I postulate further that the WH2/DAD enhances severing by insertional binding between actin subunits in the filament.

806

Different modes of Spir-actin interaction.

C. Chen[1], M. Phillips[2], E. Reisler[2], M. Quinlan[2]; [1]UCLA, Los Angeles, CA

Spir is a WH2-containing actin nucleator, which is essential for establishing an actin mesh during Drosophila oogenesis. Spir was reported to not only nucleate filaments but also sever them and sequester actin monomers in a stable complex. Here we provide new evidence for Spir's ability to sever, albeit weakly, and depolymerize filaments. We measured Spir's severing activity in real-time with TIRF microscopy. Significant severing was only observed at concentrations of Spir stoichiometric to actin, and its severing activity was very slow compared to that of cofilin. We also observed significant depolymerization at the barbed end of actin filaments in these assays. When Spir was added to actin filaments in bulk assays, it induced their rapid depolymerization. Based on our single filament assays, we attribute this to Spir's sequestration activity rather than its weak severing activity. To probe the positioning of monomers by Spir into a nucleating complex, we performed velocity sedimentation and crosslinking experiments, and monitored excimer emission from pyrene-labeled actin mutants, Q41C (which reports longitudinal contacts) and S265C (to report lateral contacts). Under polymerizing conditions, both S265C and Q41C produce high excimer signals in the presence of Spir suggesting both lateral and longitudinal proximities of labeled sites in these complexes. Interestingly, we only observed crosslinking when Spir was mixed with S265C actin. Taken together, these data indicate that although the orientation of adjacent monomers is not precisely filament-like, they do form lateral contacts in the presence of Spir. Velocity sedimentation data show different binding modes of Spir-ABCD, which contains all four WH2 domains, and Spir-CD, which contains only two WH2 domains. A broad distribution of species can be seen with up to three monomers bound to ABCD. A narrower distribution of CD bound predominantly to two monomers was observed. Combining the crosslinking, spectroscopic, and velocity sedimentation data provides insight into the complex and dynamic Spir-bound lateral and longitudinal actin structures.

807

Regulation of actin dynamics by the formin FMNL3 requires the C-terminus: Relationship to the formins INF2 and mDia1.

E. G. Heimsath Jr[1], H. N. Higgs[1]; [1]Biochemistry, Dartmouth Medical School, Hanover, NH

Actin filaments are integral components in at least 15 cellular structures. Due to actin's widespread use, cells must rigorously control when and where new actin filaments assemble. Formin proteins are attractive candidates for site-specific actin polymerization regulation, being able to accelerate actin nucleation and to regulate filament elongation. Mammals possess

genes for 15 formin proteins. FMNL3 is a mammalian formin that can bundle actin filaments, in addition to influencing actin polymerization rates. In this work, we aim to delineate the molecular mechanism of FMNL3's effects on actin polymerization. Here, we find that the C-terminal 74 amino acids of FMNL3 dramatically accelerates actin polymerization and filament production by the FH2 domain, similar to recent work on INF2 and mDia1. We characterize an actin-binding motif within the C-terminus of FMNL3 that directly interacts with both actin monomers and actin filament barbed ends, slowing monomer polymerization and inhibiting filament elongation. This motif bears some similarity to WH2 motifs, although one conserved aliphatic residue has diverged in FMNL3. Both profilin and WH2 domains from other proteins (VopL and ciboulot) compete with FMNL3-Cterm for actin monomer binding, suggesting a common binding interface. Specific point mutations within this motif strongly inhibit the actin binding ability of the C-terminus. Curiously, however, these mutations do not influence the ability of the FH1-FH2-C construct to accelerate actin polymerization. Thus, the high affinity actin binding site in the C-terminus is not necessary for actin polymerization acceleration by FMNL3. In the context of the formin family, this work illustrates that, while the C-termini of three different formins (FMNL3, INF2, mDia1) can interact with actin monomers, these interactions differ greatly in both affinity of the interaction and consequence for actin polymerization.

808

Effects of the actin cytoskeleton on Golgi architecture through the formins INF2 and mDia1.

F. V. Korobova[1], V. Ramabhadran[1], H. N. Higgs[1]; [1]Biochemistry, Dartmouth Medical School, Hanover, NH

Formins represent a widely expressed family of actin assembly factors, accelerating nucleation and regulating barbed end elongation. Mammals have 15 formin genes. One mammalian formin, INF2, has the unique ability to accelerate both actin polymerization and depolymerization. INF2 can be expressed in two C-terminal splice variants, either the prenylated CAAX isoform, which is ER-localized, or the non-prenylated nonCAAX isoform, which localizes in an actin-dependent meshwork pattern. We have shown that INF2 expression is cell-specific, with the CAAX variant highly expressed in mouse fibroblasts, and the nonCAAX isoform expressed in U2OS human carcinoma and Hela cells. In this study we focused on elucidating cellular functions of the INF2-nonCAAX variant, particularly on its recently identified role in Golgi morphology. INF2 knockdown in U2OS cells causes dispersion of Golgi stacks, both the cis and trans compartments. In contrast, treatment with LatrunculinB for 30 min causes Golgi compaction, and reverses the INF2 knockdown effect. These results suggest an actin-dependent action of INF2 on maintenance of Golgi architecture, and we wished to examine this possibility in more detail. Analysis of confocal sections of U2OS cells reveals actin patches closely associated with the Golgi stacks. The number of these patches decreases about 30 % in cells with INF2 knockdown. Another formin, mDia1, which is known to interact with INF2, has an opposite effects on Golgi morphology and actin patch number. Knockdown of mDia1 results in Golgi compaction (similar to recently published work by Zilberman et al (2011) MBoC), and increases the number of Golgi-associated actin patches to 153% from control. INF2 and mDia1 also have different effects on some aspects of actin stress fiber morphology. INF2 knockdown causes a decrease in dorsal stress fibers, an increase in ventral stress fibers, and an increase in focal adhesion number and size. Additionally, ventral stress fibers in INF2 knockdown cells show greater resistance to Latrunculin B treatment than in control cells. In contrast, mDia1 knockdown reduces the number of ventral stress fibers and focal adhesions, but does not influence dorsal stress fiber number. Taken together, these data show that INF2 and mDia1 have opposing effects on both Golgi and stress fiber architecture. Currently, we are examining the relationship between Golgi, Golgi-associated actin patches, and stress fibers.

809

Cooperation between Drosophila Spire and Cappuccino.

C. Vizcarra[1], M. Quinlan[1,2]; [1]Department of Chemistry & Biochemistry, University of California Los Angeles, Los Angeles, CA, [2]Molecular Biology Institute, University of California Los Angeles

The actin nucleators Spire (Spir) and Cappuccino (Capu) interact directly and are both essential for polarity establishment in the Drosophila oocyte. We are interested in why there are two nucleators in a single actin regulatory pathway. One possible model is that Spir acts as the filament-nucleating site, while Capu is the elongation factor, protecting the growing barbed end from capping protein. To test this model we are studying the interaction using a combination of binding assays, pyrene-actin polymerization assays and single filament fluorescence imaging to localize Spir and Capu on growing filaments. We found that the kinase non-catalytic C-lobe domain (KIND) of Spir binds with nanomolar affinity to a short (~30 aa) sequence at the very C-terminus of Capu, adjacent to the actin filament-nucleating FH2 domain. Although this sequence is distinct from the Diaphanous auto-regulatory domains (DADs) of Diaphanous-related formins, we found that the C-terminal tail of Capu plays a critical role in actin assembly similar to that recently described for DADs (Gould et al, 2011). Additionally, both DADs and the Capu tail bind to G-actin. We also found that in the presence of Spir-KIND, a construct containing the FH1, FH2, and tail domains of Capu was unable to protect the barbed end from capping protein. These observations explain how Spir binding to the Capu tail inhibits nucleation but not why processive elongation is blocked. Therefore, we are now investigating the role of the tail in Capu's barbed end elongation and F-actin binding activities. Our findings indicate that in order for the nucleation/elongation cooperation model to be true, there must be another component in the pathway that breaks the Spir-Capu interaction.

810

Involvement of Formin in the Suppression of a Saccharomyces cerevisiae Mutant Actin-Associated Phenotype by a Mutant Profilin.

K-K. Wen[1], M. McKane[1], E. Stokasimov[1], P. Rubenstein[1]; [1]Biochemistry, University of Iowa, Iowa City, IA

In the S. cerevisiae actin-profilin interface, actin A167 of the barbed end W-loop and H372 near the C-terminus form a clamp around a profilin segment from residue R81 to Y79. Modeling suggests that altering steric packing in this interface may regulate actin activity. An actin A167E alteration, which occurs in muscle actin, should increase interface crowding and alter actin regulation. A167E actin causes a severe growth defect resulting in large part from mitochondrial dysfunction accompanied by loss of mt DNA staining and aggregation of mitochondrial fragments near the bud neck. To test this packing hypothesis, we altered Y79 to S hoping its decreased mass would relieve interface strain and rescue the mitochondrial phenotype. Y79S profilin alone caused no growth defect in WT actin cells but did rescue the mitochondrial defects caused by A167E actin. We then investigated the molecular basis of this rescue. WT profilin accelerates actin ATP exchange rate about 3X. Y79S profilin did not accelerate the ATP exchange rate of WT actin but slightly increased that of A167E actin. Thus, acceleration of actin nucleotide exchange by profilin does not appear to be important for WT yeast cells. Both mutant and WT profilins similarly inhibited either WT or A167E actin filament nucleation. Thus, Y79S profilin rescue does not appear to result from direct effects on actin polymerization. The yeast formin Bni1 elongates actin filaments using the actin-profilin complex. We thus tested the impact of A167E actin and Y79S profilin on formin-regulated actin polymerization. The Bni FH1-FH2

fragment accelerated WT actin polymerization more efficiently than A167E actin. WT profilin inhibited bulk Bni-mediated WT actin polymerization in a concentration-dependent fashion over the entire range tested. Lower WT profilin concentrations inhibited Bni-mediated A167E actin polymerization. However, with A167E actin, profilin/actin ratios higher than 1:1 produced a sigmoidal rather than the hyperbolic polymerization curve observed with WT actin. Y79S profilin exhibited approximately the same inhibition of formin-dependent WT actin polymerization as did WT profilin. However, Y79S profilin converted the sigmoidal behavior seen with WT profilin and A167E actin to the hyperbolic behavior associated with the WT protein mixture. This result indicates a rescue of the system by the mutant profilin to a WT-like state. In vivo, as visualized by binding to GFP-ABP140, WT actin cables moved from the neck to the base of the mother cell with an average rate of 1.8 μm/sec, whereas A167E actins moved with a rate of 2.2 μm/sec. However, cables in both WT and A167E cells expressing Y79S profilin moved significantly slower (1.5 and 1.4 μm/sec respectively). In summary, the phenotype caused by the A167E actin mutation appears to result from an inappropriate actin-profilin complex affecting its utilization by the formin Bni1 in regulating actin filament dynamics. The rescue observed with Y79S profilin seems to occur from restoring the appropriate use of this complex by formin.

811

Autoregulation of the Drosophila Actin Nucleator Cappuccino.

B. Bor[1], C. Vizcarra[2], M. Quinlan[2]; [1]Molecular Biology Institute, Univ California-Los Angeles, Santa Monica, CA, [2]Chemistry and Biochemistry, Univ California-Los Angeles

Formins are a conserved class of proteins known to enhance actin polymerization. Five of the seven groups of metazoan formins are regulated by autoinhibitory interactions between the C-terminal diaphanous autoregulatory domain (DAD) and the N-terminal diaphanous inhibitory domain (DID). Based on the lack of DID/DAD sequence homology, the formin group of formins is not predicted to be autoregulated. Previously published data for the *Drosophila* formin Cappuccino (Capu) is consistent with this prediction (Rosales-Nieves et al., NCB 2006). However, the mammalian ortholog of Capu, Formin-1, is autoinhibited (Kobielak et al., NCB 2004). We, therefore, re-examined Capu and found that it is, in fact, autoinhibited. In pyrene-actin polymerization assays, Capu's N-terminal half (Capu-NT) inhibits the C-terminal half's (Capu-CT) ability to stimulate actin polymerization. Furthermore, truncating the recently described C-terminal tail of Capu (Vizcarra et al., PNAS 2011) completely abolished Capu-NT's inhibition activity, suggesting Capu has an autoregulatory domain situated in a position similar to the DAD of other formins. Consistent with this observation, adding purified Capu tail to the polymerization assay in the presence of both Capu-CT and Capu-NT restored Capu-CT's activity. This result indicates that Capu tail binds to Capu-NT, freeing Capu-CT to stimulate polymerization. We measured a tight interaction between the tail and Capu-NT by fluorescence anisotropy (K_D~ 300 nM). Using truncations and limited proteolysis approaches, we mapped the Capu tail binding site or Cappuccino inhibitory domain (CID) to the first 321 residues of Capu. Interestingly, the Capu tail also binds to the Spire KIND domain (Pechlivanis et al., JBC 2009; Vizcarra et al., PNAS 2011). None of the single Capu tail point mutations sufficient to abolish the tail/KIND interaction affect the tail/CID interaction. We have identified two residues that contribute to tail/CID binding and the double mutant greatly diminishes the tail/CID interaction. Future experiments will be aimed at understanding the role of Capu autoinhibition in the presence of Spire and *in vivo*.

Regulation of Actin Dynamics I

812

Actin-dependent regulation of Golgi integrity by the formin, INF2.

V. Ramabhadran[1], F. Korobova[1], H. Higgs[1]; [1]Biochemistry, Dartmouth Medical School, Hanover, NH

INF2 is a unique formin which can both polymerize and depolymerize actin filaments, with depolymerization requiring a severing step that depends upon ATP hydrolysis and phosphate release from the actin filament. Mutations in INF2 cause the kidney disease focal and segmental glomerulosclerosis. INF2 can be expressed as two C-terminal splice variants: CAAX and nonCAAX. The CAAX isoform contains a C-terminal prenyl group, and is tightly bound to the endoplasmic reticulum (ER). The localization pattern and cellular function of the nonCAAX isoform is not clear. Recently, INF2 was shown to interact with and inhibit another formin, mDia1. Our objective in this study was to understand the cellular consequences of INF2-mediated actin dynamics, and how INF2 activity is regulated. We find that INF2-CAAX and nonCAAX isoforms have dramatically different functions. While INF2-CAAX is ER-localized in an actin-independent manner, INF2-nonCAAX localizes in an actin-dependent meshwork pattern distinct from ER. INF2-nonCAAX is loosely attached to this meshwork, being extracted by brief digitonin treatment. Suppression of INF2-nonCAAX causes fragmentation of the Golgi apparatus, and this effect is counter-acted by treatment with the actin monomer sequestering drug, Latrunculin B. We find a reduction in actin patches around the Golgi apparatus upon INF2-nonCAAX depletion. Coupled with recent results showing that mDia1 causes Golgi dispersal, our hypothesis is that INF2 and mDia1 are counter-acting factors in maintenance of a cytoplasmic actin meshwork that influences Golgi integrity. We are currently testing this theory biochemically and in cells. Using full-length mouse INF2 expressed in insect cells, we show that purified INF2 is not subject to autoinhibition, despite possessing autoinhibitory sequences. However, INF2 expressed in a variety of culture cells does not cause aberrant actin polymerization unless the autoinhibitory regions are mutated or deleted, suggesting that additional factors are necessary for inhibition. The inhibitory DID region of mDia1 binds tightly to INF2’s C-terminal DAD sequence, but mDia1-DID alone does not inhibit INF2. We are currently testing reciprocal regulation between INF2 and mDia1 using full-length purified proteins.

813

ITB3 encodes a novel regulator of ADF and is required for normal actin organization and Golgi body development in *Arabidopsis.*

D. G. Oppenheimer[1], X. Zhang[1,2], P. H. Grey[1], J. C. Roney[1], S. Dugas[1], K. Cuddy[1]; [1]Biology, University of Florida, Gainesville, FL, [2]Section of Cell and Developmental Biology, UC San Diego, La Jolla, CA

Introduction Actin filament turnover is required for many actin-dependent cellular processes including cell motility and membrane trafficking. Members of the actin depolymerizing factor/cofilin (ADF) family of actin-binding proteins are essential for severing and depolymerizing actin filaments. The predominant mode of regulation of ADF activity is by phosphorylation of a

conserved Ser residue near the N-terminus, which inhibits ADF binding to actin. We identified a protein of unknown function by map-based cloning of the *IRREGULAR TRICHOME BRANCH 3* (*ITB3*) gene in *Arabidopsis*. The *ITB3* gene is responsible for normal epidermal hair (trichome) shape; *itb3* mutants show reduced trichome expansion and branching. To uncover the function of ITB3, we carried out a yeast 2-hybrid screen for interacting proteins. We found that ADF interacts with ITB3.

Objectives The objectives of this study were to determine if ITB3 regulates ADF activity, and to determine if *itb3* mutants show defects in actin organization. Finally, we aimed to conceptually connect the trichome cell expansion defects observed in *itb3* mutants with putative changes in ADF activity.

Methods Pull-down assays showed that ITB3 and ADF interact in vitro. Actin organization in developing wildtype and *itb3* trichomes was observed using fluorescent phalloidin and confocal microscopy. *In vitro* actin polymerization assays were used to examine ADF activity in the presence of ITB3. Golgi bodies were observed in plants stably transformed with a YFP-sialyltransferase fusion protein.

Results We verified that ITB3 interacts with ADF *in vitro* and inhibits the interaction of ADF with actin. We found that developing trichomes of *itb3* mutants showed severe actin defects including an increase in the number of thick actin filament bundles culminating in an “actin knot” surrounding the cell nucleus. The *itb3* mutants also showed an increase in Golgi body number, but no discernible effect on Golgi body motility.

Conclusions Our results demonstrate that ITB3 functions as an inhibitor of ADF activity, and loss of ITB3 leads to severe actin organization defects *in vivo*. The major players in plant cell expansion –cellulose synthase, non-cellulosic polysaccharides, and cell wall proteins– are trafficked through the Golgi on their way to the plasma membrane and cell wall. Our finding that *itb3* mutants show Golgi body abnormalities suggests a connection between actin dynamics and cell expansion that goes beyond myosin-based transport of Golgi stacks.

814

Roles for ADF/cofilin in membrane blebbing and new actomyosin cortex assembly.

O. Wiggan[1], J. G. DeLuca[1], J. R. Bamburg[1]; [1]Department of Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

The contractile actomyosin cortex is important for cell morphogenesis and crucial for a form of cell motility based on dynamic plasma membrane bleb protrusions. The mechanism for new actomyosin cortex assembly is poorly understood. We show here that ADF/cofilin actin dynamizing proteins are essential for cortical actomyosin remodeling and new cortex assembly during blebbing. In human cells depletion of ADF/cofilin results in dynamic or persistent blebs dependent on residual levels of ADF/cofilin. At blebs, ADF/cofilin proteins are essential for modulating actomyosin turnover and for preservation of a pool of actin filaments that are utilized for new cortex assembly and consequently for bleb retraction. Efficient bleb retraction requires dynamic turnover of the newly assembled cortex, indicating further roles for ADF/cofilin proteins in this process. We present a model for the involvement of ADF/cofilin in the regulation of various stages of the bleb life cycle. Our findings implicate key roles for ADF/cofilin in the motility of cells, during normal development and cancer pathogenesis, which rely on dynamic membrane bleb protrusions.

Phospho-Regulation of Cofilin is Essential for Shear Stress-Mediated Actin Microfilament Realignment.

J. B. Slee[1], L. J. Lowe-Krentz[1]; [1]Biological Sciences, Lehigh University, Bethlehem, PA

In vivo and *in vitro* evidence indicates that fluid shear stress (FSS) causes endothelial cell and actin microfilament alignment in the direction of FSS. Regulation of actin microfilament dynamics depends in part upon the Actin Depolymerizing Factor (ADF) family of proteins, of which cofilin is a prominent player. It is well-documented that phospho-cofilin is dephosphorylated by cofilin phosphatases, including chronophin and the slingshot (SSH) family of protein phosphatases which are known to be regulated by various external stimuli. Once dephosphorylated, cofilin induces the disassembly of actin filaments, promoting actin reorganization. Utilizing immunofluorescent staining and laser scanning confocal microscopy, it was previously determined that exposing bovine aortic endothelial cells (BAECs) to 15dynes/cm^2 FSS results in a decrease in cytoplasmic phospho-cofilin levels. This decrease in cytoplasmic phospho-cofilin levels was accompanied by an increase in nuclear phospho-cofilin and a slight increase in cytoplasmic total cofilin. These results suggest that under FSS, phospho-cofilin translocates to the nucleus, a finding seen in other cell types and under various cellular stresses. Working with the knowledge that cofilin location and possibly activity is altered during FSS, two cofilin mutants were employed to further understand its role in FSS-mediated actin microfilament realignment. A constitutively active, phosphorylation defective cofilin (Serine-3-Alanine – S3A) mutant construct and a constitutively inactive, phosphomimic cofilin (Serine-3-Aspartic Acid – S3D) mutant construct both disrupt multiple stages of the actin realignment process. The S3A cofilin mutant cells exhibit largely normal actin structures at 15 min and still form a cortical actin band at 30 min of 15dynes/cm^2 FSS, albeit the actin is less organized. The actin in the S3D mutant cells is disorganized at 15 min and fails to form cortical actin bands at 30 min of 15dynes/cm^2 FSS. Both S3A and S3D mutant cells fail to elongate and form stress fibers in the direction of FSS at 60 min. The S3D mutant cells also possess non-traditional actin structures which appear to be short actin clumps near cell nuclei. These results suggest that cofilin activity is involved in FSS-induced actin realignment and that the regulated phosphorylation and dephosphorylation of cofilin is necessary for proper realignment of the whole cell and actin microfilaments in the direction of FSS. Research in the Lowe-Krentz lab is supported in part by NIH grant HL54269.

816

Effects of Caldesmon and Cofilin on the Depolymerization of Actin Filaments.

R. Huang[1], K. Nomura[2], S. Ono[2], C-L. A. Wang[1]; [1]Boston Biomedical Research Institute, Watertown, MA, [2]Emory University, Atlanta, GA

We have previously reported that actin undergoes an obligatory conformational transition (maturation) during polymerization; caldesmon, or its C-terminal fragment, H32K, if present before the transition, inhibits this process and arrests the actin filament at the pre-transitional young state (Huang et al., JBC 285:71, 2010). Since phosphorylated caldesmon is localized to the cell periphery where the actin cytoskeleton undergoes active remodeling, it is thought that caldesmon therein could stabilize young actin filaments and promote actin dynamics. To test this hypothesis we have investigated actin filaments disassembly by monitoring the fluorescence change of pyrene-labeled actin. Upon dilution into either G- or F-buffer, actin filaments were protected against depolymerization by unphosphorylated H32K, but not by the mutant D3D4 that mimics ERK-phosphorylated protein, or in the presence of Ca^{2+}/calmodulin. The actin depolymerizing factor cofilin, when added to fully polymerized mature F-actin, resulted in a dose-dependent decrease of pyrene emission, with a stoichiometry of 1 per actin monomer.

The rate of the pyrene-actin fluorescence decrease was fast (~0.2 min^{-1}) and independent of the cofilin concentration. D3D4 showed no protection against cofilin-induced depolymerization. For H32K-bound mature filaments, addition of cofilin also resulted in a large drop of the pyrene fluorescence, but the rate was cofilin concentration-dependent and slower than that of actin alone, indicating the caldesmon fragment exerts some protection, especially when the amount of cofilin is low. For H32K-stabilized young filaments, cofilin apparently resulted in both displacement of H32K, thus allowing filament to mature, and subsequent severing of the filament. Since the mature filament exhibited unattentuated pyrene emission, the net fluorescence change depended on the concentration of cofilin relative to that of actin. Our results are consistent with that the ERK-phosphorylated caldesmon facilitates cofilin-mediated disassembly of actin filaments by maintaining the filament at the young state, which binds cofilin with a higher affinity, yet permitting severing to proceed. Supported by an NIH grant.

817

Novel phosphorylation site(s) of cofilin by PKCα and its negative role in the degranulation from RBL-2H3 mast cells.

M. Sakuma[1], Y. Shirai[2], M. Kuramasu[1], K-I. Yoshino[3], T. Nakamura[1], K. Mizuno[4], I. Hide[5], Y. Nakata[5], N. Saito[2]; [1]Kobe Univ., Kobe, Japan, [2]Kobe Univ., Japan, [3]Kobe Univ., [4]Tohoku Univ., [5]Hiroshima Univ.

Mast cells are known as the major effector cells in allergic diseases. Protein kinase C (PKC) activity is essential to the IgE-induced the release of histamine from mast cells. However, the role of individual PKC isoform is controversial and downstream molecules of PKCs are unknown in the degranulation. Here we show that PKCβI is a positive but PKCα is a negative regulator of degranulation from RBL mast cells using specific inhibitors and kinase-negative mutants of PKCα and βI. In addition, mass spectrometric analysis and mutagenesis technique revealed that PKCα phosphorylates cofilin at Ser23 and/or Ser24 during the degranulation. Furthermore, a mutant of cofilin mimicking the phosphorylation did not able to bind F-actin and lost F-actin depolymerizing and/or severing activity, resulting in the F-actin polymerization. These results indicate that the PKC-mediated novel phosphorylation site(s) of cofilin contribute to F-actin polymerization, which is necessary for proper termination of the degranulation. The novel phosphorylation site(s) are conserved within mammals and birds but not in fishes, suggesting its importance for specified function of cofilin in degranulation in higher organisms.

818

Unexpected roles for Srv2/CAP in driving cofilin-mediated actin filament severing and turnover.

K. Little[1], F. Chaudhry[1], D. Breitsprecher[1], C. Suarez[2], L. Blanchoin[2], O. Sokolova[3], B. Goode[1]; [1]Brandeis University, Waltham, MA, [2]CNRS/CEA/INRA/Université Joseph Fourier de Grenoble, Grenoble, France, [3]Moscow State University, Moscow, Russia

Srv2/CAP has been one of the most enigmatic components of the eukaryotic actin machinery. While highly conserved, ubiquitously expressed, and critical for maintaining normal actin cytoskeleton organization and turnover in a wide range of model organisms, its specific functional roles in regulating actin dynamics have remained elusive. Further, the functional importance of Srv2/CAP hexamerization has been unclear. Here, we show that Srv2/CAP performs two distinct and biochemically/genetically separable roles in driving actin turnover. The C-terminal half of the protein forms dimers and potently stimulates nucleotide exchange on ADP-actin monomers, overcoming cofilin's inhibition of this process. The N-terminal half forms hexamers and performs a highly unanticipated role in directly enhancing cofilin-mediated severing and disassembly of actin filaments, observed in bulk fluorescence and TIRF

microscopy assays. Consistent with these activities, we found that mutations in the N-terminus but not the C-terminus of Srv2/CAP are synthetic lethal with mutations in Aip1, another co-factor in cofilin-mediated actin disassembly. These genetic observations emphasize that in vivo cofilin is not sufficient to drive actin filament disassembly, and that Srv2/CAP and Aip1 share an equally essential role in this process. Consistent with their distinct activities, both halves of Srv2/CAP were required for rapid cofilin-mediated F-actin turnover in phosphate release assays and bead motility assays. Remarkably, the two halves of the protein functioned in trans with equal efficiency to intact Srv2/CAP, further supporting their distinct roles. These results were corroborated in vivo by co-expression of each half of Srv2 in cells. Finally, we used electron microscopy and single particle analysis to show that the hexameric N-terminal half of Srv2 forms a wheel with six symmetrical protrusions that are sites of cofilin/actin-interaction. Disruption of hexamerization by a deletion of the N-terminal coiled coil domain in Srv2/CAP compromised its biochemical activities and genetic functions, suggesting that hexamerization is important for enhanced actin disassembly and raising intriguing possibilities for the severing mechanism.

819

Mutant Huntingtin Causes Defective Actin Remodeling During Stress: Nuclear Shuttling of Cofilin is Essential to the Cofilin-Actin Rod Stress Response.

R. Truant[1], L. Munsie[2]; [1]McMaster University, Hamilton, ON, Canada, [2]McMaster University, Canada

Huntington's disease (HD) is caused by a polyglutamine expansion in the 350 KDa huntingtin protein. Cellular stresses can trigger the release of huntingtin from the endoplasmic reticulum (ER), allowing huntingtin nuclear entry. We have discovered that full-length huntingtin localizes to nuclear cofilin-actin rods during stress and is required for the proper stress response involving actin re-modeling. Mutant huntingtin induces a dominant, persistent nuclear rod phenotype. Using live cell temporal studies, we show that this stress response is similarly impaired when mutant huntingtin is present, or when normal huntingtin levels are reduced. In HD patients, we have quantitatively detected cross-linked complexes of actin and cofilin with complex formation varying in correlation with disease progression. By live cell studies FLIM-FRET and western blot assays, we quantitatively observed that stress-activated tissue transglutaminase 2 (TG2) is responsible for the actin-cofilin covalent cross-linking observed in HD. These data support a direct role for huntingtin in nuclear actin re-organization, and describes a new pathogenic mechanism for aberrant TG2 enzymatic hyperactivity on cofilin-actin rods in neurodegenerative diseases.
We have characterized the active nuclear export of cofilin through a leptomycin-B sensitive, CRM1-dependent, nuclear export signal. Using FLIM-FRET between cofilin moieties and actin, as well as automated image analysis in live cells, we have defined subtle mutations in the amino-terminal half of the cofilin nuclear localization signal that allow cofilin to maintain its actin binding ability but affect cofilin dynamics during stress. We propose that active nuclear shuttling is critical for the role of cofilin in the cofilin-actin rod stress response.

820

Nuclear import and export mechanisms of actin.

J. Dopie[1], K. Skarp[2], E. Rajakylä[2], M. Vartiainen[2]; [1]Institute of Biotechnology, University of Helsinki, Helsinki, Finland, [2]Institute of Biotechnology, University of Helsinki

Actin is a major cytoskeletal protein that is also present in the nucleus. Nuclear actin is a vital component of important nuclear complexes and influences all stages of the gene expression, but the mechanistic connection is not known. For example, the form of actin responsible for individual stages of the gene expression process is debatable. In the cytoplasm, actin exists in

dynamic equilibrium between monomeric (G) and filamentous (F) forms; controlled by numerous actin-binding proteins. However, the relation between nuclear G-actin and F-actin is unclear although many major actin-regulating proteins are localized into the nucleus. Moreover, it is unclear how the nuclear and cytoplasmic actin pools are connected. Two export receptors, exportin 6 and Crm1, have been linked to nuclear export of actin, but the nuclear import mechanism has not been characterized.
Here we show by Fluorescence Recovery after Photobleaching (FRAP) and Fluorescence Loss in Photobleaching (FLIP) that actin actively shuttles between the nucleus and the cytoplasm and the rate of movement is dependent on the availability of actin monomers. This suggests that nuclear and cytoplasmic actin pools are dynamically linked, and that although actin (43 kDa) could potentially diffuse through the nuclear pores, it uses an active mechanism for both nuclear entry and exit. We have further utilized RNAi in both Drosophila and mammalian cells to identify proteins responsible for nucleo-cytoplasmic shuttling of actin, and show that nuclear export of actin is dependent on exportin-6, but not Crm1. We also identify importin 9, a member of the importin beta superfamily, as the nuclear import receptor for actin. Also cofilin, an actin-binding protein, is required for the active nuclear localization of actin. Importin 9 interacts with both cofilin and actin and the interaction is sensitive to RanGTP. We further show that the active maintenance of nuclear actin levels by importin 9 is required for maximal transcription. Taken together, these results establish a dynamic connection between nuclear and cytoplasmic actin networks and identify an active nuclear import mechanism for actin, which is required to drive essential nuclear processes.

821

Sequential action of formin family proteins during fibroblast adhesion and spreading

T. Iskratsch[1], M. Sheetz[2]; [1]Columbia Univ, New York, NY

Closely examining the initial attachment and spreading of cells have gained many important insights into cell migration. This process can be broken down into three consecutive phases: the initial cell attachment (P0), fast increase in spread area (P1) and lateral waves of protrusion and retraction events (P2). All three phases depend on actin nucleation, polymerization, depolymerization, bundling and crosslinking and multiple proteins regulate each of these processes. Actin nucleation and polymerization factors are grouped into several classes, such as the ARP2/3 complex or the formin family proteins. Although formins are known to participate in the regulation of actin dynamics in fibroblasts, their role during adhesion and spreading is still not clear. Here we investigate a potential role of formins during fibroblast adhesion and spreading by using smiFH2, a specific formin inhibitor. Furthermore, we investigate the expression and activation pattern of formin family members by RT-PCR, confocal microscopy, live cell imaging, western blotting and co-immunoprecipitation and find sequential action of different formins, amongst them FHOD1, mDia1 and mDia2.

822

The Effect of Formin Actin Assembly Properties on Fission Yeast Cytokinesis.

A. J. Bestul[1], B. J. Scott[2], E. M. Neidt[2], D. R. Kovar[1,2]; [1]Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, [2]Department of Biochemistry and Molecular Biology, University of Chicago

Formins stimulate actin assembly through a novel mechanism by remaining processively associated with the elongating barbed end and driving the rapid addition of profilin-actin. Eukaryotic cells typically express multiple formin isoforms that are differentially required for diverse cellular processes. We hypothesize that in addition to activation at the right time and place, the specific actin assembly properties tailor formin isoforms for a particular cellular role.

We are investigating the physiological importance of actin assembly properties in fission yeast, which expresses three formins with unique cellular roles: Cdc12 (cytokinesis), For3 (polarization) and Fus1 (mating). We found that all three formins share fundamental biochemical properties, however particular reaction rates vary significantly such as nucleation efficiency and barbed end elongation. We then constructed fission yeast strains that exclusively express cytokinesis formin Cdc12 chimeras, in which its actin assembly domains were replaced with the actin assembly domains from biochemically diverse formins (SpFus1, SpFor3, ScBni1, MmDia1, MmDia2, and CeCYK-1). With the exception of SpFus1, all strains are viable, however they exhibit a large range of cytokinesis defects from mild to severe. Quantitative time-lapse imaging reveals significant delays in contractile ring assembly and maturation. Furthermore, the mechanism of contractile ring assembly varies significantly between formin chimera strains from the search, capture, pull, release (SCPR) pathway to the leading cable (spot) pathway.

823

Concerted Effects of Multiple Formin Regulators on Yeast Actin Cable Architecture.

J. A. Eskin[1], M. A. Chesarone-Cataldo[1], A. B. Johnston[1], C. Guérin[2], J. H. Yu[3], R. Wedlich-Söldner[3], L. Blanchoin[2], B. L. Goode[1]; [1]Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA, [2]Université Joseph Fourier / Institut de Recherches en Technologies et Sciences pour le Vivant, CEA Grenoble, [3]Research Group Cellular Dynamics and Cell Patterning, Max Planck Institute of Biochemistry, Martinsried, Germany

While the role of formins as actin assembly factors is well established, a key unanswered question is how their potent activities are controlled in vivo with the spatial and temporal precision required to assemble actin networks that have particular architectures and dynamics. After their initial release from an autoinhibited state, formins must still be tightly controlled in a temporal manner to produce actin networks with proper filament length and organization. We recently identified two different inhibitors of the yeast formin Bnr1, which exhibited distinct biochemical activities and mutant phenotypes. Bud14 displaced the FH2 domain of Bnr1 from filament ends, and loss of *BUD14* in vivo led to abnormally long, buckled cables that were resistant to latrunculin A (Chesarone et al., 2009). In contrast, Smy1 slowed the rate of filament elongation by Bnr1 without displacing the formin from filament ends, and loss of *SMY1* in vivo led to wavy/kinked actin cables that grew abnormally fast and fluctuated in thickness (Chesarone-Cataldo et al., 2011). Consistent with these inhibitors having distinct regulatory effects on Bnr1, *bud14Δ smy1Δ* double mutants also showed compounded defects in cell growth and actin cable organization. More recently, we have introduced point mutations into Smy1 that weaken its inhibitory effects on Bnr1 in vitro, and we are in the process of analyzing their effects in vivo. Further, we have identified an important functional motif in Smy1 that is shared with Bud14, despite the differences in their biochemical and cellular activities. We hypothesize that this may be a commonly used FH2-binding motif that is combined with other sequences in the contexts of different proteins to produce distinct formin regulatory effects. Finally, we are performing a surface scanning mutagenesis of the Bnr1 FH2 domain to identify its regulatory surfaces, and dissecting the mechanistic relationship of Bud14 and Smy1 and their coordinated effects on Bnr1.

Regulation of the Diaphanous-related formin, DAAM1, in mammalian cells.

B. E. Docter[1], C. M. June[1], B. J. Wallar[1]; [1]Chemistry, Grand Valley State University, Jenison, MI

Diaphanous-related formins (DRFs) are a highly conserved family of proteins critical to the regulation of the cytoskeleton. The regulation of DRFs involves an autoinhibitory process in which the binding of the C-terminal Diaphanous- autoregulatory domain (DAD) to the N-terminal

Diaphanous-inhibitory domain (DID) keeps the protein in an inactivated state. Upon binding of an activated Rho GTPase to the DRF GTPase binding domain (GBD), the DID-DAD interaction is released, thereby activating the DRF protein. One DRF family member that has been shown to be localized to both axons and dendrites of neuronal cells is the Dishevelled-associated activator of morphogenesis-1 (DAAM1). DAAM1 has also been demonstrated to interact with the Rho GTPases, RhoA and Cdc42, and play an important role in a variety of biological processes and pathways, including gastrulation and the development of the tracheal cuticle in the respiratory system. Our laboratory has created constitutively active full-length DAAM1 and mDia3 to elucidate the localization and cellular effects of the protein in cells. Here, analogous to the M1041A and M1182A mutations in the DAD regions of mDia2 and mDia1 respectively, we show that the F1032 residue (DAAM1) and M1053 (mDia3) are critical to the DID-DAD autoregulatory interaction of the proteins. Fluorescence anisotropy demonstrates that these mutations in DAD result in the complete inability to bind to the DID region. The loss of DID-DAD binding is consistent with the localization and impact of full-length constitutively active DAAM1 and mDia3 in mammalian cells. Expression of constitutively active versions of DAAM1 and mDia3 in three different cell lines (NIH3T3/mouse fibroblast, PC12/rat pheochromocytomas, N1E-115/mouse neuroblastomas) resulted in cells with an increased number of abnormally-shaped filopodia and cellular protrusions. The F1032A DAAM1 was found to be evenly distributed throughout the entire filopodia, which was in contrast to the constitutively active mDia3 being mostly localized to the tips of the filopodia. Interestingly, the inhibition of Rho GTPases by C3 transferase did not decrease the ability of constitutively active DAAM1 and mDia3 to cause cellular protrusions, nor did it significantly inhibit the formins' ability to activate serum response factor in cells. Lastly, the localization of the activated mDia3 at the filopodia tips was dependent on its ability to nucleate actin. Together, these results demonstrate the critical contribution of F1032 (DAAM1) and M1053 (mDia3) to the autoregulation process, as well as shed some light on the cellular effects and localization of full-length constitutively active DAAM1 and mDia3.

825

Probing the role of phosphorylation in the mechanism of formin mDia2.

Z. Garlets[1], C. M. June[1], B. J. Wallar[1]; [1]Grand Valley State University, Ada, MI

Diaphanous-related formins are a highly conserved family of proteins that influence numerous cellular processes by regulating cytoskeletal dynamics. One such way that formins affect cytoskeletal dynamics is through nucleating actin filaments, by recruiting actin monomers as the filament elongates and decreasing actin depolymerization at the barbed end. Since the formins are an important focal point which affect so many cellular processes, it is vital that they are tightly regulated and only activated in response to cellular signals, as uncontrolled formins can result in dire consequences for a cell. The regulation of one specific mammalian formin, mDia2, is regulated by intramolecular interactions between the N- and C-terminus, in order to inhibit the domain responsible for actin polymerization (FH2). The autoinhibitory binding occurs between the diaphanous inhibitory domain (DID) at the N-terminus and the diaphanous auto regulatory domain (DAD) at the C-terminus. Thus far, it is understood that formins are activated when a Rho GTPase binds to the GTPase binding domain, but binding of a GTPase may not fully activate the protein. Other signals seem to be necessary in order to fully activate the formin. Previously, we identified a specific cellular protein, p21 activated kinase (PAK1), that phosphorylates mDia2 and potentially serves to regulate the formin in cells. We have identified the specific amino acid sites on mDia2, in both the DID and DAD domains, that are modified by PAK1. In addition, we have verified that PAK1 phosphorylates mDia2 in mammalian cells. Using isothermal titration calorimetry and fluorescence anisotropy, we have shown that PAK1 binds to both DID and DAD regions of mDia2, and this binding does not seem to have a significant effect

on the DID-DAD affinity. Lastly, we have attempted to trace the interplay of the different formin domains with PAK1 by measuring actin polymerization in vitro. Preliminary data suggest that the presence of PAK1 may inhibit the promotion of actin nucleation by mDia2 FH1FH2DAD by potentially enhancing DID-DAD interactions. With the observation of DRF phosphorylation by kinases that are known to interact closely with Rho GTPases, we hope to provide valuable insight into the mechanism of mDia2 regulation.

826

Single Molecule Visualization of Cooperation Between the Actin Nucleators mDia1 and APC.

D. Breitsprecher[1], R. Jaiswal[1], J. P. Bombardier[1], J. Gelles[1], B. L. Goode[1]; [1]Brandeis University, Waltham, MA

Evidence for cooperation between actin nucleators and elongation factors in vivo is growing. Such mechanisms have been postulated for formins interacting with Spire, the tumor-suppressor adenomateous polyposis coli (APC), Bud6, and Arp2/3 complex. However, the mechanisms underlying this proposed cooperation have remained obscure. Here we employed triple-color TIRF microscopy to reconstitute and visualize actin filament formation by APC and the formin mDia1 in real-time and at the single molecule level. TIRF microscopy on SNAP-tagged fluorescently labeled mDia1 and APC-C showed that each protein is a dimer, and enabled us to track their dynamics during actin filament formation. Capping protein and profilin were included to suppress spontaneous nucleation and elongation of filaments and mimic the cellular environment. Using this experimental setup, we visualized for the first time the processive movement of single formin molecules (dimers) on the rapidly growing ends of actin filaments. SNAP-mDia1 and SNAP-APC directly interacted to form transient prenucleation complexes with actin monomers. Upon initiation of filament polymerization, the APC-mDia1 complex was immediately released, resulting in rapid processive translocation of SNAP-mDia1 on the barbed end, leaving SNAP-APC at the pointed end. Notably, Latrunculin B treatment resulted in long-lived prenucleation complexes, suggesting that processive translocation of mDia1 at the barbed end provides the driving force for mDia1-APC separation. Higher concentrations of SNAP-APC led to filament bundling and the formation of APC-clusters from which multiple mDia1-elongated filaments sprouted into filament ‘bouquets’. Finally, APC-mDia1 interactions required sequences in mDia1 C-terminal to the FH2 domain, suggesting parallels between APC-formin and Spire-formin. Thus, the mechanisms visualized here may recapitulate general principles of cooperation between formins and other actin nucleators.

827

Structure, Mechanism, and Regulation of the Formin Nucleation Promoting Factor Bud6.

B. R. Graziano[1], D. Tu[2], A. Michelot[3], A. DuPage[1], D. Breitsprecher[1], J. Moseley[4], I. Sagot[5], M. Eck[2], L. Blanchoin[3], B. Goode[1]; [1]Brandeis University, Waltham, MA, [2]Harvard Medical School, Boston, MA, [3]Institut de Recherches en Technologie et Sciences pour le Vivant, Grenoble, France, [4]Dartmouth Medical School, [5]Université de Bordeaux and Centre National de la Recherche Scientifique, France

Recent studies indicate that cells often bring together two different actin assembly-promoting factors with complementary strengths to overcome physiological barriers to polymer formation such as profilin and capping protein. While formins efficiently protect growing actin filament ends from capping protein, their nucleation activities in the presence of profilin are weak. Thus, the ability of formins to overcome the profilin barrier to nucleation in vivo may require nucleation-promoting factors (NPFs), and indeed, this has recently been suggested for formins that interact with Spire and adenomatous polyposis coli (APC). Here, we show that the yeast formin-binding

protein Bud6 represents a functional counterpart to these metazoan NPFs. Using TIRF microscopy, we demonstrate that Bud6 elevates formin nucleation activity without affecting rate of filament elongation. Through the generation of separation-of-function alleles, we show that Bud6 NPF activity in vitro and in vivo requires two distinct domains in Bud6 that bind to the formin DAD domain and actin monomers. We demonstrate that Bud6 is a dimer, which can bind two actin monomers. Thus, each formin dimer, with its two DAD domains, can recruit two Bud6 dimers, and in turn four actin monomers, which we propose are organized into a nucleation seed from which the formin FH2 domain elongates a filament. We present the crystal structure of a core segment of Bud6 (residues 550–688) that binds to the formin. The structure reveals a novel triple helical coiled-coil dimer, and we identify conserved surface residues that mediate DAD binding and are critical for NPF activity. Finally, we show that Bud6 interacts with the two yeast formins (Bni1 and Bnr1) through distinct mechanisms, and that these associations are differentially regulated in vivo by a novel cellular binding partner of Bud6 that we identified. These unexpected results demonstrate that a single NPF can be employed in vivo to differentially control the activities of two distinct formins depending on the availability of specific binding partners.

828

Formin proteins have distinct mechanisms of microtubule/actin interaction.

H. N. Higgs[1], J. Gaillard[2], V. Ramabhadran[1], L. Blanchoin[2], M. Vantard[2]; [1]Biochemistry, Dartmouth Medical School, Hanover, NH, [2]Laboratoire Physiologie Cellulaire & Vegetale, CEA, Grenoble, France

A number of cellular processes utilize both microtubules and actin filaments, but the molecular machinery linking these two cytoskeletal elements remains to be elucidated in detail. Formins are actin-binding proteins that have multiple effects on actin dynamics, as well as influencing microtubule stability and positioning in interphase and mitotic cells. Although several formins have been shown to bind microtubules directly, the binding mechanisms are poorly understood. Here, we show that three formins, INF2 (active in the secretory pathway), mDia1 (focal adhesion/stress fiber assembly), and mDia2 (cytokinesis), display important fundamental differences in their interactions with and effects on microtubules. All three formins bind microtubules with high affinity (K_d < 100 nM), and require the formin homology 2 (FH2) domain for this interaction. However, only mDia2 binds microtubules with 1:1 stoichiometry, while INF2 and mDia1 display saturating binding at 1:3 (formin dimer:tubulin dimer). INF2 is a potent microtubule bundling protein, an effect that results in a large reduction in catastrophe rate. In contrast, neither mDia1 nor mDia2 bundle microtubules appreciably. The C-termini of mDia2 and INF2 have different functions in microtubule interaction, with mDia2's C-terminus required for high affinity binding and INF2's C-terminus required for bundling. These formins also differ in their abilities to bind actin and microtubules simultaneously. Microtubules strongly inhibit actin polymerization by mDia2, while they moderately inhibit mDia1 and have no effect on INF2. Conversely, actin monomers inhibit microtubule binding/bundling by INF2, but do not affect mDia1 or mDia2. Our conclusion is that, while all three formins require the FH2 domain for high affinity microtubule interaction, they differ markedly in their effects on microtubules and the ability to interact with actin and microtubules simultaneously, with INF2 assembling extensive actin/microtubule co-bundles whereas mDia1 and mDia2 do not. These biochemical differences result in substantial differences in the abilities of these three formins to interact with actin and microtubules simultaneously in cells.

829

Evidence that rapid release of VCA from filament-bound Arp2/3 complex is required for actin branch formation.

B. A. Smith[1], S. B. Padrick[2], L. K. Doolittle[2], K. Daugherty-Clarke[3], B. L. Goode[3], M. K. Rosen[2], J. Gelles[1]; [1]Department of Biochemistry, Brandeis University, Watham, MA, [2]Howard Hughes Medical Institute and Department of Biochemistry, University of Texas Southwestern Medical Center, Dallas, TX, [3]Department of Biology and Rosenstiel Basic Medical Science Research Center, Brandeis University, Waltham, MA

* First and second authors contributed equally to this work.

During cell locomotion and endocytosis, actin filament nucleation by Arp2/3 complex is stimulated by the VCA domain of WASP family proteins, which likely exist in multimeric clusters on membrane surfaces. The mechanism of actin filament nucleation by Arp2/3 complex has been well studied using bulk measurements. While these studies have revealed many details regarding the nucleation mechanism, the kinetic mechanism of how VCA association with Arp2/3 complex, Arp2/3 complex binding to an existing filament and new filament nucleation are coordinated remains unclear. Here, we address this challenge by using a colocalization single molecule spectroscopy (CoSMoS) approach to directly visualize the assembly of actin filament branches with fluorescently labeled actin, Arp2/3 complex and VCA in vitro. Preceding nucleation, VCA is often bound to Arp2/3 complex at the time of docking on a pre-existing filament, but then is released very quickly (lifetime <0.05s for monomeric VCA). Release of dimeric WASP VCA from the nascent branch site is somewhat prolonged, but its lifetime is still short (0.2-0.4 s). The majority of Arp2/3-diVCA-filament interactions are unproductive in nucleation, and result in rapid release of Arp2/3-diVCA complexes from the filament. Further, using a set of N-WASP VCA dimers with engineered point mutations we find that weaker affinity for Arp2/3 complex corresponds with higher nucleation activity. From these results we hypothesize that rapid release of VCA from the nascent branch is required for daughter filament growth. Such a mechanism could explain how mother filament binding and daughter filament nucleation are coordinated.

830

α-Catenin: An Inhibitor of Arp 2/3 Complex-Mediated Actin Polymerization.

L. Case[1], M. Raab[1], W. J. Nelson[1], A. V. Kwiatkowski[1]; [1]Physiology Course, Marine Biological Laboratory, Woods Hole, MA

Cell-cell adhesion occurs through cadherins on cell membranes, which link to the internal actin cytoskeleton. β-Catenin (β-cat) binds to the cytoplasmic domain of E-cadherin (E-cad) and α-catenin (α-cat) binds to β-cat, and they collectively form the ternary cadherin-catenin cell-cell adhesion complex. α-Cat binds and bundles F-actin and is considered the primary link between cadherin-mediated cell-cell adhesion complexes and the actin cytoskeleton. However, the E-cad/β-cat/α-cat ternary complex binds weakly to F-actin *in vitro*, whereas α-cat alone can bind F-actin and regulate actin dynamics. We postulated that α-cat regulates actin dynamics at cell-cell junctions by dissociating from the ternary complex and binding F-actin. To test this hypothesis, we coated beads with an equimolar mixture of ActA – an activator of the Arp2/3 complex – and the E-cad cytoplasmic tail in the absence or presence of β-cat and α-cat (i.e., the E-cad/β-cat/α-cat ternary complex); these beads were then incubated with a mixture of fluorescent G-actin, capping protein, and Arp2/3 complex to promote actin network assembly. We found that reconstitution of the E-cad/β-cat/α-cat complex on beads significantly reduced the rate of Arp2/3 complex-dependent actin network assembly. In addition, the presence of the

ternary complex altered gross F-actin morphology, consistent with inhibition of Arp2/3 complex activity. Removal of α-cat from the complex (E-cad/β-cat alone) restored actin assembly rates to control (no complex) levels, indicating that α-cat is required for inhibition of actin network formation by the E-cad ternary complex. To visualize α-cat localization during actin network growth, we reconstituted the ternary complex with EGFP-labeled α-cat (E-cad/β-cat/EGFP-α-cat). We observed EGFP-α-cat throughout the F-actin network and distal to the bead surface, suggesting that α-cat can dissociate from the ternary complex and subsequently bind F-actin. We propose that unbinding of α-cat from E-cad ternary complex and binding to actin filaments inhibits Arp2/3 complex-dependent actin assembly. These results have implications for mechanisms involving the E-cad ternary complex and α-cat in the regulation of actin dynamics at cell-cell adhesions.

831

Activation of the Arp2/3 complex by nucleation promoting factors.

E. L. Benanti[1], A. D. Siripala[1], E. A. Znameroski[1], M. D. Welch[1]; [1]Molecular and Cell Biology, Univ California-Berkeley, Berkeley, CA

Branched actin networks are critical for cellular processes such as endocytosis, vesicle trafficking and membrane protrusion. The Arp2/3 complex, which is an evolutionarily conserved seven protein complex consisting of Arp2, Arp3 and ARPC1-5 subunits, is a central factor in the construction of branched actin networks. Upon activation by a nucleation promoting factor (NPF), the Arp2/3 complex binds to the sides of existing actin filaments and nucleates new daughter filaments to form Y-branches. Distinct NPFs harness Arp2/3 activity for different processes within the cell. A key step in Arp2/3 activation is NPF binding, and recent evidence indicates that two NPF-binding sites exist on the complex. However, a variety of experimental approaches have suggested more than two possible regions to which NPFs may bind. To localize NPF binding on the complex, we have used site-directed mutagenesis to engineer recombinant human Arp2/3 complexes that are mutated in candidate NPF-binding sites, including a basic patch on Arp3 and hydrophobic residues of Arp2. Pyrene actin polymerization assays demonstrate that both of these sites are important for Arp2/3-mediated actin nucleation and suggest that they represent two distinct NPF binding sites. In the future, affinity measurements of mutant complexes for different NPFs will directly address the importance of each site in Arp2/3-NPF binding and also determine if distinct NPFs exhibit binding site preferences. Additionally, experiments examining the role of each NPF-binding site in Arp2/3 activation in the context of its cellular functions, such as membrane protrusion and lamellipodia dynamics, will dissect the contributions of two NPF binding events and the associated recruitment of two actin monomers to Y-branched actin network formation in cells.

832

Arp2/3 complex and myosin II both contribute to the dynamic behavior of actin filament veils in neuronal growth cones.

Q. Yang[1], X-F. Zhang[1], T. Pollard[1], P. Forscher[1]; [1]Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT

Arp2/3 complex nucleates actin filaments and generates actin filament networks at the leading edge of motile cells, but the role of Arp2/3 complex in neuronal growth cones has been questioned. The growth cone's peripheral domain (P-domain) contains a treadmilling network of actin filaments that assembles at the leading edge and moves centripetally by a process referred to as "retrograde actin flow". Normal rates of retrograde flow depend both on actin assembly and the actions of more centrally localized non-muscle myosin II. When myosin II is

inhibited, retrograde flow persists at reduced rates that now fully depend on "pushing" forces generated by leading edge actin assembly. A specific role for Arp2/3 complex in retrograde flow and/or possible interdependencies of Arp2/3 complex and myosin II have not been reported. Here, we investigated the effects of a small molecule Arp2/3 complex inhibitor, CK666, on actin filament structure and dynamics in growth cones. CK666 treatment delocalized Arp2/3 complex from the leading edge, markedly decreased the density of actin filament barbed ends in the P-domain, reduced actin density in veil networks and resulted in actin veil retraction. CK666 treatment left structure and dynamics of filopodia remarkably intact and significantly increased residual actin retrograde flow rates in the P-domain. In contrast, inhibition of both myosin II activity and Arp2/3 complex decreased retrograde flow and veil retraction was no longer observed. Together, these results suggest Arp2/3 complex and myosin II both contribute to actin veil structure and dynamics.

833

Coupling Arp2/3 Complex-mediated Actin Branching and Membrane Deformation by the Exocyst Component Exo70.

Y. Zhao[1], J. Liu[1], C. Yang[1], Y. Sun[3], Y. Goldman[2], T. Svitkina[1], W. Guo[1]; [1]Department of Biology, University of Pennsylvania, Philadelphia, PA, [2]Department of Physiology, School of Medicine, University of Pennsylvania

Actin dynamics and membrane remodeling are tightly coordinated spatially and temporally to generate cell surface protrusions for morphogenesis and migration. However, the molecular mechanism for this coordination is unclear. Here we report that Exo70, a component of the exocyst complex, couples actin assembly and membrane curvature induction. Using pyrene actin assay and dual-color total internal reflection fluorescence (TIRF) microscopy, we found that Exo70 synergizes with WAVE2 to kinetically stimulate the Arp2/3 complex-mediated actin polymerization and branching. We also found that Exo70 is able to generate tubular invaginations toward the lumen of in vitro synthesized large unilamellar liposomes (LUVs) and giant unilamellar liposomes (GUVs). In cells, Exo70 induces actin-free filopodial protrusions, which are subsequently stabilized by actin filaments as observed by correlative light and electron microscopy. Cells expressing Exo70 mutants deficient in interacting with the Arp2/3 complex or bending membranes are defective in lamellipodia formation and directional cell migration. Together, our findings provide a novel mechanism for the coordination of actin organization and plasma membrane remodeling during cell morphogenesis and migration.

834

Interactions Among IQGAP1, Cdc42/Rac1, N-WASP and Actin Quantified by In vitro Reconstitution and Live Cell, Three-Color FRET Microscopy.

H. Wallrabe[1,2], Y. Cai[1], Y. Sun[2], A. Periasamy[1,2], R. Luzes[3,4], X. Fang[1], H-M. Kan[1], L. C. Cameron[3,4], D. A. Schafer[1,5], G. S. Bloom[1,5]; [1]Department of Biology, University of Virginia, Charlottesville, VA, [2]Keck Ctr for Cellular Imaging, University of Virginia, Charlottesville, VA, [3]Laboratorio de Bioquimica de Proteinas, Universidade Federal do Estado do Rio de Janeiro, Brazil, [4]Instituto de Genetica e Bioquimica, Universidade Federal de Uberlandia, Uberlandia, Brazil, [5]Department of Cell Biology, University of Virginia

IQGAP1 stimulates branched actin filament nucleation by activating N-WASP, which in turn activates the Arp2/3 complex. N-WASP can be activated by other factors, including GTP-bound Cdc42 or Rac1, which also bind IQGAP1. In pyrene-actin assembly assays in the presence of N-WASP and the Arp2/3 complex, Cdc42 and IQGAP1 cooperatively stimulated actin filament nucleation. Cdc42 also stimulated binding of IQGAP1 to N-WASP in a dose dependent manner. In contrast, Rac1 showed an inhibitory effect of IQGAP1 binding to N-WASP. The two G

proteins and their association with IQGAP1 therefore have a distinct impact on N-WASP and the downstream nucleation of actin filaments. To assess the physiological significance of these *in vitro* findings we developed a novel three-color FRET microscopy assay, in which live MDCK cells simultaneously expressed various combinations of fluorescent fusion proteins of Cdc42, Rac1, N-WASP, IQGAP1 and actin by co-transfection. Cdc42 fluorescence was not correlated with the distance between IQGAP1 and actin, whereas increasing Rac1 fluorescence correlated with increasing IQGAP1-actin distance. In the presence of IQGAP1, N-WASP fluorescence levels decreased with rising Rac1 fluorescence, while the opposite was true for Cdc42. Moreover, the distance between IQGAP1 and N-WASP decreased with increasing Cdc42 fluorescence, but rose as Rac1 fluorescence rose. The live cell triple FRET data therefore confirm the conclusion from *in vitro* reconstitution experiments that Cdc42 and Rac1 respectively strengthen and weaken the binding of IQGAP1 to N-WASP, and suggest corresponding positive and negative effects on actin polymerization. More broadly, these data establish three-color FRET microscopy as a powerful tool for studying dynamic multi-molecular interactions in live cells.

836

PIP2 dynamics couples Calcium/InsP3 and N-WASP/F-actin oscillations to coordinate secretory vesicle recruitment and fusion at the plasma membrane.

R. Wollman[1], T. Meyer[1]; [1]Chemical and Systems Biology, Stanford University, Stanford, CA

Secretory granules have to pass through the actin cortex with a mesh size typically much smaller than average vesicle diameter, suggesting that the actin cortex acts as barrier for secretory granules. Yet Myosin Va a transport motor that is important for vesicle recruitment and docking, requires the actin cortex for its function, suggesting that the cortex acts as a carrier of secretory granules. How does the cell consolidate these seemingly opposing roles of the actin cortex? Here we show that during the FceRI response in RBL-2H3 cells, the levels of F-actin at the cell cortex oscillate. The oscillations of cortical actin are a result of oscillations in the levels of plasma membrane recruitment of N-WASP. We demonstrate that these F-actin/N-WASP oscillations are coupled to the cell's Ca2+/InsP3 oscillations via oscillatory changes in the levels of PIP2 in the plasma membrane. The oscillatory dynamic of the actin cortex allows temporal partitioning of the barrier and carrier roles of the actin cortex, thereby consolidating the two opposing roles of the actin cytoskeleton during secretory exocytosis.

837

The WAVE Regulatory Complex Links Neuronal Receptors to the Actin Cytoskeleton.

B. Chen[1], Z. Chen[1], C. Pak[1], Y. Liao[1], S. Shi[1], N. V. Grishin[1], M. K. Rosen[1]; [1]UT Southwestern Medical Center, HHMI, Dallas, TX

Wiskott-Aldrich syndrome protein WAVE activates Arp2/3 complex to stimulate actin polymerization adjacent to membranes. This activity is important for many membrane-associated cellular activities, including cell migration and adhesion. In vivo, WAVE exists as inhibited in a 400kD heteropentameric complex, known as WAVE regulatory complex (WRC) consisting of Sra, Nap, Abi, HSPC300 and WAVE. Although a few known regulators can activate WRC, what ligands link its activity to specific cellular processes is largely unknown. Recently a neuron-specific adhesion receptor protocadherin10 (PCDH10) was reported to interact with WRC via its cytoplasmic tail (CT), which then recruit WRC to cell-cell contact site. Here we report that the unstructured PCDH10 CT contains a highly conserved WRC interacting protocadherin sequence (WIPS) that binds WRC. We present crystal structures of WRC complexed with synthetic WIPS peptides, in which the peptides bind to a highly conserved hydrophobic pocket formed by Sra and Abi. Point mutations revealed a consensus WIPS that

exists in many other proteins of various functions. We further confirmed that among these proteins many neuron-specific receptors, including protocadherins, neuroligins and glutamate receptors, bound WRC using WIPS in their cytoplasmic tails. This broad, diverse and highly conserved WIPS-specific interactome for WRC may provide a general mechanism that links actin cytoskeleton to different cellular activities.

Microtubule Dynamics and Its Regulation II

CENP-E interacts with SKAP to orchestrate accurate chromosome segregation in mitosis.

Y. Huang[1], P. Yao[2], X. Wang[2], G. Fang[3], X. Ding[4], Z. Dou[3], X. Yao[5]; [1]Cell Biology, University of Science & Technology of China, Hefei, China, [2]Physiology, Morehouse School of Medicine, Atlanta, GA, [3]University of Science & Technology of China, [4]Beijing University of Chinese Medicine, [5]Morehouse School of Medicine

Mitotic chromosome segregation is orchestrated by the dynamic interaction of spindle microtubules with the kinetochore. During chromosome alignment, bi-oriented kinetochores move chromosomes by regulating the plus-end dynamics of the attached microtubules. Although previous studies show that mitotic kinesin CENP-E forms a link between attachment of spindle microtubule to the kinetochore and the mitotic checkpoint signaling cascade, the molecular mechanism underlying dynamic kinetochore-microtubule interactions in mammalian cells remains elusive. Here we identify a novel interaction between CENP-E and SKAP which functions synergistically in governing dynamic kinetochore-microtubule interactions. SKAP binds to the C-terminal tail of CENP-E in vitro and is essential for an accurate kinetochore-microtubule attachment in vivo. Immuno-electron microscopic analysis indicates that SKAP is a constituent of the kinetochore corona fibers of mammalian centromeres. Depletion of SKAP or CENP-E by RNA interference results in a dramatic reduction of inter-kinetochore tension, which causes chromosome mis-segregation with a prolonged delay in achieving metaphase alignment. Importantly, SKAP binds to microtubules in vitro, and this interaction is synergized by CENP-E. Based on these findings, we propose that SKAP cooperates with CENP-E to orchestrate dynamic kinetochore-microtubule interaction for faithful chromosome segregation.

839

Molecular delineation of TIP150 function underlying kinetochore microtubule dynamics during mitotic chromosome segregation.

T. Ward[1], L. Zhang[2], Z. Wang[2], X. Yao[2]; [1]Physiology, Morehouse School of Medicine, Atlanta, GA, [2]Morehouse School of Medicine, Atlanta

Microtubules are cytoskeletal elements that are essential for an array of intracellular processes such as mitosis and cellular division. Mammalian plus-end-tracking proteins (+TIPs) localize to the growing ends of microtubules, and regulate their dynamic behavior and interactions with kinetochores during mitosis. Tip150 is a novel microtubule plus end binding protein essential for dynamic kinetochore-microtubule attachments and proper cellular division. Previous biochemical and immunofluorescence analyses show that TIP150 interacts with plus end bind proteins EB1 (end bind protein 1) and MCAK (mitotic centromere associated kinesin). However, the molecular behavior of TIP150 on microtubules and how it regulates microtubule dynamics remains elusive. To understand the molecular biophysics underlying TIP150-elicited end-tracking, we reconstituted an in vitro particle tracking experimentation system using purified

+TIP proteins, which allowed the delineation of EB1-TIP150 interactions on microtubule ends at the nanometer scale. This total internal reflection fluorescence microscopy assay enables us to observe dynamic plus end tracking in vitro, and the quantitative analysis of single +TIP molecule turnover at the growing microtubule ends in the presence or absence of mitotic kinases. The consolidation of those in vitro molecular dynamics of +TIPs coupled with specific protein-protein interaction manipulation in vivo will allow us to build a model accounting for the function of +TIPs in mitotic chromosome segregation.

840

PLK1-MCAK interaction orchestrates kinetochore microtubule dynamics essential for faithful chromosome segregation.

L. Zhang[1], G. Adams[2], T. Ward[2], X. Yao[2]; [1]Physiology, Morehouse School of Medicine, Atlanta, GA, [2]Morehouse School of Medicine, Atlanta, GA

During cell division, interaction between kinetochores and dynamic spindle microtubules governs chromosome movements. The microtubule depolymerase mitotic centromere-associated kinesin (MCAK) is a key regulator of mitotic spindle assembly and dynamics. However, the regulatory mechanisms underlying its depolymerase activity during the cell cycle remain elusive. We have recently showed that PLK1 is a novel regulator of MCAK essential for accurate chromosome dynamics in mitosis (Zhang et al., 2011. J. Biol. Chem. 286, 3033-3046). MCAK interacts with PLK1 in vitro and in vivo. The neck and motor domain of MCAK associates with the kinase domain of PLK1. MCAK is a novel substrate of PLK1, and the phosphorylation stimulates its microtubule depolymerization activity of MCAK in vivo. Overexpression of a polo-like kinase 1 phosphomimetic mutant MCAK causes a dramatic increase in misaligned chromosomes and in multipolar spindles in mitotic cells, whereas overexpression of a nonphosphorylatable MCAK mutant results in aberrant anaphase with sister chromatid bridges, suggesting that precise regulation of the MCAK activity by PLK1 phosphorylation is critical for proper microtubule dynamics and essential for the faithful chromosome segregation. We reasoned that dynamic regulation of MCAK phosphorylation by PLK1 is required to orchestrate faithful cell division, whereas the high levels of PLK1 and MCAK activities seen in cancer cells may account for a mechanism underlying the pathogenesis of genomic instability. Using a novel MCAK activity reporter coupled with chemical inhibitors, we are illustrating how spatiotemporal dynamics of MCAK activity is coordinated with kinetochore mechanics during mitotic chromosome movements.

The Kinesin-8 Kip3 Controls Anaphase Spindle Length.

R. Rizk[1], K. DiScipio[1], M. Gupta[1]; [1]Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

Kinesin-8 is a conserved family of microtubule motors and regulator of microtubule dynamics with important roles in chromosome alignment and spindle function in a wide range of organisms. Inhibition of Kinesin-8 was reported to produce increased anaphase spindle lengths often having a buckled morphology. These defects have long been attributed to a proposed function for Kinesin-8 in spindle disassembly following mitosis. Combining molecular genetics with fluorescence imaging revealed a novel role for the budding yeast Kinesin-8, Kip3, prior to spindle disassembly in which it actively restrains inappropriate spindle elongation during anaphase. When challenged with an anaphase arrest, spindles stopped elongating when they obtained a length approximately equal to the cell diameter. However, in the absence of Kip3, anaphase spindles failed to stop elongating, buckled, and continued to hyper-elongate throughout the arrest. To determine whether the rigid cell wall limits spindle length, we tracked

spindle elongation in cells lacking Ipl1 (Aurora B), which are known to have buckled spindles. Spindles in cells lacking Ipl1, unlike those lacking Kip3, buckled but did not hyper-elongate over extended periods of anaphase arrest. These results indicate Kip3 does not function to prevent spindles from overcoming cortical resistance and buckling but instead, can limit buckled spindles to the appropriate length. To define the mechanism by which Kip3 halts spindle elongation we measured the rates of spindle hyper-elongation. Interestingly, these rates were similar to typical anaphase rates suggesting that the same activities that drive anaphase elongation continue to drive hyper-elongation. Additionally, midzone lengths in Kip3 deletion strains with straight, buckled, and hyper-elongated spindles were unaltered compared to the midzone in control cells, demonstrating that excess microtubule polymerization at the midzone is coupled to spindle hyper-elongation. Taken together, our results reveal that, independent of a role in spindle disassembly, Kip3 plays a novel role to actively restrain inappropriate spindle elongation and maintain spindle integrity, likely through limiting microtubule polymerization at the midzone. Genetic suppressors provide insight into PP2A subunit interactions in *Caenorhabditis elegans.*

K. I. Lange[1], M. Srayko[2]; [1]Department of Biological Sciences, University of Alberta, Edmonton, AB, Canada

Phosphorylation plays an important role in regulating many mitotic events. We are studying a specific protein phosphatase 2A (PP2A) complex that regulates centrosome-based microtubule outgrowth during mitotic spindle assembly. In *C. elegans*, RSA-1 (regulator of spindle assembly) is a PP2A B'' regulatory subunit that is required for robust microtubule outgrowth from the centrosomes. RSA-1 protein locates to the centrosomes of *C. elegans* embryos, suggesting that this regulatory subunit plays an important role in centrosome-specific phosphatase activity. Embryos depleted of RSA-1 exhibit a severe reduction in microtubule outgrowth from centrosomes and a spindle-collapse phenotype whereby the centrosomes move toward the chromosome mass during spindle assembly[1]. However, the centrosomes in *rsa-1* mutants appear to have all major components and they are otherwise competent to support microtubule outgrowth[1]. In order to further characterize this complex, we performed a genetic screen for suppressors of a temperature sensitive allele of *rsa-1(or598ts)* [2]. Progeny from *or598ts/or598ts* adults exhibit 100% lethality at 26°C but only 20% lethality at 15°C, making this allele ideal for our suppressor screens. Using EMS, we have screened an estimated 150,000 mutagenized haploid genomes in three independent rounds of mutagenesis. Twenty-four candidate suppressors were isolated and 21 have since been identified. Currently all identified suppressors have been either intragenic or in *paa-1*, the structural subunit of the PP2A complex. These suppressors suggest that the *rsa-1(or598ts)* lesion disrupts the protein-protein interaction between RSA-1 and PAA-1. Yeast two-hybrid analysis has been used to confirm this hypothesis. Preliminary results suggest that the suppressor mutations in *paa-1* are capable of restoring the protein interaction with *rsa-1(or598ts)*. Immunofluorescence imaging of RSA complex components in the mutant and suppressed C. elegans embryos will be used to test this hypothesis. The remaining suppressors are currently being mapped and further characterized.

MCAK activity controls microtubule dynamics and directed cell migration.

K. A. Myers[1], C. M. Waterman[1]; [1]Cell Biology and Physiology Center, NHLBI/NIH, Bethesda, MD

Cell polarization during directed cell migration is coordinated by (MT) growth toward the leading edge. Cells can locally control MT growth or shortening through the regulation of depolymerizing kinesins (MCAK), which catalyze the destabilization of MT plus ends, causing MTs to transition from growth to shortening (catastrophe). However, it is not known if MCAK regulation affects polarized MT growth dynamics that mediate cell migration. We hypothesized that MCAK is locally inhibited to establish preferential MT growth toward the leading edge to promote directed migration. To test this hypothesis, we performed high resolution imaging of fluorescently tagged EB3 that dynamically associates with growing MT plus-ends, coupled with automated image-based tracking of MT growth speeds and growth lifetimes (1/catastrophe frequency). We found that knockdown of MCAK (MCAK-KD) promoted increased MT growth lifetimes globally, abolishing the polarized differences in MT growth lifetime in the cell center and edge seen in control cells. As a result, directional cell migration was significantly reduced, suggesting that local regulation of MCAK activity is critical for establishing polarized MT growth and directing cell migration. To determine how local regulation of MCAK might be achieved, we investigated the role of Aurora-A kinase, which when activated by phosphorylation localizes to mitotic centrosomes and behaves as a phospho-inhibitor of MCAK depolymerase activity. Phospho-Aurora-A immunoprecipitation from cell extracts revealed interaction between MCAK and the phospho-active form of Aurora-A. Live-cell measurements of MT growth dynamics showed that overexpression of Aurora-A promotes long-lived MT growth similar to MCAK-KD, suggesting that Aurora-A regulates the depolymerase activity of cytoplasmic MCAK. To identify upstream activators of Aurora-A, we expressed either constitutively active- (CA-Rac1) or dominant negative-Rac1 (DN-Rac1) and measured changes in active Aurora-A via immunolabeling with a phospho-specific Aurora-A antibody. Compared to control, cells expressing CA-Rac1 displayed a 4-fold increase of phospho-active Aurora-A, while in cells expressing DN-Rac1, phospho-active Aurora-A levels were decreased by 3-fold. In addition, live-cell imaging revealed that like GFP-MCAK, GFP-Aurora-A tracks with a subset of growing MT plus-ends in CA-Rac1 cells, but not in DN-Rac1 cells. Finally, while CA-Rac1 promoted fast and long-lived MT growth, this effect was lost by pharmacologic inhibition of Aurora-A. Together, these results suggest that Aurora-A-mediated regulation of MCAK depolymerase activity is achieved downstream of Rac1 signaling to elicit regional regulation of MT dynamics and thereby promote polarized MT growth and directional cell migration.

844

Microtubule Length Regulation by Depolymerizing Kinesins.

M. Gardner[1], M. Zanic[2], V. Bormuth[2], C. Gell[2], J. Howard[2]; [1]Genetics, Cell Biology, and Development, University of Minnesota, Minneapolis, MN, [2]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

Microtubules are dynamic filaments whose plus ends alternate between periods of slow growth and rapid shortening as they explore intracellular space and move intracellular organelles. A key question is how regulatory proteins such as the depolymerizing kinesins modulate catastrophe, the conversion from growth to shortening. To study this process, we reconstituted microtubule dynamics in the absence and presence of the kinesin-8 Kip3 and the kinesin-13 MCAK. Surprisingly, we found that even in the absence of the kinesins, the microtubule catastrophe frequency depends on the length and age of the microtubule, indicating that catastrophe is a multistep process. Kip3 slowed microtubule growth in a length-dependent manner and

increased the rate of catastrophe-inducing feature formation. In contrast, MCAK did not change the feature formation rate, but instead transformed catastrophe into a single step process. Thus, both kinesins are catastrophe factors, but influence microtubule length distribution in different ways: Kip3 mediates fine control of microtubule length by narrowing the distribution of maximum lengths prior to catastrophe, whereas MCAK promotes rapid restructuring of the microtubule cytoskeleton by making catastrophe a first-order random process.

845

Kinesin-13 targeting and functional specificity is governed by intrinsic factors and associated proteins.

J. P. Welburn[1], I. M. Cheeseman[1]; [1]Whitehead Institute for Biomedical Research, Cambridge, MA

Microtubule dynamics are essential throughout mitosis to ensure correct chromosome segregation. Microtubule depolymerization is controlled by microtubule depolymerases, including the kinesin-13 family of proteins. In humans, there are three closely related kinesin-13 isoforms that are highly conserved in their primary sequences. However, these enzymes display different localization and non-overlapping function. To understand the molecular basis for the observed differences, we conducted a comparative analysis of each isoform and we defined molecular components that determine the specificity of the kinesin-13 family members. Chimeric proteins containing the divergent N-termini of each member together with the catalytic core of another kinesin-13 indicate that the N-terminus is the primary determinant of cellular localization, and that the individual catalytic domains display different functional properties. We also identify three novel interacting partners for Kif2b that form subpopulations of Kif2b complexes in vivo. We show that these Kif2b-associated proteins display robust microtubule binding activity that is regulated by CDK activity. Thus, these associated proteins provide Kif2b complexes with a second microtubule binding site and thereby modify Kif2b functional properties. This represents a molecular paradigm for kinesin function, where it was previously thought that motors were the sole contributors to microtubule binding. Overall, we show that the kinesin-13 functional specificity and diversity in the cell originates from divergent protein domains and unique protein-protein interactions.

Control of neuronal differentiation by USP47-mediated stabilization of katanin p60.

Y. Jeon[1], S. Lee[1], S. Yang[1], E. Park[1], P. Bass[2], D. Park[1], C. Chung[1]; [1]School of Biological Sciences, Seoul National University, Seoul, Korea, [2]Department of Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA

Katanin p60 as a member of the AAA family of ATPases has a microtubule-stimulated ATPase and microtubule-severing activities in the absence of p80 subunit. Katanin p60 is essential for robust axonal growth of neurons and regulation of spindle pole during mitosis and meiosis. USP47 is a deubiquitinating enzyme that is conserved in Bilateria and predominantly expressed in neuronal tissues. Here we show that katanin p60 subunit is degraded by the ubiquitin-proteasome pathway. Conversely, USP47 specifically deubiquitinates katanin p60 and thereby stabilizes it. USP47 expression was detected in both axon and dendrite of hippocampal neurons in the early stage. In the late stage, USP47 was found to localize in the mature spines of neurons and partially colocalize with PSD-95. Moreover, overexpressioin of USP47 led to an increase in the number of dendrites and length of axon. Overexpression of katanin p60 showed a similar phenotype to that of USP47. These results suggest that the morphological changes in the neurites are regulated by USP47-mediated stabilization of katanin p60.

Testing a Novel Drug against the Beta-III Isotype of Tubulin.

R. F. Luduena[1], A. Banerjee[1], V. Prasad[1], J. Guo[1], J. Lee[1], C. Yeh[1]; [1]Department of Biochemistry, Univ. Tx Health Science Ctr at San Antonio, San Antonio, TX

Tubulin is the target of some of the most successful anti-tumor drugs, such as the taxanes and Vinca alkaloids. Tubulin is a heterodimer of α and β subunits, each of which consists of numerous isotypes differing in amino acid sequence and encoded by different genes. The taxanes and Vinca alkaloids appear to target the βII isotype. The logic of this is that βII occurs in many tumors and is relatively scarce in normal tissues, except in nerves and muscles. The latter aspect may play a role in the neurotoxicity associated with these drugs. We hypothesize that βIII would be a better target since it is associated with many aggressive and metastatic tumors and is less widely distributed in normal tissues than is βII. In nerves, βIII occurs only in neurons and we have shown that silencing βIII is much less deleterious to neurons than is silencing βII. Our results and those of others suggest that βIII may protect microtubules from free radicals. Using modeling, we designed and synthesized a novel colchicine derivative, CH-35, to bind better to βIII. Testing against cancer cell lines showed IC50's in the 3-4 nM range. We are now testing it in a mouse model of breast cancer and also in cultured breast cancer cell lines with different levels of βIII. In the former system we find that CH-35 is about equally effective as taxol in inhibiting growth of mouse mammary tumors. Our objective with cell lines is to measure the effect of βIII level on the sensitivity of the cell lines to CH-35. We also intend to test the effect of irofulven, an inhibitor of thioredoxin and thioredoxin reductase to see if it can synergize with CH-35. Inhibition of HDAC6, a Microtubule Deacetylase, Increases Microtubule Stability.

J. Asthana[1], R. Mohan[1], D. Panda[1]; [1]Wadhwani Research Centre, Department of Biosciences and Bioengineering, Indian Institute of Technology Bombay, Mumbai, India

In this study, we investigated the role of acetylation in regulating microtubule stability and dynamics by inhibiting the enzyme HDAC6, a known microtubule deacetylase. HDAC6 was inhibited using different strategies namely pharmacological inhibition by two small molecule inhibitors, tubastatin A and trichostatin A (TSA), and inhibition of HDAC6 gene expression using siRNA. We found that the inhibition of HDAC6 increased the acetylation level of microtubules in MCF-7 cells. Microtubules were found to resist nocodazole and cold-induced depolymerization in the presence of tubastatin A and TSA. Microtubules that resisted the destabilizing effects of nocodazole or cold-treatment were found to be predominantly acetylated. In TSA and tubastatin A treated cells, the proportion of detyrosinated tubulin increased indicating that the microtubules were stabilized in presence of these agents. Further, the effect of inhibition of HDAC6 on microtubule dynamics was determined using live cell imaging of microtubules in EGFP-tubulin transfected MCF-7 cells. Tubastatin A was found to suppress the dynamics of individual microtubules of MCF-7 cells. For example, the growth and shortening rates of microtubules were decreased by 25 and 32%, respectively in the presence of 15 μM tubastatin A. Microtubules spent 37 and 68% time in the pause state neither growing nor shortening detectably in the absence or the presence of tubastatin A, respectively. In addition, tubastatin A reduced the dynamicity (dimer exchange per unit time) of microtubules by 64%. Like tubastatin A, TSA also suppressed the dynamic instability of microtubules in MCF-7 cells. While the depletion of HDCA6 using siRNA did suppress the nocodazole induced depolymerization of microtubules, the extent of microtubule stabilization was not similar to that exhibited in the presence of TSA or tubastatin A suggesting that the presence of HDAC6 might partly stabilize

microtubules. The results together suggested a role of HDAC6 in microtubule dynamics and stability. (The work is supported by a grant from Department of Atomic Energy, Government of India).

Tubulin posttranslational modifications - how to approach them?

C. Janke[1], M. Bosch Grau[1], M. M. Magiera[1], J. Souphron[1], C. Rocha[1], S. Heurtebise[1], P. Marques[1]; [1]Institut Curie, Orsay, France

Posttranslational modifications of tubulin, such as polyglutamylation, polyglycylation, detyrosination and acetylation are known for many years now. These intriguing modifications, which take place on alpha- and/or beta-tubulin, are expected to regulate multiple functions of the microtubule cytoskeleton. Despite their potentially high impact on microtubule functions, only little insight into the roles of these modifications has been gained so far.
One of the reasons only few researchers have undertaken to study the role of tubulin posttranslational modifications is that only a limited number of tools and techniques are available, which are furthermore often cumbersome and difficult to access for outsiders of the field. Here we present an overview of tools and techniques to analyze tubulin modifications, and discuss recent advances frontiers in this research field.

850

Microtubule acetylation induced by chronic alcohol consumption impairs nuclear translocation of STAT5B, but not SMAD 2/3, in polarized hepatocytes.

D. J. Fernandez[1], D. J. Tuma[2], P. L. Tuma[1]; [1]The Catholic University of America, Washington, DC, [2]University of Nebraska Medical Center, Omaha, NE

Although alcoholic liver disease is clinically well-described, the molecular basis for alcohol-induced hepatotoxicity is not well understood. Previously we found that alcohol exposure led to increased microtubule acetylation and stability in polarized, hepatic WIF-B cells and in livers from ethanol-fed rats. Because increased microtubule acetylation is known to impair STAT5B nuclear translocation, we chose to explore a paradox regarding growth hormone signaling in alcohol-exposed hepatocytes. Although the circulating levels of growth hormone are increased in alcoholics and ethanol-fed animals, its hepatoprotective and hepatomitogenic responses are greatly reduced. Does alcohol-induced tubulin acetylation impair STAT5B nuclear translocation leading to impaired signaling? STAT5B and Jak2 (STAT5Bâ€™s activating kinase) protein levels did not change in ethanol-treated WIF-B cells or in livers from ethanol-fed rats indicating that decreased signaling cannot be simply explained by decreased protein amounts. Although STAT5B is partially cytosolic in control cells both biochemically and morphologically, increased cytosolic levels were observed in ethanol-treated cells with a reciprocal decrease in nuclear amounts. STAT5B nuclear levels also decreased to similar extents by addition of taxol (a microtubule stabilizing drug) or trichostatin A (TSA; a deacetylase inhibitor), agents that promote microtubule acetylation in the absence of alcohol. These results suggest that the alcohol-induced impairment of STAT5B nuclear translocation can be explained by increased microtubule acetylation. We also assayed nuclear translocation directly in control and treated cells after growth hormone addition. All three treatments impaired STAT5B nuclear translocation to similar extents both biochemically and morphologically indicating that microtubule hyperacetylation was responsible for the defect. Interestingly, only ethanol-treatment impaired STAT5B phosphorylation indicating that microtubule acetylation is not important for its activation by Jak2. Furthermore, nuclear exit and dephosphorylation were not changed by ethanol, taxol or TSA exposure indicating these processes are also independent of microtubule acetylation. Interestingly, the nuclear translocation of Smad2/3 (a transcription factor whose translocation is

prevented by intact microtubules), was not changed in ethanol-treated cells indicating different mechanisms regulate the microtubule-dependent distribution of these two classes of transcription factors. These results also raise the exciting possibility that agents that promote lysine deacetylation (e.g., resveratrol) may be effective therapeutics for the treatment of alcoholic liver disease.

851

Effects of Disruption of Tubulin Post-Translational Modification on Cell Polarity.

V. Singh[1], L. Ligon[1]; [1]Rensselaer Polytechnic Inst, Troy, NY

Microtubule post translational modifications are thought to provide directional cues to molecular motors for the delivery of cargoes to specific areas in cells. The precise delivery of cargoes is particularly important for the establishment and maintenance of epithelial cell polarity as different sets of proteins are needed in the apical and basal domains. Previously, we have shown that two post-translational modifications of tubulin, acetylation and detyrosination, define functionally different populations of microtubules in epithelial cells. We showed that there is a switch in the predominant form of tubulin modification from detyrosination to acetylation as cells become polarized, and that the two populations of modified microtubules are localized to distinct regions of MDCK cells at each stage of polarization. If these modified microtubules do provide the directional cues for polarized cargo traffic, then the establishment and maintenance of cell polarity may depend upon the integrity of the modified tubulin network. Here we have disrupted the balance between tubulin acetylation and detyrosination by altering the cellular levels of a tubulin acetyltransferase and a tubulin deacetylase and assessed the effects on cell polarity though immunofluorescence of the tight junction protein, ZO-1, as well as other apical markers.

852

Microtubules Modified by Different Tubulin Post-Translational Modifications Show Differential Stability.

P. Mattingly[1], G. Quinones[1], R. Persaud[1], V. Singh[1], L. Ligon[1]; [1]Rensselaer Polytechnic Inst, Troy, NY

Microtubules with tubulin post-translational modifications have long been correlated with the population of stable microtubules that does not undergo dynamic instability, but the precise relationship between tubulin modifications and microtubule stability has remained a mystery. Previously we have shown that in epithelial cells, there are multiple subpopulations of microtubules, some of which are acetylated only, some of which are detyrosinated only, some of which appear to only have polyglutamylation, and some with combinations of each of these modifications. We went on to show that these subpopulations were differentially localized in cells. Here we show that these microtubule subpopulations show differential sensitivities to both nocodozole-induced depolymerization and cold-induced depolymerization, and further that the sensitivities to nocodozole and cold differ from one another. We also separate the soluble tubulin pool from the polymer tubulin pool after both nocodozole and cold depolymerization and show that the reversal rates of different tubulin post-translational modifications is different. Tubulin re-tyrosination is relative rapid in these cells, but de-acetylation and de-glutamylation are slow. In addition, these results suggest that there may be significant soluble pools of tubulin dimers with these modifications. Together, these data suggest that there are multiple subpopulations of microtubules that differ in their subunit composition, their localization within the cell and their dynamic characteristics. This complexity may provide specificity for subcellular localization of microtubule-based activities, such as trafficking by molecular motors.

853

A TOG:αβ-tubulin complex structure reveals conformation-based mechanisms for a microtubule polymerase.

P. Armutlu[1], P. Huddleston[1], L. Rice[1]; [1]Biochemistry, UT Southwestern Medical Center at Dallas, Dallas, TX

Microtubules are highly regulated, dynamic polymers of αβ-tubulin that have essential roles in intracellular organization and chromosome segregation. Proteins in the evolutionarily conserved Stu2p/XMAP215/Dis1 family are the major regulatory factors that promote fast microtubule growth in vivo. These proteins use multiple tubulin-interacting TOG domains to bind unpolymerized αβ-tubulin and to selectively recognize one end of the microtubule, where they catalyze microtubule elongation. The molecular details of TOG domain function remain poorly understood, in part because the structural basis of TOG:tubulin interations has not yet been defined. Here we report the 2.9 Å resolution structure of a complex between the TOG1 domain from Stu2p and a polymerization-blocked mutant of yeast αβ-tubulin that we developed to facilitate crystallization. The structure reveals that the TOG1 domain makes significant contacts with both α- and β-tubulin, and that the conformation of GTP-bound αβ-tubulin resembles a 'curved', microtubule-incompatible conformation observed previously in the structure of αβ-tubulin bound to a stathmin-like protein. The TOG1-interacting epitopes on α- and β-tubulin revealed by the structure do not overlap αβ-tubulin polymerization interfaces, and biochemical experiments demonstrate that TOG1 discriminates between αβ-tubulin conformations, binding preferentially to a curved one. We propose a conformation-based hand-off mechanism that explains how Stu2p family proteins can bind tightly to unpolymerized ab-tubulin and still promote their incorporation into the microtubule.

Cilia and Flagella II

854

Regulation of intraflagellar transport by the MAP kinases MAK, MRK, and MOK.

J. R. Broekhuis[1], G. Jansen[2]; [1]Dept. of Cell Biology, ErasmusMC, Rotterdam, Netherlands

Cilia are microtubule-based organelles that can be found on the surface of almost all vertebrate cells. They were first noted for their function in motility, however were soon found to have a sensory function as well. Cilia are assembled and maintained by intraflagellar transport (IFT), which uses IFT particles to move cargo bi-directionally along the axoneme of the cilium. Regulation of IFT does not only allow modulation of cilia length, but also influences the different signaling pathways that initiate in the cilium.

We recently identified and characterized the *C. elegans* gene *dyf-5*. The *dyf-5* gene encodes a conserved MAP kinase. Loss of function and overexpression studies showed that DYF-5 affects IFT, and negatively regulates ciliary length. DYF-5 has three mammalian homologues: MAK (male germ cell-associated kinase), MRK (MAK-related kinase) and MOK (MAPK/MAK/MRK overlapping kinase). In this study, we aim to determine if MAK, MRK and MOK have similar functions as *C. elegans'* DYF-5.

We have generated GFP fusion constructs for MAK, MRK and MOK to determine their subcellular localization. All three *dyf-5* homologues localize along the microtubule axis of the cilium of IMCD3 (inner medullary collecting duct) and RPE (retinal pigment epithelium) cells, and show accumulation at the distal tip. Knockdown of MRK in IMCD3 cells, which express MRK and MOK, results in longer cilia. In RPE cells, which express all three *dyf-5* homologues, the knockdown of MOK also results in longer cilia. Overexpression of MAK and MRK in IMCD3

cells results in short and stumpy cilia. Interestingly, overexpression of MOK does not affect cilia length in IMCD3 cells. These effects on cilia length are in line with our data from *dyf-5* loss of function and overexpression worms.
We have generated IMCD3 cell lines that stably express GFP-fusion constructs of different components of the IFT complex: Kinesin-II (mCit-Kif3b), Kif17 (Kif17-mCit), complex A (IFT43-YFP), complex B (IFT20-GFP), and the BBSome (GFP-BBS8). This allows us to visualize the IFT particles, and measure their velocity. Preliminary experiments show an average anterograde speed of ~0,3 μm/s and a retrograde speed of ~0,4 μm/s for these GFP fusion proteins. We are currently performing knockdown experiments of the dyf-5 homologues in these stable cell lines to see whether they also affect IFT rates in mammalian cells.

855

Temporary dikaryons in Chlamydomonas reveal that transport of I1 dynein in the cilium requires the intermediate chain subunit IC140 and Ida3p.

R. Viswanadha[1], L. Fox[1], R. Yamamoto[1], W. Sale[1], M. Wirschell[1]; [1]Cell Biology, Emory University, Atlanta, GA

To determine mechanisms of assembly and transport for ciliary dynein motors, we focused on the Chlamydomonas inner dynein arm, I1, as a model. Fractionation of cytoplasmic extracts from wild type (WT) cells revealed that I1 dynein forms a 20S complex in the cytoplasm prior to entry to the ciliary compartment. Analysis of cytoplasmic extracts from ida7 (IC140-null) reveals that the intermediate chain subunit IC140 is required for assembly of the 20S I1 complex. In another mutant that fails to assemble I1 dynein in the axoneme, ida3, the 20S I1 dynein complex assembles in the cytoplasm as in WT but fails to enter the cilium. We used cytoplasmic complementation in dikaryons to test the hypothesis that I1 dynein is transported to the tip of the cilium for assembly in the axonemes (Johnson and Rosenbaum, JCB 1992). In dikaryons formed between WT and I1 dynein mutants (or between ida1 x ida7 or ida1 x ida3), rescue of I1 assembly began at the distal tip of the mutant cilium and proceeded from tip to base. Thus, I1 dynein complexes are transported, possibly by IFT, to the distal end of the cilium prior to assembly in the axoneme. However, in contrast to other dikaryon combinations, I1 dynein assembly was significantly delayed in dikaryons between the ida7 (IC140-null) and ida3 (predicted to be defective in Ida3p). We postulate that IC140 / Ida3p form an obligate complex and new protein synthesis is required for rescue of I1 dynein assembly in axonemes from ida3 x ida7 dikaryons. Consistent with this hypothesis, cyclohexamide completely blocked rescue of I1 dynein assembly in ida7 x ida3 dikaryons. Cyclohexamide did not block rescue of I1 dynein assembly in any other combination of WT or I1 dynein mutants. We conclude that: [1] assembly of the 20S I1 dynein complex in the cytoplasm requires IC140; [2] I1 dynein is transported to the tip of the cilium prior to assembly in the axoneme; and [3] transport is dependent on a complex between IC140 and Ida3p. We postulate that IDA3 encodes a novel adapter protein, Ida3p, which links I1 dynein to the IFT machinery for transport in the cilium.

856

Genetic analysis of individual IFT proteins in the transport of Hedgehog signaling components.

Y. Liang[1], B. T. Keady[2], G. J. Pazour[2]; [1]Program in Molecular Medicine, University of Massachusetts Medical School, Worcester, MA

Primary cilia extend from the apical surface of most vertebrate cells and function in a sensory manner to translate extracellular cues into intracellular responses. The IFT particle is a highly conserved multiprotein complex required for assembling primary cilia. Mutations in IFT proteins impair Hedgehog signaling due to either defective assembly of cilia or defective transport of

signaling components. However, the underlying contributions of individual IFT proteins to these processes remain obscure. We are using a cell culture system of immortalized cell lines derived from IFT mutant mice to decipher the molecular mechanisms that make individual IFT proteins indispensable for Hedgehog signaling. Ift20 mutant cells completely lack cilia, Ift140 mutant cells assemble short structurally abnormal cilia and Ift25 mutant cells assemble normal cilia that are defective for Hedgehog signaling. We are using these cells to test the ability of deletion and point mutants to rescue important phenotypes such as IFT particle integrity, cilia assembly, and ciliary trafficking of Hedgehog components.

857

IFT46, IFT52, and IFT88 play different roles in IFT Complex B assembly, stability, and apical basal body localization in Chlamydomonas reinhardtii.

E. Richey[1], H. Qin[2]; [1]Biology, Texas A&M University, Lola, TX

Cells form cilia, hair-like appendages projecting from the cell membrane, in a process known as ciliogenesis. The key mechanism for ciliogenesis and maintenance of cilia is called intraflagellar transport (IFT). The main components necessary for effective IFT are Complexes A and B, anterograde motor kinesin-II, and retrograde motor IFT-dynein, although other proteins are involved. Direct protein-protein interaction analysis has shown that the core of Complex B is divided into three main subcomplexes: IFTs 52, 88, 46, and 70; IFTs 74, 81, and 72; and IFTs 27 and 25. By analyzing complex B mutants, in this study, we investigate the different roles of IFT46, IFT52, and IFT88 in IFT Complex B assembly and stability in Chlamydomonas reinhardtii. Our results show that a cell lacking IFT52 is not able to form Complex B, and this is most likely the reason why flagella do not form in bld1, an IFT52 null mutant. Cells without IFT88 also do not form flagella, even though this mutant allows the formation of a smaller Complex B. The reason for the lack of flagella in ift88 null mutants may be due to the fact that IFT88 is important for allowing proper localization of the IFT particles to the base of the flagella. Unlike bld1 and ift88, ift46 null mutants form short flagella perhaps because they still form an operable Complex B. The reason the cilia are so short and there are less IFT particles in ift46 mutants, is probably due to the importance of IFT46 in the stability of Complex B. These results clearly show that IFT46, IFT52 and IFT88, three subunits within the same subcomplex B, have distinct roles in complex B assembly, stability and apical basal body localization. This research is supported by the National Science Foundation.

The RABL5 homolog IFT22 regulates the cellular pool size and the amount of IFT particles partitioned to the flagellar compartment in Chlamydomonas reinhardtii.

D. Silva[1], X. Huan[1], R. Behal[2], D. Cole[2], H. Qin[1]; [1]Biology, Texas A&M University - College Station, College Station, TX, [2]Biological Sciences, University of Idaho

Cilia and flagella, sensory and motile structures protruding from the cell body, rely on the continuous bidirectional traffic of intraflagellar transport (IFT) particles to ferry flagellar precursors into flagella for assembly. Cells synthesize a large pool of IFT particle proteins in the cell body, but only a small portion engages in active transport within the flagella at any given time. The atypical small G protein Rab-like 5 (RABL5) has been shown to move in an IFT-like manner in the flagella, but its function in ciliogenesis is controversial. In this report, we demonstrate that IFT22, the Chlamydomonas reinhardtii homolog of RABL5, is a bona fide IFT particle complex B subunit. Although the amount of IFT22 remains unaffected by depletion of either complex A or B, depletion of IFT22 leads to a smaller pool of both complex A and B. Strikingly, the smaller cellular pool of IFT particles does not lead to a reduced distribution of IFT particles to flagella. Instead, the amount of IFT particle proteins, including IFT22 itself, increase

in the flagella. Moreover, severely shortened flagella filled with IFT particles are observed in cells over-expressing IFT22 several-fold. Taken together, these data indicate that, in C. reinhardtii, IFT22 controls the cellular levels of both complex A and B, thus plays a critical role in determining the cellular availability of IFT particles. In addition, although IFT22 may not directly carry any precursors for flagellar assembly, it controls how many IFT particles out of the cellular pool participate in ferrying precursors into flagella.

Control of IntraFlagellar Transport dynamics by the Planar Cell Polarity effector Fuzzy.

E. Brooks[1], J. Wallingford[2]; [1]University of Texas at Austin, Austin, TX, [2]University of Texas at Austin and the Howard Hughes Medical Institute

Multi-ciliated cells are critical for development and homeostasis in many vertebrate organs, and Planar Cell Polarity (PCP) proteins have recently emerged as key regulators of multi-ciliated cell function, governing both ciliogenesis and the generation of polarized ciliary beating. However, it remains unclear how PCP is connected to the core cellular machinery underlying the formation and maintenance of cilia, the IntraFlagellar Transport pathway (IFT). We have developed an in vivo method for reliably imaging the dynamics of IFT within the multi-ciliated cells of the *Xenopus* embryonic muco-cilliary epidermis using high-speed confocal microscopy. Utilizing this method, we have characterized the dynamics of IFT within the axonemes of these cells and have found that IFT proceeds at rates comparable to those reported in studies of other ciliated cell types. Specifically, we find that IFT proceeds at a rate of 0.84 μm/sec in the anterograde direction and 0.87 μm/sec in the retrograde configuration. We also note that these rates have a wide distribution, with rates varying from 0.3 μm/sec to 1.4 μm/sec, likely reflecting differences in train composition or the molar ratio of attached motor proteins. In addition to our rate quantitation, we have qualitatively observed behaviors at the level of single IFT trains, including release and return of trains from the peri-basal body pool, as well as pausing of trains before they reach the distal tip of the axoneme. Excitingly, we found that the PCP effector Fuzzy (Fuz) is important for proper axonemal IFT function. When Fuz function is impaired, IFT trains accumulate along the length of the axoneme in large, extremely static foci, indicating that Fuz is a critical regulator of vertebrate IFT dynamics. Additionally, we have shown that loss of Fuz function leads to strong defects in patterning the distal--but not proximal--domain of multi-ciliated cell axonemes, supporting a role for Fuz in the regulation of axonemal IFT. This work presents the first detailed analysis of IFT behaviors in a multi-ciliated cell population, and provide the basis for a more thorough analysis of in vivo IFT behavior at the resolution of single trains. Our findings also argue that Fuz is an important regulator of vertebrate IFT, providing a key link between PCP signaling and the conserved machinery of ciliogenesis.

A Source and Sink Model for IFT Cargo Transport and Unloading.

K. Lechtreck[1], G. Witman[1]; [1]Department of Cell Biology, University of Massachusetts Medical School, Worcester, MA, Worcester, MA

The assembly of eukaryotic cilia and flagella requires intraflagellar transport (IFT) to move ciliary precursors (cargo) from their place of synthesis in the cell body (source) to the sites of assembly in the cilium (sink). To investigate how defects in the sink affect IFT, we analyzed three *Chlamydomonas* mutants having large-scale defects in the axoneme: *pf15*, defective in katanin p80 and lacking the central pair apparatus; *pf14*, defective in radial spoke protein RSP3 and lacking radial spokes; and *oda1*, defective in the dynein docking complex component DC2 and lacking outer dynein arms. We observed that IFT complex A- and B-particle proteins and anterograde and retrograde IFT-motor components are highly enriched in the flagella of all three

mutants compared to wild type. Further, a much larger proportion of the IFT proteins in the mutant flagella is less mobile and less soluble by detergent extraction. In *pf14* and *pf15*, the insoluble IFT material has accumulated in the space normally occupied by the radial spokes or central pair, respectively. Concomitant with accumulation of IFT particles, there is an accumulation of unassembled IFT cargos, including those that are not components of the defective structure. Based on these observations, we propose the following model for IFT cargo transport: In the cell body, free IFT particles and cargos are in an equilibrium with IFT particle-cargo complexes. The latter, however, can enter the flagellum, removing IFT particle-cargo complexes from the equilibrium and ensuring efficient loading. Within the flagellum, IFT particle-cargo complexes dissociate and reassociate, reestablishing the equilibrium. At the tip of wild-type flagella, free cargos are removed by binding to appropriate high-affinity sink structures, and free IFT particles are removed by activation of the retrograde motor and export from the flagellum. However, in the mutant flagella, the absence of an appropriate cargo sink causes the equilibrium to shift toward IFT particle-cargo complexes, which are not efficiently removed from the flagellum. The resulting increase in IFT particles also affects the equilibrium between IFT particles and cargos that are not part of the missing structure, so that these cargos also accumulate. While other factors may control details of this process, the described principle could be the driving force for IFT cargo delivery and flagellar assembly. The model could explain previously enigmatic features of the mutants, including their slower flagellar regeneration kinetics and shorter flagella.

861

Phospholipase D Requires the BBSome and Retrograde IFT for Export from *Chlamydomonas* Flagella.

K. Lechtreck[1], J. Sampaio[2], G. Witman[1]; [1]U. Mass. Med. School, Worcester, MA, Worcester, MA, [2]MPI-CBG, Dresden, Germany, Dresden, Germany

Bardet-Biedl syndrome is a rare ciliopathy caused by defects in the BBSome. This conserved seven-subunit protein complex is required to maintain proper composition of the ciliary membrane; how the BBSome regulates ciliary membrane composition is unknown. The flagella of *Chlamydomonas bbs* mutants accumulate certain membrane-associated proteins. For example, phospholipase D (PLD) is accumulated ~150x compared to wild-type flagella, which contain only traces of PLD. PLD is abundant in wild-type cell bodies and reduced by about 50% in *bbs4* mutant cell bodies. These observations suggest that the BBSome efficiently prevents PLD accumulation in flagella. Lipidomic analysis of *bbs* mutant flagella revealed large changes in flagellar membrane lipid composition; these changes included a 30% decrease in the PLD substrate phosphatidylethanolamine and 50% and 4000% increases in the PLD products phosphatidic acid and ethanolamine respectively, and a 500% increase in the downstream product diacylglycerol. Therefore, PLD is active in mutant flagella and its presence there is likely to contribute to the non-phototactic phenotype characteristic of *Chlamydomonas bbs* mutants. To learn more about the role of the BBSome, we determined the kinetics of PLD accumulation in *bbs4* mutant flagella. Only small amounts of PLD are present in newly assembled mutant flagella; PLD accumulates over the course of several hours as the flagella age. We also observed that some flagellar proteins, e.g. carbonic anhydrase, were initially present in *bbs4* flagella at near wild-type levels but were lost over time, suggesting that their loss is a secondary effect. The continuous accumulation of PLD implicates the BBSome in either PLD flagellar entry control or PLD flagellar export. To distinguish between these possibilities, wild-type BBSomes were introduced into *bbs* mutant flagella by mating *bbs4-1* gametes with wild-type gametes to generate cells possessing 4 flagella, 2 of which originated from wild type and two from the mutant, in a common cytoplasm. PLD was removed from the mutant flagella within minutes after cell fusion. This rapid removal suggests an efficient BBSome-dependent flagellar export

mechanism for PLD. PLD also accumulates in flagella of *Chlamydomonas dhc1b*-ts, a hypomorphic mutant for the retrograde IFT motor dynein1b. This strain has elevated levels of flagellar BBS4/BBSomes, indicating that BBSome transport by retrograde IFT is required for PLD flagellar export. Our data show that BBSome-dependent ciliary protein export is important for maintaining a proper ciliary membrane.

862

IFT and precursor pool regeneration in long and short flagella mutants of Chlamydomonas reinhardtii.

K. Wemmer[1], W. Ludington[1], E. Kannegaard[1], H. Rego[2,3], W. F. Marshall[4]; [1]UCSF, [2]Physiology Course, Marine Biological Laboratory, [3]Janelia Farm, Howard Hughes Medical Institute, [4]Department of Biochemistry and Biophysics, Univ California-San Francisco, San Francisco, CA

The flagella of Chlamydomonas provide an excellent model system in which to investigate the basic question of organelle size control. The powerful genetics of this organism have allowed a number of mutations to be identified in which flagellar length is increased or decreased, but while many of these genes have been cloned, the mechanisms by which they alter length remain to be determined. Here, we investigate the long and short flagella mutants of Chlamydomonas using quantitative assays. We find that the four existing long flagella mutants (lf1 - lf4), all show increased levels of intraflagellar transport as judged by live cell TIRF microscopy. We hypothesize that these mutants have long flagella because of increased intraflagellar transport, which would support a key role for IFT in length control. We also have analyzed a set of short flagella (shf) mutants, and found that mutations in the PF15 gene, which encodes the p80 subunit of katanin, appear to have short flagella due to a defect in induction of the flagellar precursor pool. Although we do not know precisely why pool regeneration is defective, we suggest it could reflect a competition between cytoplasmic and flagellar microtubules for a common pool of tubulin, such that decreased microtubule severing in the cytoplasm leads to increased sequestration of newly synthesized tubulin, forcing shorter flagella to grow.

863

A role for the Rab-interacting lysosomal protein family in cilia function.

J. R. Schaub[1], T. Stearns[2,3]; [1]Cancer Biology Program, Stanford University School of Medicine, Stanford, CA, [2]Department of Biology, Stanford University, [3]Cancer Biology Program, Stanford University School of Medicine

Many cell types in the mammalian body have a single non-motile primary cilium, a microtubule-based sensory organelle. Disruption of cilium form or function is the cause of a diverse set of human diseases collectively known as ciliopathies. Other specialized mammalian cell types have multiple motile cilia. Though these types of cilia are distinct, they share several structural and functional features. Most importantly, each cilium is nucleated by a centriole, the microtubule structure at the heart of the centrosome. To identify genes that are important for cilium structure and function we determined the transcriptional profile of ciliogenesis in cultured mouse tracheal epithelial cells (MTECs), which form hundreds of motile cilia per cell. One gene that is significantly upregulated during ciliogenesis is Rab-interacting lysosomal protein like 2 (Rilpl2). Rilpl2 is a member of a family of proteins that share two unique domains of sequence similarity. The founding family member, Rilp, is a Rab7/Rab34/Rab36 effector involved in vesicle trafficking to the lysosome. The only known role for Rilpl2 is an interaction with MyoVa that affects dendritic spine formation in neurons. There is no known function for the remaining family member Rilpl1. We show that Rilpl1 localizes to the mother centriole and both Rilpl1 and Rilpl2 localize to the primary cilium in fibroblast and epithelial cell lines. The C-terminal domains

of Rilpl1 and Rilpl2 are sufficient for centriolar and ciliary localization. In addition, the C-terminal domain of Rilpl2 can block ciliogenesis. Depletion of Rilpl1 or Rilpl2 alone or in combination does not affect ciliogenesis, but does prevent proper epithelial cell organization in three-dimensional culture, suggesting a disruption of cilium-dependent signaling. Our biochemical studies show that Rilpl2 self-interacts and we are currently assessing potential interactors. In summary, Rilpl2 was initially identified in our motile cilium formation model and has now been localized to the primary cilium along with its related protein Rilpl1. These data along with Rilpl2's role in neurons and the function of the related protein Rilp, suggest that Rilp-like proteins may be involved in trafficking or cytoskeletal rearrangements required for cilia function.

864

IFT20 is a common component in macroautophagy and cilia formation.

O. Pampliega[1], P. Satir[2], A. M. Cuervo[1], B. H. Satir[2]; [1]Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, [2]Department of Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Mouse embryo fibroblasts (MEFs) in culture grow primary cilia upon serum starvation for 6-48 h. Macroautophagy (MA), a process that mediates degradation of cellular components in lysosomes through the formation of autophagic vacuoles (AV), is also activated in most cells by starvation at the time of ciliogenesis. We hypothesized that ciliary growth and MA are interrelated, sharing certain common components. One such component might be IFT20, a protein that shuttles between the Golgi apparatus and ciliary IFT particles (Follit et al., MBC, 2006). When IFT20 is knocked down MEF clones do not grow cilia. Similarly formation and clearance of AVs is reduced in IFT20 KD MEFs. These results suggest that interfering with MA will increase IFT20 available for ciliogenesis. To test this, MEFS defective in Atg5, an essential component of MA, are used. In the presence of serum, ciliary growth is minimal in wt MEFS. However, Atg5 KO MEFS have increased cilia formation and changes in the intracellular distribution of IFT20. Upon starvation, the reduction in IFT20 levels observed in wt cells is markedly attenuated in Atg5 KO cells and the % of ciliated cells is greatly increased. We conclude that IFT20 is a common component in ciliogenesis and MA.

Ift88 Orchestrates Cell Polarization During Development And Repair Of The Corneal Endothelium.

C. Iomini[1,2], L. Gusella[3], J. Danias[4], M. Mlodzik[1,2]; [1]Ophthalmology, Mount Sinai School of Medicine, New York, NY, [2]Developmental and Regenerative Biology, Mount Sinai School of Medicine, New York, NY, [3]Medicine, Mount Sinai School of Medicine, New York, NY, [4]Cell Biology, SUNY Downstate Medical Center

Directed cell migration generally requires polarization of cellular organelles such as the basal body (bb) and the Golgi apparatus. Very little is known, however, about how extracellular cues instruct intracellular polarity. Corneal endothelial cells (CEC) migrate or stretch with a precise directionality during development and repair of the corneal endothelium (CE), the cellular monolayer of the cornea facing the anterior chamber of the vertebrate eye. Our recent studies have shown that primary cilia are required for CE patterning and assemble during development and repair of CE but disassemble during normal adult CE steady state (1). Here we utilize the in vivo paradigm offered by the mouse CE to test the hypothesis that cilia are required for cell polarization during directed cell migration.

To assess cell polarization during postnatal development of the CE we have determined the position of the bb and IFT20 within CEC located at the center and periphery of the cornea. IFT20 is a component of the intraflagellar transport machinery required for assembly and

maintenance of cilia that not only localizes at the bb and cilia like all the IFTs but also at the Golgi. In central CEC of wild-type mice the majority of the bb and the IFT20 were localized near the cell center. In contrast, the bb and IFT20 were shifted toward the periphery in CEC located at the CE periphery. Strikingly, the position of the bb and distribution of IFT20 in peripheral CEC was random in orpk mice that carry a mutation in the IFT88 gene and show short cilia and defective CE patterning. A similar cell polarization was also found in CEC involved in in vivo wound healing of a mechanical injury. After 30h healing cytoplasmic IFT20 also polarized toward the leading edge of cells close to the wound whereas in intact CE, IFT20 localized perinuclearly and at the bb. We have found that the cilium instructs cell polarization of CEC involved in directed cell migration during development. We are currently using a conditional mutant for IFT88 to determine whether cellular polarization during repair also requires an intact cilium.

An IFT74 truncation alters the balance of complexes A and B in flagella and leads to increased numbers of central microtubules.

J. M. Brown[1], D. A. Cochran[1], G. B. Witman[1]; [1]Univ Massachusetts Med Sch, Worcester, MA

Intraflagellar transport (IFT), originally discovered as a bidirectional movement of large protein particles within *Chlamydomonas reinhardtii* flagella, is required for ciliary assembly in numerous organisms. IFT particles contain ~20 different proteins and are separable into two complexes known as complex A and complex B. Despite recent progress on involvement of IFT in specific signaling pathways, identification of some IFT cargoes, and elucidation of protein-protein interactions within complexes A and B, detailed information on the functions of individual IFT proteins is still largely lacking. In our ongoing screen for *Chlamydomonas* mutants defective in ciliary assembly and function, we have isolated an insertional mutant with a disruption in exon two of the gene encoding the complex B protein IFT74. Western blotting and sequencing of *ift74* cDNA indicated that this mutant expresses a truncated IFT74 protein missing the N-terminal 196 amino acids. Importantly, this mutant assembles flagella of ~40% wildtype (WT) length, allowing a more detailed analysis of the resulting flagella than is possible with complex B mutants lacking flagella. IFT particles visible by high-resolution DIC microscopy are dramatically decreased in frequency in the mutant flagella compared with WT. Sucrose density gradient centrifugation of flagellar membrane-plus-matrix showed that the truncated IFT74 protein enters flagella as part of a complex B with altered mobility in the gradient. Moreover, the molar ratio of complex A to complex B is reduced in mutant flagella, suggesting a requirement for the N-terminus of IFT74 for normal association of complexes A and B and transport of complex A into flagella. Transmission electron microscopy indicated that *ift74* cells are missing the wedge-shaped microtubule-membrane connectors visible in longitudinal sections of WT transition zones. Since a number of other *Chlamydomonas* flagellar assembly mutants also lack these structures, this may be a secondary effect of having partially assembled flagella. In addition, ~25% of *ift74* axonemes have increased numbers of central pair microtubules, with most of these having a 9+3 or 9+4 structure. Extra central pair microtubules are occasionally observed in some radial spoke mutants; however, radial spoke head proteins RSP1 and RSP10 are present at normal levels in the *ift74* flagella. Several reproducible protein differences between mutant and WT flagella visible on SDS-PAGE gels may hold clues to the mechanisms behind the imbalance between complexes A and B and the increase in central pair microtubules. We are currently analyzing these differences.

867

Chlamydomonas IFT20 is essential for flagellar assembly but dispensable for IFT subcomplex assembly.

B. Craige[1], D. Cochran[2], Y. Hou[2], M. J. Chapman[2], J. Follit[3], K. Lechtreck[4], S. Takada[5], G. Pazour[3], G. B. Witman[2]; [1]Cell Biology, University of Massachusetts Medical School, Worcester, MA, [2]Cell Biology, University of Massachusetts Medical School, [3]Program in Molecular Medicine, University of Massachusetts Medical School, [4]Cellular Biology, University of Georgia, [5]Biochemistry, Molecular Biology and Biophysics, University of Minnesota

Intraflagellar transport (IFT), the bidirectional movement of particles along the length of flagella and cilia, is required for the assembly and maintenance of these organelles. IFT particles are sub-divided into complex A and complex B. The protein IFT20 is part of complex B, and in mammalian cells IFT20 localizes to basal bodies, cilia, and the Golgi apparatus. To learn more about the function of IFT20, we are studying a *Chlamydomonas* insertional mutant that contains a complete deletion of the *IFT20* gene. The *ift20* null cells mostly lack flagella; constructs encoding wild-type, HA-, and GFP-tagged IFT20 rescue the mutant phenotype. The tagged proteins co-localize and co-immunoprecipitate with other IFT complex B proteins, but do not display Golgi localization, a pattern confirmed in wild-type cells using antibodies to endogenous IFT20. Consistent with this, *Chlamydomonas* lacks a homologue of GMAP210, which is required to localize IFT20 to the Golgi in mammalian cells. In contrast to deletions in all other IFT genes we have analyzed, loss of IFT20 does not affect the whole cell levels of other IFT proteins; we also found that IFT subcomplexes assemble normally in the cytoplasm in the absence of IFT20. This is consistent with IFT20 being peripherally associated with complex B (Lucker et al, 2005, J. Biol.Chem. 280:27688). Another study demonstrated that IFT20 binds to kinesin II (Baker et al., 2003, J. Biol.Chem. 278:34211), which functions in the anterograde movement of IFT particles. Together with our observation that IFT20 is dispensable for IFT particle subcomplex assembly, we hypothesized that IFT20 is an essential linker that bridges the IFT particle with the kinesin motor. To test this, we treated living cells with DSP, a membrane-permeable protein cross-linker that is cleaved in the presence of reducing agents, and then immunoprecipitated the cross-linked IFT complexes and analyzed their content by SDS-PAGE. Treatment of wild-type or rescued cell lines resulted in cross-linking of kinesin to IFT particles; this association was lost in *ift20* mutant cells. In addition, complex B was cross-linked to complex A in wild-type cells; this association was also not observed in *ift20* mutant cells. We are now testing two models that could explain these results: a) IFT20 interacts directly with both kinesin II and complex A, or b) complex B must first bind to either complex A or kinesin before binding the other, and one of these interactions is dependent on IFT20.

868

RIIa and Dpy-30 domains dock discrete effectors to two amphipathic helices in a flagellar AKAP.

P. Sivadas[1], K. Ciruelas[1], P. Yang[2]; [1]Biological Sciences, Marquette University, Milwaukee, WI

A-kinase anchoring proteins (AKAPs) contain an amphipathic helix (AH) that anchors the dimerization and docking (D/D) domain, RIIa, in cAMP-dependent protein kinase (PKA). This localization mechanism for PKA has been exploited to discover many proteins with a RIIa-binding AH. Yet the D/D domain has broader applications, since RIIa and a similar Dpy-30 domain are adjacent to disparate molecular modules in proteins implicated in unrelated processes, like flagellar beating, membrane trafficking and epigenetic regulation. These molecules with a putative D/D domain and their anchoring proteins remain poorly characterized. We found that a dimeric AKAP, RSP3, in the flagellar radial spoke form a structural scaffold extending throughout the RS. It harbors two discrete AHs for anchoring RIIa and Dpy-30

domains in four spoke proteins that mediate the assembly and modulation of the complex. Interestingly, one AH can bind both types of D/D domains in vitro. In the same vein, Dpy-30 domain in Set1-like histone methyltransferase complex also interacts with a sequence containing a similar AH. Thus AHs and D/D domains constitute a versatile and promiscuous system for localizing various effector mechanisms. These results greatly expand the current concept about anchoring mechanisms and AKAPs.

869

The vertebrate DYF-13 homologue undergoes IFT and is required for cilia formation and maintenance.

H. Ishikawa[1], W. Marshall[2]; [1]University of California, San Francisco, San Francisco, CA

Primary cilia are hair-like organelles that protrude from the surface of most cells in our body and are composed of nine parallel microtubule doublets surrounded by an extension of the plasma membrane. Recent studies have shown that the primary cilium acts as a sensory organelle to detect a wide variety of extracellular signals. Ciliary defects have been implicated in a diverse spectrum of diseases including retinal degeneration, polycystic kidney disease, left-right asymmetry defects and hydrocephalus. Primary cilia are assembled and maintained by the process of intraflagellar transport (IFT), a highly conserved mechanism in almost all eukaryotes. We analyzed the ciliary protein TTC26, which is the vertebrate homologue of *C. elegans* DYF-13. Mutants of *dyf-13* cause a dye-filling defect in *C. elegans* sensory neurons. GFP-labeled TTC26 localizes to the basal bodies and primary cilia of cultured mammalian cells. In addition, TTC26-GFP undergoes bidirectional movement in primary cilia. Moreover, tandem affinity purification analysis indicates that TTC26 makes a complex with other IFT proteins. Knockdown of TTC26 in zebrafish embryos produces short cilia within the Kupffer's vesicle and pronephric ducts and produces typical cilia-related defects including pronephric cysts, hydrocephalus, and the randomization of left-right asymmetry. We hypothesize that TTC26 is an IFT protein that is required for cilia formation and maintenance.

870

Dual-colour live imaging in amphid channel cilia of *Caenorhabditis elegans* to study intraflagellar transport.

A. van der Vaart[1], S. Rademakers[1], G. Jansen[1]; [1]Department of Cell Biology, Erasmus Medical Center, Rotterdam, The Netherlands, Rotterdam, Netherlands

Primary cilia are conserved extensions that protrude from most post-mitotic vertebrate cells and they play important roles in sensory processes. Intraflagellar transport (IFT) is a specialized transport mechanism inside cilia, required to transport proteins from the base of the cilium to the tip and back. Two kinesin motor complexes mediate anterograde transport in cilia of *C. elegans*; kinesin-II and OSM-3. Together these motors transport particles in the middle segment of cilia, while only OSM-3 enters the distal segment where it moves at a higher speed. The motors are attached to a complex of IFT proteins, which can be separated biochemically into complex A and B. The BBS proteins stabilize the two complexes and modulate the coordination of the two motor proteins. Several mutants have been identified, including the *bbs*, *dyf-5* and *gpa-3*, in which the two anterograde motors move at different speeds, and thus seem uncoordinated. The composition of the IFT particles in these mutants and in wild type animals has been mostly derived from speed measurements of different fluorescently-tagged IFT proteins independently. It has not been shown directly that IFT particles are transported by the two kinesins together, nor has it been shown what happens to the IFT particle composition in e.g. *bbs* mutants. Our objective is to determine the composition of IFT particles in the amphid cilia of *C. elegans* in

both wild type and mutant worms using dual-colour live imaging of fluorescently-tagged IFT proteins.
Constructs have been generated to express fluorescently-tagged OSM-3, KAP-1 (kinesin-II subunit), XBX-1 (dynein subunit), DAF-10 (complex A), CHE-13 (complex B) and BBS-8 in the cilia of one pair of amphid channel neurons. Interestingly, the dynamics of the fluorescently-tagged IFT protein is affected by its expression level. When the *osm-3::gfp* concentration is too high, its speed in the middle segment is higher than reported, while too much *kap-1::gfp* results in a reduced speed. This is likely caused by an uncoupling of the motor proteins. These results are in accordance with the current model of kinesin-II and OSM-3 moving together and support that the stoichiometry of these proteins is important for their coordination. We are currently testing whether overexpressing complex A, B, XBX-1 or BBS proteins affects IFT dynamics. In addition, we are generating transgenic animals co-expressing two different fluorescently-tagged IFT proteins.

871

Endocytosis genes facilitate protein and membrane transport in C. elegans sensory cilia.

O. Kaplan[1], D. Doroquez[2], S. Cevik[1], K. Kida[1], R. Bowie[1], J. Rappoport[3], P. Sengupta[2], O. Blacque[1]; [1]School of Biomolecular and Biomedical Science, University College Dublin, Ireland, [2]Department of Biology and National Center for Behavioral Genomics, Brandheis University, [3]School of Biosciences, University of Birmingham

Cilium formation and function relies on efficient and regulated targeting of proteins and membranes to the organelle. Transport almost certainly involves multiple modalities such as intraflagellar transport and there is increasing evidence for involvement by the exocytic and endocytic pathways. Although endocytic events near the cilium/flagellum base are suggested to facilitate membrane and ciliary protein trafficking, this model is not well tested. Thus, we examined the role of endocytosis in ciliogenesis and ciliary protein transport in the genetically tractable nematode, *C. elegans*. In worms, cilia extend from the distal dendrite tips of 60 highly polarized sensory neurons, house sensory signaling molecules, and enable the worm to sense environmental stimuli. Here we describe a ciliary endocytic zone (CEZ) at the base of sensory cilia; this zone appears to be a morphologically distinct compartment of the distal dendrite and contains pools of endocytosis-associated proteins such as the clathrin light chain, AP-2 clathrin adaptor, dynamin and RAB-5. Disruption of endocytic gene function causes expansion of membrane area both at the CEZ and in specialized olfactory cilia, as well as differential effects on the localization and transport dynamics of ciliary transmembrane, membrane-associated and IFT proteins. Expansion of ciliary membranes in dynamin and AP-2 mutants requires the functions of BBS-8 and RAB-8. Together, these data implicate an endocytic sorting station at the base of *C. elegans* sensory cilia, and suggest that this station facilitates the retrieval of ciliary membrane in a manner that may be counter-balanced by BBS-8 and RAB-8-mediated membrane delivery.

872

Ciliary proteins are found on isolated cytoplasmic membrane vesicles and bioactive membrane vesicles are released from flagella.

K. Huang[1,2], C. R. Wood[1], D. R. Diener[1], J. L. Rosenbaum[1]; [1]Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT, [2]Institute of Hydrobiology, Wuhan, China

We are using the flagellated algal model system, Chlamydomonas reinhardtii, to compare the protein composition of 1. cytoplasmic vesicles targeted to the cilium, 2. plasma membrane, 3. flagellar membrane, and 4. membrane vesicles released from flagella. Western blot analysis of

these membrane compartments show several membrane and axonemal proteins including PKD2, IFT polypeptides, axonemal precursors and tubulin to be enriched in a specific cytoplasmic membrane compartment, and also in the flagellar membrane. IFT polypeptides and tubulin are not enriched in the plasma membrane. The results lend support to our hypothesis that almost all ciliary polypeptides, both membrane and axonemal, are first associated with cytoplasmic vesicles, some passing through the RER and Golgi, and others derived from free polysomes which piggyback on the Golgi vesicles, and that these vesicles then go through exocytosis in the pericentriolar region, and their polypeptides moved through the ciliary transition zone by IFT onto the flagellar membrane. The enrichment of ciliary membrane and axonemal proteins in the purified flagellar membrane fraction indicates that these ciliary precursors, IFT and its motors, form a complex with the flagellar membrane during their movement to the flagellar tip assembly site.

Real-time observation by DIC or fluorescence microscopy of fluorescently-tagged flagellar membrane shows flagellar membrane is released into the medium. This pinching off of flagellar vesicles was also documented by electron microscopy. Vesicles isolated from the culture medium are enriched for a subset of flagellar polypeptides such as α-tubulin (but not β), 14-3-3, PKD2 and high molecular weight ubiquitinated proteins, suggesting that flagellar membrane vesicle release is an active, selective process. Indeed, the rate of flagellar vesicles released increases when Chlamydomonas gametes attach to each other by their flagella, the first step in the mating process. Flagella are also required for the release of daughter cells from the mother cell wall, and this is dependent on the release of a vesicle-associated protease from the flagella. Cells without flagella are not released from the mother cell wall. We hypothesize that a similar release of biologically active vesicles probably occurs from many types of cilia, thereby signaling adjacent cells during development. Supported by NIH grant GM14642.

873

The plasma membrane is a pool for some, but not all flagellar membrane proteins.

W. L. Dentler[1]; [1]Univ Kansas, Lawrence, KS

Flagellar membrane proteins are associated with a variety of functions, including signaling and cell-cell interactions. Protein transport is dynamic, with selected surface proteins moving into the cilium upon stimulation by extracellular signals (Rohatgi & Snell, 2010) or when surface proteins are removed (Nakamura et al, 1996). Pulse-labeling revealed rapid incorporation of newly synthesized proteins (Song & Dentler, 2001; Stephens, 2001), interpreted as turnover. To determine if flagellar membrane lipids may turnover, Chlamydomonas cells were treated with up to 36μM Brefeldin A (BFA). BFA disrupted Golgi and induced flagellar shortening; BFA removal restored Golgi and flagella regrew, suggesting that Golgi-derived membrane lipids may be required to maintain flagella. We could not detect lipid recycling but discovered that flagellar membranes and surface proteins are released to the medium during an 8-hour period. If membrane and membrane proteins are released, then we predict that they must be replaced to maintain flagellar length. Possibly “turnover” is one-way: membrane and proteins are delivered to the flagellar base and released at flagellar tips. BFA may deplete the pool of available membrane lipids but what about membrane proteins? Despite rapid incorporation of newly synthesized membrane protein (above), new protein is not required to maintain flagella: they maintain normal length for more than 8 hrs. if protein synthesis is inhibited by cycloheximide. This suggests that there is be a pool of flagellar membrane proteins that does not depend on Golgi-delivery. To determine if the plasma membrane is the source of this pool, flagellated cells were biotinylated with NHS-LC Biotin, flagella were amputated, and new flagella were allowed to regenerate. Biotinylated proteins were detected on western blots of labeled and regenerated flagella and cell bodies. Regenerated flagella contained the same labeled bands that were present in initially biotinylated flagella, although the levels of some proteins were reduced. A

second deflagellation and regeneration revealed that the plasma membrane still served as a reservoir for selected flagellar proteins. These results reveal that the plasma membrane is a reservoir for most (surface accessible) membrane proteins and that flagella may draw on two pools of membrane protein, one of which is stationed on the plasma membrane and one that either is not accessible to biotinylation or must be delivered via membrane trafficking.

874

Assembly and persistence of primary cilia in dividing *Drosophila* spermatocytes.

T. L. Megraw[1], M. G. Riparbelli[2], G. Callaini[2]; [1]Biomedical Sciences, Florida State Univ, Tallahassee, FL, [2]Evolutionary Biology, University of Siena, Siena, Italy

Observations in many cell types suggest that the basal body must be freed from the cilium and transition to a centriole to organize functional centrosomes in dividing cells. Hence, dividing cells appear unable to form primary cilia. This has lead to wide acceptance of the principle of a mutually exclusive centriole/basal body life during cell cycle progression. Contrary to this general view, we show here that cilia assemble at G_2 phase of the cell cycle in *Drosophila* primary spermatocytes, and persist through two meiotic divisions. Using markers for centrioles and a marker specific for basal bodies (uncoordinated (UNC), the *Drosophila* ortholog of vertebrate OFD1), we show that basal bodies form in G_2 phase in spermatocytes. Acetylated tubulin marks cilia axonemes distal to spermatocyte basal bodies concomitantly with UNC recruitment to centrioles. Remarkably, all four centrioles assemble primary cilia, in contrast to most cell types that typically assemble only one primary cilium from the mother centriole. At prophase, all four centriole-cilium complexes disengage from the plasma membrane, and transit into the cytoplasm encased in a packet of membrane. Centrioles then recruit centrosomal material into microtubule-organizing centers, and persist at the spindle poles through division. Thus, at cell division, spermatocyte centrioles organize centrosomes and cilia simultaneously. These cilia persist through two meiotic divisions, partially disassemble in new spermatids, and then reassemble into the long spermatid flagellum. Moreover, spermatocyte cilia have a unique “9+1” ultrastructure, a rare departure from the usual cilium architecture. Cilium resorption may therefore not be necessary to enter the cell cycle. These findings challenge the prevailing view that cilia antagonize cell cycle progression, and raise the possibility that cilium retention in dividing cells may occur in other organisms and in certain cell types.

875

A Size-Exclusion Permeability Barrier and Nucleoporins Form a Ciliary Pore Complex that Regulates Transport into Cilia.

H. Kee[1], J. F. Dishinger[1], T. Blasius[1], E. Breznau[1], K. J. Verhey[1]; [1]Cell & Developmental Biology, University of Michigan, Ann Arbor, MI

The primary cilium is a microtubule-based organelle with a unique complement of proteins for motility and signaling functions. Entry into the ciliary compartment is proposed to be regulated at the base of the cilium. Recent work demonstrated that components of the nuclear import machinery, including the RanGTPase and importins, regulate ciliary entry. We hypothesized that the ciliary base contains a ciliary pore complex (CPC) whose molecular nature and selective mechanism are similar to the nuclear pore complex (NPC). By microinjecting fluorescently-labeled dextrans and recombinant proteins of various sizes, we characterize a size-dependent diffusion barrier similar to that of the NPC, for the entry of cytoplasmic molecules into primary cilia in mammalian cells. We demonstrate that nucleoporins localize to the base of primary and motile cilia in mammalian cells and that microinjection of anti-nucleoporin antibodies restricts the ciliary entry of KIF17 motors. Together, this work demonstrates that the physical and molecular

nature of the CPC is similar to the NPC, and further extends functional parallels between nuclear and ciliary import.

Centrosomes

876

Myosin II-Dependent Traction Forces Regulate Centrosome Positioning.

W-H. Guo[1], A. Rape[1], Y-L. Wang[1]; [1]Carnegie Mellon University, Pittsburgh, PA

Fibroblasts maintain centrally localized centrosomes on 2D surfaces but show off-centered centrosomes when embedded in a 3D collagen gel. This study aims to investigate the mechanism of centrosome positioning and the reason why it differs between cells in 2D and 3D. By combining substrate micropatterning and traction force microscopy, we show that cells with a highly elongated shape, similar to those seen in collagen gels, have significantly decreased traction forces and off-centered centrosomes. Blebbistatin, an inhibitor of myosin II-dependent traction forces, also causes centrosomes to scatter, indicating that traction forces are required for maintaining centrosome location. Furthermore, when plated on micropatterned substrates to create well-spread cells with small focal adhesions, cells also show reduced traction forces and scattered centrosomes, suggesting that shape per se is not a determining factor. Our results indicate that actomyosin contractility, in addition to forces generated by microtubules and dynein, plays an important role in centrosome positioning.

877

Determining the role of Nek2 in regulating β-catenin function at centrosomes.

B. Mbom[1], W. J. Nelson[1], A. Barth[1]; [1]Biology, Stanford University, Menlo Park, CA

Beta-catenin is a multifunctional protein with critical roles in cell-cell adhesion, Wnt-signaling and bipolar spindle formation. Whereas the roles of β-catenin in adhesion and Wnt-signaling have been extensively studied, the mechanism(s) by which β-catenin regulates bipolar spindle formation is poorly understood. The centrosomal NIMA-related protein kinase 2 (Nek2) binds and phosphorylates β-catenin and stimulates centrosome separation. Nek2, like β-catenin, is required for bipolar spindle formation. Using *in vivo* and *in vitro* approaches, we analyzed the effects of Nek2 on β-catenin localization, function and stability at centrosomes. Nek2 phosphorylates regulatory sites in the N-terminus of β-catenin. Nek2 inhibits β-catenin ubiquitylation and promotes β-catenin stability independent of its kinase activity. Nek2 depletion dramatically reduces β-catenin levels at centrosomes, inhibits centrosome separation, and delays mitotic progression. Over-expression of kinase-dead Nek2 also inhibits centrosome separation but does not appear to strongly affect centrosomal β-catenin levels. These results indicate that although Nek2 protein is required for β-catenin recruitment and stability at centrosomes, its kinase activity is not. In order to assay the function of Nek2-phosphorylated β-catenin, we have developed an *in vitro* assay for centrosome separation (loss of centrosome cohesion). This assay confirms previous findings that Nek2 activity is required for centrosome separation and allows us to further elucidate the key role of Nek2 and β-catenin in regulating centrosome cohesion during the cell cycle.

878

Voltage Dependant Anion Channel 3 (VDAC3), a novel centrosomal protein regulating ciliogenesis and centriole assembly.

S. Majumder[1], A. Cash[1], H. A. Fisk[1]; [1]Department of Molecular Genetics, The Ohio State University, Columbus, OH

In cycling cells centrosomes undergo duplication to serve as the poles of the mitotic spindle, whereas in quiescent cells the maternal centriole is converted to a basal body in order to organize a primary cilium. Since the cilium must be resorbed upon cell cycle re-entry, a mechanism must exist to control the inter-conversion of basal body and centriole in order to coordinate the centriole duplication cycle and ciliary assembly-disassembly. We have demonstrated earlier that the centrosomal pool of Mps1 is crucial for the proper control of centriole duplication, but how Mps1 is targeted to centrosomes is not known. In an attempt to characterize the mechanisms of Mps1 targeting to centrosomes, we used yeast two-hybrid to identify protein(s) that can bind to the Mps1 centrosome localization domain. One of the candidates identified from this screen was VDAC3, a member of mitochondrial porin family of proteins, which was also found in the sperm flagella outer dense fiber. The molecular interaction between VDAC3 and Mps1 was validated by in vitro pull down assays and co-immunoprecipitation between Mps1 and GFP-VDAC3 expressed in HeLa cells. Moreover, GFP-VDAC3 localizes to centrosomes and a VDAC3-specific antibody predominantly stains the mother centriole, suggesting that VDAC3 is a bonafide centrosomal protein. VDAC3 depletion led to a significant reduction in the centrosomal Mps1 levels and an inhibition of centriole duplication as judged by an increase in the number of S-phase cells with unreplicated centrioles. Depletion of VDAC3 also leads to aberrant formation of primary cilia in growing human RPE-1 cells while the ectopic expression of GFP-VDAC3 in quiescent RPE-1 cells suppressed their ability to form cilia. Depletion of Mps1 also induced aberrant formation of cilia but in a smaller number of cells compared to VDAC3 depletion. Thus, our observations suggest that VDAC3 regulates a decision between ciliogenesis and centriole assembly, at least in part by regulating the recruitment of Mps1 to centrosomes.

879

CEP135 carries two functional domains and is required for centriole assembly.

Y-C. Lin[1], C-W. Chang[1], C-J. Tang[1], C-T. Wu[1], E-J. Chou[2], Y-N. Lin[1], T. K. Tang[1]; [1]Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan, [2]Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan

The centrosome is the primary microtubule-organizing center (MTOC), which is composed of two centrioles surrounded by an electron-dense matrix known as pericentriolar material. Centrioles are usually composed of nine triplets microtubules (MTs) organized around a cartwheel structure, which is located at the proximal end of the centriole and is required for the initiation of daughter centriole assembly. Recently, several key conserved proteins including PLK4, hSAS-6, CPAP, and CEP135 have been reported to be involved in the early event of centriole duplication in human cells. In *Chlamydomonas reinhardtii,* both Bld10p and SAS6 function in the formation of the nine-fold symmetrical cartwheel and are essential for an early step of centriole/basal body assembly. CEP135, the human ortholog of Bld10p, was reported to be required for PCM integrity, centrosome cohesion, and PLK4-induced centriole amplification. However, the molecular basis of how CEP135 functions in the cartwheel and participates in centriole assembly is not clear. Here, we show that CEP135 directly interacts with hSAS-6 and is associated with microtubules (MTs). Using co-immunoprecipitation, GST pulldown, yeast two-hybrid, and MT cosedimentation assays, we found that the C-terminal domain of CEP135 (residues 896-1140) interacts directly with hSAS-6 (residues 146-586) and the N-terminal

domain of CEP135 (residues 1-460) is cosedimented with microtubules. Interestingly, overexpression of either N-terminus or C-terminus of CEP135 perturbs centriole duplication, suggesting that these truncated polypeptides exert a dominant negative effect on centriole duplication. Furthermore, depletion of CEP135 results in inhibition of normal centriole duplication and reduction of centriole amplification induced by overexpression of PLK4, hSAS-6, or STIL. CEP135 depletion also inhibits CPAP-induced centriolar microtubule assembly, implying that CEP135 may have addition roles in stabilizing the microtubules cylinder. From electron microscopic analysis, we further observed defective centrioles with abnormal numbers of triplets and reduced centriole length in CEP135-depleted cells. In light of these findings, we propose that CEP135 plays an essential role to connect the inner cartwheel to outer microtubules triplets during the initiation of daughter centriole assembly, followed by CPAP-mediated centriole elongation at later stage.

The Role of Mps1 Kinase in Centrosome Duplication in Human Breast Cells.

D. B. Sawant[1], C. Kasbek[1], S. Majumder[1], H. A. Fisk[1]; [1]Department of Molecular Genetics, The Ohio State University, Columbus, OH

Each centrosome contains two symmetric centrioles that strictly duplicate once every cell cycle and mediate the proper segregation of chromosomes during mitosis. Errors in this duplication produce extra centrioles that lead to chromosome mis-segregation and aneuploidy in cultured cells. Centrosome amplification has been found in pre-malignant lesions, in-situ tumors of the breast and in over 70% of invasive breast tumors. However, the factors that contribute to aberrations in centriole duplication and the correlation between aneuploidy and tumorigenesis remain elusive. Studying centrosomal proteins and their functions will shed light on potential mechanisms of centrosome amplification. Our long-term goal is to improve breast cancer prognosis and widen our knowledge on potential targets for therapeutic intervention. Mps1 is a protein kinase that localizes to the centrosomes and is involved in centriole duplication. Microarray data shows strong positive correlations between high levels of Mps1 mRNA and breast tumor grade. Preventing the degradation of Mps1 at centrosomes is sufficient to cause centriole re-duplication during prolonged S-phase arrest in various cell lines. We have found that stable expression of the non-degradable form of Mps1 (Mps1Δ12/13) in 293 cells leads to the production of excess centrosomes in cycling cells, and leads to colony formation in limiting dilution plating assay. These data suggest that Mps1 is an important regulator of centrosome numbers and studying its functions may contribute to a better understanding of the possible link between centriole duplication and tumorigenesis. Owing to the frequent presence of centrosome defects early in the progression of breast cancer, we sought to study the precise role of Mps1 in centriole duplication in non-transformed human mammary cells. Preliminary data suggests that transient over-expression of both Mps1 and Mps1Δ12/13 in MCF10A cells leads to centrosome re-duplication with the number of extra centrosomes being higher in the latter. We hypothesize that deregulation of the degradation of Mps1 will cause centriole re-duplication and chromosomal instability in cycling breast cells, contributing to tumorigenesis. To test the hypothesis, we are generating breast cell lines that inducibly express the non-degradable Mps1 mutant (Mps1Δ12/13), and we will examine centrosome numbers and ploidy upon induction of Mps1Δ12/13. Further, the effect of Mps1Δ12/13 on in-vitro transformation and tumor formation in mice will be studied.

881

Mps1 in the Plk4 Centriole Biogenesis Pathway.

A. N. Pike[1], C. Kasbek[1], H. A. Fisk[1]; [1]Molecular Genetics, The Ohio State University, Columbus, OH

Even upon culmination of all the recent advances in the structural and functional understanding of the centriole, and despite remarkable conservation, the exact molecular mechanisms of the Plk4 induced centriole biogenesis pathway in human cells remains unclear. Plk4, the presumptive orthologue of *C. elegans* ZYG-1, is thought to be the major driver of centriole assembly. However, the physiological substrates of Plk4 remain to be identified, and Plk4 is not functionally interchangeable with ZYG-1. Moreover, unlike the case in *C. Elegans,* Plk4 has not been shown to phosphorylate hSas6, nor is it required for recruitment of hSas6 to the procentriole, though Plk4 does have a direct or indirect role in the maintenance of hSas6 at the procentriole. Overexpression of Mps1, Plk4, or HsSas6 is capable of producing extra centrioles, indicating the importance of strict regulation of these proteins throughout the cell cycle. Our preliminary data suggests that centriole amplification in human cells caused by overexpression of hSas6 does not require Plk4. This suggests that other centrosomal kinases can compensate for the absence of Plk4, and one study has suggested that ZYG-1 is more closely related to Mps1 than it is to Plk4. While the requirement of Mps1 in centrosome duplication remains controversial, it is clear that Mps1 plays several roles in centriole assembly, and defects in its regulation promote centrosome re-duplication. We have found that Mps1-dependent re-duplication requires Plk4, suggesting that the two kinases cooperate to promote centriole overproduction. However, the regulation between these two centrosomal kinases remains unclear. In this study, we explore the potential interplay between Mps1 and Plk4 using various combinations of overexpression and depletion of these two kinases.

882

The molecular interplay between CEP63 and CEP152 in the vertebrate centrosome.

J-H. Sir[1], A. R. Barr[1], A. K. Nicholas[2], O. P. Carvalho[2], A. Sossick[3], C. D'Santos[1], C. G. Woods[2], S. Reichelt[1], F. Gergely[1]; [1]Department of Oncology, Cancer Research UK Cambridge Research Institute, University of Cambridge, Cambridge, United Kingdom, [2]Department of Medical Genetics, Cambridge Institute for Medical Research, University of Cambridge, Cambridge, United Kingdom, [3]Gurdon Institute, University of Cambridge, Cambridge, United Kingdom

We have recently established CEP63 as a protein required for maintaining normal centrosome numbers in vertebrate cells. In this study, we carried out a proteomics screen to find that CEP63 interacts with CEP152, a highly conserved centrosomal protein essential for centrosome duplication in flies and mammals. Furthermore, we identified C-terminal 321 amino acids of CEP63 as CEP152 interaction domain. In line with CEP63-CEP152 interaction, we found that CEP63-deficient centrosomes were unable to accumulate CEP152, a defect most pronounced in mitosis. Tethering CEP152 to CEP63-deficient centrosomes restored normal centrosome numbers to CEP63-knockout cells, indicating that CEP63 controls centrosome duplication by targeting CEP152 to the centrosome. In addition, centrosomal localisation of CEP152 seems to be regulated by Polo like kinase 1 (PLK1), a kinase implicated in centriole biogenesis. We found that inhibition of PLK1 with a small-molecule inhibitor, BI-2536, dramatically increased centrosomal CEP152 levels in mitosis. Overall, our data suggest that centrosomal levels and distribution of CEP152 are positively regulated by CEP63 and negatively by PLK1 activity. To gain further insight into the molecular roles of CEP63 and CEP152, we have also disrupted the CEP152 gene in vertebrate cells and will also present characterisation of centrosome function in this cell line.

883

PLK1 phosphorylation of pericentrin initiates centrosome maturation at the onset of mitosis.

K. Lee[1], K. Rhee[1]; [1]Department of Biological Sciences, Seoul National University, Seoul, Korea

The microtubule-organizing activity of centrosome oscillates during cell cycle, reaching the highest at M phase. At the onset of mitosis, the centrosome undergoes maturation, which is characterized by a drastic expansion of the pericentriolar matrix (PCM) and a robust increase in microtubule organizing activity. It is known that PLK1 is critical for the initiation of centrosome maturation. Here, we report that pericentrin (PCNT), a PCM protein, is specifically phosphorylated by PLK1 during mitosis. The phospho-resistant point mutants of PCNT did not recruit centrosomal proteins, such as CEP192, GCP-WD, gamma-tubulin and Aurora A into the centrosome during mitosis. The centrosomal recruitment of PLK1 is also dependent on phospho-PCNT most likely in a positive feedback mechanism. However, centrosomal recruitment of CEP215 depends on PCNT irrespective of the phosphorylation status. Furthermore, ectopic expression of the PLK1-PCNT fusion proteins induces the centrosomal accumulation of CEP192, GCP-WD and gamma-tubulin even in interphase cells, mimicking centrosome maturation. Based on these results, we propose that PLK1-mediated phosphorylation of PCNT initiate centrosome maturation by organizing the spindle pole-specific PCM lattice.

884

SAS-6 dimers adopt a folded conformation required for centriole assembly.

M. Bush[1], D. Lyumkis[2], S. Tsutakawa[3], J. A. Tainer[3], C. S. Potter[2], C. D. Putnam[1], A. K. Shiau[1], B. Carragher[2], A. Desai[1], K. Oegema[1]; [1]LICR/University of California, San Diego, La Jolla, CA, [2]National Resource for Automated Molecular Microscopy and Department of Cell Biology, The Scripps Research Institute, [3]Life Sciences Division, Lawrence Berkeley National Laboratory

SAS-6 is a component of the universal module required for centriole assembly. SAS-6 has an N-terminal globular domain, a central coiled-coil, and a C-terminal domain that is predicted to be unstructured. Recent structural work revealed that SAS-6 dimers associate with each other through their N-terminal globular domains to form a 9-fold symmetric circular plate that resembles the cartwheel seen in EM cross-sections of centrioles. In the current model, the N-terminal domains form an ~23 nm diameter circular hub, and the SAS-6 coiled-coils extend out from the hub as rigid rods to form the cartwheel spokes. No function has yet been ascribed to the predicted unstructured C-terminal domain of SAS-6. We have analyzed SAS-6 full-length and the SAS-6 coiled-coil alone using a combination of analytical ultracentrifugation, small angle X-ray scattering (SAXS), and electron microscopy. Surprisingly, single particle EM revealed that the SAS-6 dimer is not a rigid rod, but folds back upon itself to adopt a bent conformation. This observation was consistent with SAXS analysis, which indicated that full-length SAS-6 is more compact (smaller radius of gyration and maximum distance between scatterers, Dmax) than the SAS-6 coiled-coil alone. The folded SAS-6 conformation requires the unstructured C-terminal tail, and a weak interaction between the C-terminal tail and the rest of SAS-6 can be detected *in vitro*. Using a single copy transgene insertion system in *C. elegans*, we found that the C-terminal tail is essential for centriole assembly. Mutational analysis identified a small region in the tail that is essential. Perturbation of the tail or the more defined region does not affect the interaction of SAS-6 with SAS-5, excluding disruption of this interaction as a potential reason for the centriole assembly failure. We propose that this region in the unstructured SAS-6 C-terminus interacts with a region in the coiled-coil to generate a folded conformation that is important for centriole assembly. We are currently investigating the precise step at which centriole assembly fails when this intramolecular interaction is disrupted.

885

A Dual Role For Bld10 During Basal Body Assembly.

B. Bayless[1], T. H. Giddings Jr.[2], M. Winey[2], C. G. Pearson[1]; [1]University of Colorado Denver, Aurora, CO, [2]University of Colorado Boulder

Centriole dysfunction causes ciliopathies and has been implicated in cancer. These multifunctional organelles form the core of centrosomes and are required for nucleation of cilia. Centrioles that function to assemble and maintain cilia are referred to as basal bodies. Due to the torque generated by the beating of motile cilia, basal bodies require proteins to stabilize the structure. Thus both basal body assembly and stability are integral to ciliary function. While much has been done to illuminate the proteome of basal bodies there remains a substantial gap of knowledge concerning the mechanism of basal body assembly. Basal body structure is well conserved across eukaryotes with a key domain being the cartwheel. The cartwheel is composed of nine symmetrically spaced spokes radiating out from a central hub. Attached to the end of each spoke are triplet microtubules which form the length of the basal body. Formation of the cartwheel is the first identified step in basal body assembly. The central hub and the spokes of the cartwheel are made up, at least in part, of the conserved basal body protein Sas6. Bld10/Cep135 is an additional conserved protein that localizes to and is required for cartwheel assembly. This large coiled-coil domain containing protein is required for basal body formation in most systems tested. However the functional role that Bld10/Cep135 plays in basal body assembly is uncharacterized. We identified a single conserved Bld10/Cep135 gene, TtBld10, that encodes a 171 kDa protein in the ciliate Tetrahymena thermophila. We find that Bld10 localizes to the periphery of the cartwheel which raises the possibility that Bld10 helps attach microtubules triplets to the cartwheel. Additionally, we find that Bld10 has two distinct incorporation profiles. One population of Bld10 incorporates in a stable manner only during new basal body assembly. Another population of Bld10 accumulates at the basal body slowly with time. Once assembled, both of these populations remain stable at the centriole. We propose that the early localizing population of Bld10 is required for assembly of basal bodies and the late accumulating population of Bld10 is required for basal body stability. A complete genomic knockout of Bld10 disrupts cell swimming and causes pronounced cortical shape irregularities. Cell lethality occurs by 48 hours in bld10Δ cells. Furthermore, we find that assembly of new basal bodies is inhibited in bld10Δ cells. In addition to inhibition of new basal bodies assembly, we find that existing basal bodies in bld10Δ cells disassemble with time suggesting that Bld10 is required for basal body stability. Thus we find that Tetrahymena Bld10 functions in both the assembly and stability of basal bodies.

886

Centrosome Loss in the Evolution of Planarians.

J. Azimzadeh[1], M. Wong[1], D. Miller Downhour[2], A. Sanchez Alvarado[3], W. Marshall[1]; [1]Biochemistry and Biophysics, UCSF, San Francisco, CA, [2]School of Medicine, University of Utah, Salt Lake City, UT, [3]Stowers Institute for Medical Research, Kansas City, MO

The centrosome, a cytoplasmic organelle formed by cylinder-shaped centrioles surrounded by a microtubule-organizing matrix, is a hallmark of animal cells. The centrosome is conserved and essential for the development of all animal species described so far. We show that, unlike the rest of animals, planarians and possibly other flatworms as well completely lack centrosomes. We found that planarians assemble centrioles de novo in ciliated cells, but lack the pathway for centriole duplication underlying centrosome reproduction in other animal species. This unique characteristic allowed us to identify a large set of conserved proteins required for centriole assembly in animals, as well as the centrosome signature proteins missing from the planarian

genome. Our study uncovers the molecular architecture and evolution of the animal centrosome and emphasizes the plasticity of animal cell biology and development.

887

Genes and post-translational modifications required for acentrosomal mitosis.

O. A. Cabrera[1], V. Mottier-Pavie[2], T. L. Megraw[1]; [1]Biomedical Sciences, Florida State University, Tallahassee, FL, [2]Molecular Biology, University of Texas Southwestern Medical Center

Centrosomes serve as the major microtubule-organizing centers (MTOC) for animal cells at mitosis. In *Drosophila*, centrosomin (Cnn) is required for recruitment of the pericentriolar material (PCM) and for mitotic MTOC activity. Cells that are deficient in Cnn, either *in vivo* or in cell culture, assemble mitotic spindles by an alternative "acentrosomal" pathway. Cells divide efficiently using this alternative mode of mitosis, and are capable of supporting development into an adult fly. Synthetic lethality between *cnn* mutations and mutations in other non-lethal genes have been reported, and suggests that an alternative pathway is involved in acentrosomal mitosis. Regulation of this pathway remains unclear. We have employed a genetic screen to dissect the genes involved in this pathway, and a proteomic approach to identify changes in protein levels or modifications that are different between centrosomal and acentrosomal mitosis. By using this combination of genetic and proteomic approaches, we will define the differences between these pathways. Using 2D-Difference Gel Electrophoresis (2D-DIGE), we found 15 proteins that are differentially expressed or post-translationally modified between wild-type and *cnn* mutant tissues. For the genetic approach, we identified 26 mutations that are synthetic lethal with *cnn*. Two of these mutants exhibit non-lethal phenotypes (infertility) when present in a *cnn* heterozygous background. The preliminary results suggest that at least one of these genes is required for proper spindle assembly in acentrosomal mitosis, but not in centrosomal mitosis. By combining these genetic and proteomic approaches we can define the major differences between centrosomal and acentrosomal mitosis, and gain a mechanistic understanding of mitotic spindle assembly *in vivo*. These results could lead to new targets for halting cell division in a therapeutic setting.

888

Analysis of fungal homologs of Mozart1, a newly identified spindle pole protein.

T. Horio[1], H. Masuda[2], T. Toda[2], B. R. Oakley[1]; [1]Department of Molecular Biosciences, University of Kansas, Lawrence, KS, [2]Laboratory of Cell Regulation, Cancer Research UK, London, United Kingdom

Mozart1 is a small (82 aa) centrosomal protein that was identified by high-throughput genome-wide screening of animal cells. It plays an important role in mitosis including establishment of bipolar spindles (Hutchins et al., Science 2010, 328, 593). Orthologs of Mozart1 were found in the genomes of a wide range of eukaryotes including most fungi suggesting that the function of this protein has been conserved throughout evolution. We analyzed the function of the Mozart1 orthologs in the filamentous fungus *Aspergillus nidulans* (MZTA) and the fission yeast *Schizosaccharomyces pombe* (Mzt1). In *A. nidulans,* a homolog of Mozart1 that exhibits about 50% amino acid identity is encoded by a single gene (*mzt*A). Tagging MZTA with fluorescent proteins revealed that MZTA localizes to spindle pole bodies (SPBs) indicating that this polypeptide is likely to be an functional homolog of Mozart1. Strains carrying a deletion of *mzt*A were viable but exhibited a weak temperature sensitivity. In *mzt*A deletants, fewer cytoplasmic microtubules were observed suggesting that nucleation of the microtubules is suppressed in the absence of MZTA. We investigated the functional relationship between MZTA and the γ-tubulin complex proteins (GCPs). Double deletants of *mzt*A and nonessential GCP genes (*gcp*D~F)

exhibited a variety of synthetically sick phenotypes. While the absence of these nonessential GCPs alone does not affect growth significantly, depleting both MZTA and any one of these GCPs at the same time caused a significant growth reduction. *S. pombe* Mzt1 is essential for growth, and colocalizes with the γ-tubulin complex to the SPBs throughout the cell cycle and to the eMTOC, a site for cytoplasmic microtubule formation upon mitotic exit. We created a number of temperature-sensitive *mzt1* mutants and found that *mzt1* mutant cells are defective in bipolar spindle assembly and elongation, and formation of interphase arrays of cytoplasmic microtubules. Our data indicate that the homologs of Mozart1 play an important role in organizing microtubules in fungi by interacting with γ-tubulin and/or γ-tubulin complex proteins.

Plant Homologues of GCP2, 3, 4, 5, and 6 Proteins are Components of Gamma-tubulin Complexes in Acentrosomal Plant Cells.

L. Kohoutova[1], H. Kourova[1], P. Halada[1], A. Doskocilova[1], J. Volc[1], J. Chumova[1], O. Benada[1], P. Binarova[1]; [1]Institute of Microbiology, AS CR, Prague, Czech Republic

Gamma-tubulin complexes that present major microtubule nucleators from centrosomes are believed to be conserved in all eukaryotes. Microtubules are nucleated in acentrosomal plant cells from sites dispersed in cytoplasm, with membranes, and with pre-existing microtubules. There are orthologues of genes encoding all mammalian gamma-tubulin complex proteins (GCPs) present in Arabidopsis genome, except recently reported GCP8 protein. However, data on composition and function of plant gamma-tubulin complexes are still largely missing. We identified Arabidopsis GCPs homologues AtGCPs 2, 3, 4, 5, and 6 among proteins that co-purified either with endogenous or with expressed gamma-tubulin-GFP. Here we provide data on homologue of GCP3 protein, a member of the small g-TUSC complexes, and on AtGCP4 protein that is a representative of the large g-TURC in animal cells. We found that AtGCP3 and 4 were together with gamma-tubulin spun down with taxol polymerized plant microtubules. Association of AtGCP3 and AtGCP4 with microtubules was proven on cellular level, immunofluorescent staining further revealed localization of both GCPs in the nuclei. Complexes of gamma-tubulin with AtGCP3 and AtGCP4 proteins were purified from the cytosolic and microsomal fraction. Presence of AtGCP3 and AtGCP4 proteins in size heterogeneous gamma-tubulin complexes with maximum >1 MDa was further indicated by size exclusion chromatography. Our data suggest that AtGCP2-6 proteins are components of large gamma-tubulin complexes. Our proteomic analysis identified further proteins that belong to the cell cycle signaling and Ran GTPase pathway co-purified with gamma-tubulin. Regulatory functions of gamma-tubulin that recently emerged in cells equipped with centrosomes or spindle pole bodies might be therefore preserved also in acentrosomal plant cells.

Functional characterization of CP148, a novel key component for centrosome integrity in Dictyostelium.

O. Kuhnert[1], O. Baumann[2], I. Meyer[1], R. Graef[1]; [1]Cell Biology, Univ Potsdam, Potsdam, Germany, [2]Animal Physiology, Univ Potsdam, Potsdam, Germany

The Dictyostelium centrosome consists of a layered core structure surrounded by a microtubule-nucleating corona. A tight linkage through the nuclear envelope connects the cytosolic centrosome with the centromeres that are clustered in the pericentrosomal region of the nuclear matrix. At the G2/M transition the corona dissociates and the core structure duplicates yielding

two spindle pole bodies. CP148 is a novel centrosomal component identified in a proteomic screen. It is a coiled coil protein with no significant homology to other proteins. Confocal deconvolution microscopy revealed that CP148 is a component of the centrosomal corona. Moderate expression of GFP-CP148 demonstrated a cell cycle-dependent centrosomal localization. The fusion protein is present at the centrosome during interphase but it is absent from mitotic centrosomes. Its cell cycle-dependent presence and absence at the centrosome correlates with dissociation of the corona in prophase and its reformation in late telophase. Live cell imaging revealed the appearance of many cytosolic GFP foci in early telophase, which coalesced later in telophase and finally joined the centrosome. This explains the hypertrophic appearance of the corona in interphase cells upon strong overexpression of GFP-CP148, which was confirmed by electron microscopy. Since CP148 is a corona protein and the time frame of GFP foci formation coincides with corona formation, we concluded that CP148 is required for corona organization and functions as glue for corona proteins. To confirm this idea, we depleted endogenous CP148 by RNAi. This resulted in a virtual loss of the corona and consequently disorganization of interphase microtubules. Surprisingly, formation of the mitotic spindle and astral microtubules was unaffected by CP148-RNAi, which indicates that microtubule nucleation complexes employ different means of association with centrosomal core components during interphase and mitosis, respectively. Furthermore, CP148 RNAi caused dispersal of the usually clustered centromeres and altered distribution of Sun1 at the nuclear envelope suggesting a role of CP148 in the nuclear envelope-spanning linkage of centrosomes and centromeres. Taken together we have shown that the novel Dictyostelium protein CP148 is an essential factor for the formation and organiziation of the microtubule-nucleating centrosomal corona and suggest that centrosome/nucleus attachment occurs through corona components.

891

Aurora Kinase and the formation of the blepharoplast, a centrosome-like particle that nucleates *de novo* formation of basal bodies in *Marsilea vestita*.

A. Windhausen[1], S. M. Wolniak[1]; [1]Cell Biology and Molecular Genetics, University of Maryland, College Park, College Park, MD

The development of the *Marsilea vestita* microspore into motile sperm occurs in 11 hours at 20°C, with all of the cellular divisions occurring during the first 5 hours. The blepharoplast is a structure that arises *de novo* ~3.5 hours after the dry spores are placed in water. The particle disappears then reappears at 4 hours and functions as a MTOC in a centrosome-like fashion for the spindle during the final mitotic division. After this division, it matures and eventually serves as the *de novo* assembly site for ~140 basal bodies. We are interested in the role and function of Aurora Kinases in the *de novo* synthesis of the blepharoplast. Aurora Kinases are a conserved family of serine/threonine kinases that are essential in regulating the replication machinery of most organisms. Aurora is essential in the orientation and function of the mitotic spindle and in the attachment and segregation of chromosomes. We have identified three isoforms of Aurora Kinase in *M. vestita*. These isoforms all contain the large central protein kinase domain that is conserved in all members of the Aurora family and have unique 3' and 5' ends. Each of the 3 isoforms have different mRNA expression patterns during the first 8 hours of development in the gametophyte, with all 3 being present at 3 to 4 hours after the onset of development. This time point coincides with the formation of the blepharoplast. When Aurora knocked down using RNAi, both the development and formation of the blepharoplast were blocked. In severe knockdowns, the gametophytes mitosis was totally inhibited, and the nuclei were enlarged and irregularly shaped. Less severe knockdowns allowed a few of the early divisions to occur, but the formation of the blepharoplast was not observed. The blepharoplast either failed to form, or it assembled but failed to develop and segregate basal bodies at the appropriate time. This suggests that Aurora Kinase is necessary for the proper progression of

cell cycles in the microspore, and for the assembly of the blepharoplast and *de novo* basal body formation. This research was supported by NSF grant 0842525 to S.M.W.

Polo-like kinase 4 stability is controlled by autophosphorylation of multiple residues within its downstream regulatory element.

J. E. Klebba[1], D. W. Buster[1], N. M. Rusan[2], G. C. Rogers[1]; [1]Cellular and Molecular Medicine, University of Arizona, Tucson, AZ, [2]National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD

Polo-like Kinase 4 (Plk4) is a conserved regulator of centriole duplication and performs the particularly crucial function of initiating the sequence of events culminating in the assembly of a new daughter centriole. Previous work by our lab has demonstrated that Plk4 protein levels oscillate during the cell cycle, peaking in mitosis when we believe Plk4 is active but practically vanishing during the rest of the cycle. Except for the brief mitotic spike, the absence of Plk4 prevents centriole reduplication and is brought about by the E3 ubiquitin-ligase complex, SCF^{Slimb}. Plk4 autophosphorylation promotes its recognition and ultimate destruction by SCF^{Slimb}, and therefore we performed a detailed study of the Plk4 autophosphorylated residues and their roles in Plk4 stabilization. First, we used mass spectrometry to identify autophosphorylated residues. Plk4 autophosphorylates its consensus Slimb-binding domain (SBD) and multiple residues flanking this region. To understand what effect autophosphorylation has on Plk4 regulation, we chose 11 phosphorylatable residues flanking the SBD and systematically mutated them to non-phosphorylatable alanines. These mutants were expressed in cultured *Drosophila* S2 cells, with or without Slimb depletion by RNAi. Our data show that residues besides those found in the canonical SBD are involved in SCF^{Slimb} recognition of Plk4 and additionally, that these residues may be used by an alternative degradative pathway to regulate Plk4 levels.

893

SV40 small tumor antigen exploits PP2A's role in stabilizing Plk4 to induce centriole amplification.

C. W. Brownlee[1], J. E. Klebba[1], D. W. Buster[1], N. M. Rusan[2], G. C. Rogers[3]; [1]Cellular & Molecular Medicine, University of Arizona, Tucson, AZ, [2]National Heart, Lung, and Blood Institute, National Institutes of Health, [3]Univ Arizona, Tucson, AZ

Centriole duplication is a tightly-regulated process that must occur only once per cell cycle, otherwise supernumerary centrioles can lead to chromosomal instability and tumorigenesis. Initiation of this process is a key point of regulation and is initiated by the conserved enzyme, Polo-like kinase 4 (Plk4). Consequently, regulation of centriole duplication is achieved by control of cellular Plk4 protein levels. Throughout interphase, autophosphorylation of Plk4 triggers its ubiquitin-mediated proteolysis, thus preventing centriole amplification. However, Plk4 activity is required during mitosis for proper centriole duplication, but the mechanism stabilizing Plk4 is unknown. Here we identify a mechanism which increases Plk4 activity: Drosophila Protein Phosphatase 2A (PP2A) (with the regulatory subunit Twins) counteracts Plk4 autophosphorylation, thus stabilizing Plk4 and promoting centriole duplication. Twins is a rate-limiting component in this regulatory mechanism. Like Plk4, Twins protein levels peak during mitosis and are required for centriole duplication. However, untimely Twins expression stabilizes Plk4 inappropriately, inducing centriole amplification. Paradoxically, expression of tumor-promoting SV40 small t-antigen (ST), a well-established PP2A inhibitor, was shown to promote centrosome amplification by an unidentified mechanism. We solve this mystery by

demonstrating that ST does not inhibit all PP2A activities but instead functionally mimics Twins in stabilizing Plk4 and inducing centriole amplification.

894

Autoregulated instability of Polo-like kinase 4 limits centrosome duplication to once per cell cycle.

A. Holland[1], D. Fachinetti[1], W. Lan[1], S. Niessen[2], H. Hoover[2], D. Cleveland[1]; [1]Department of Cellular and Molecular Medicine, Ludwig Institute for Cancer Research. University of California, San Diego, La Jolla, CA, [2]The Center for Physiological Proteomics. Department of Chemical Physiology, The Scripps Research Institute

Accurate control of the number of centrosomes, the major microtubule-organizing centers of animal cells, is critical for the maintenance of genomic integrity. Abnormalities in centrosome number can promote errors in spindle formation that lead to subsequent chromosome missegregation and extra centrosomes are found in many cancer cells. Centrosomes are comprised of a pair of centrioles surrounded by an amorphous pericentriolar material and centrosome duplication is controlled by centriole replication. In vertebrates and invertebrates, the conserved protein kinase Polo-like kinase 4 (Plk4) plays a key role in initiating centriole duplication and overexpression of Plk4 promotes centriole overduplication and the formation of extra centrosomes. Using isogenic stable cell lines and an analogue sensitive Plk4 allele, we show kinase active Plk4 is inherently unstable and targeted for degradation by the proteasome. Plk4 multiply self-phosphorylates within a 24 amino-acid “phospho-degron” that is required to integrate Plk4 kinase activity with protein stability. Using gene targeting in human cells we demonstrate the autoregulated instability of Plk4 self-limits Plk4 activity and forms an important mechanism to limit normal centriole duplication to once per cell cycle. Preventing Plk4 auto-regulation leads to centrosome amplification that inhibits proliferation of non-transformed cultured cells. However, cells carrying amplified centrosomes can be induced to proliferate through expression of the viral oncogene SV40 large-T antigen, suggesting compensatory mutations may be required to allow the propagation of cells with extra centrosomes.

895

Inhibition of Clathrin Dependent Endocytosis Results in Senescence-like phenotype and Plk4-mediated Centrosome Overduplication.

M. B. Olszewski[1], P. Chandris[1], E. Eisenberg[1], L. E. Greene[1]; [1]NHLBI/NIH/CBPC/LCB, Bethesda, MD

Coordination of DNA synthesis, centrosome duplication and cell division is essential for unperturbed mitosis and accurate chromosome segregation between daughter cells. Supernumerary centrosomes and aneuploidic genome are common features of many malignant tumors. Recent reports suggest that several proteins involved in endocytosis also play a role in centrosome and mitotic spindle function. One of them is cyclin G-associated kinase (GAK) that interacts with clathrin heavy chain (CHC) and plays crucial role at several steps essential for vesicular trafficking and clathrin-mediated endocytosis (CME). Knockout of GAK interrupts cell cycle progression and prohibits both primary and transformed mouse embryonic fibroblasts from entering S phase, leading to senescence and overduplication of centrosomes. This arrest is associated with p53 phosphorylation on ser15 and induction of CDK inhibitor p21. Still, CDK2 is activated by thr160 phosphorylation and despite p21 binding, residual activity of CDK2/cyclin E complex is retained. Cells arrested in late G1 phase undergo multiple rounds of centrosome duplication, which shows that centrosome duplication cycle is uncoupled from cell cycle progression. Early stages of centrosome duplication cycle require Plk4 activity at the centrosome; this activity is temporally restricted, which prevents overduplication. In GAK-

depleted cells Plk4 is found on the majority of centrosomes showing that these cells are arrested at the cell cycle stage where Plk4 is active at centrosomes. Structural integrity of the resulting supernumerary centrosomes is not perturbed since they contain both centrioles and pericentriolar material. This indicates that the control of centrosome number is impaired rather than centrosomal maturation. In GAK-depleted cells centrosome overduplication is dependent on CDK2 activity and serum stimulation, but may be induced by EGF alone. GAK knockout phenotype is largely reproduced by CHC knockdown and dynamin inhibition. We conclude that perturbation of CME results in uncoupling of centrosome duplication cycle from DNA synthesis and interferes with transduction of mitogenic signaling, demonstrating that CME-independent mitogenic signaling is sufficient for triggering centrosome duplication but not for DNA synthesis

896

Kinesin-1 prevents capture of the oocyte meiotic spindle by the sperm aster.

F. J. McNally[1], J. Flynn[1], J. Milan[1], K. McNally[1], M. Ellefson[1], A. Fabritius[1]; [1]Molecular and Cellular Biology, Univ California-Davis, Davis, CA

Centrioles are lost during oogenesis and inherited from the sperm at fertilization. In the zygote, the centrioles recruit pericentriolar proteins from the egg to form a mature centrosome that nucleates a sperm aster. The sperm aster then captures the female pronucleus to join the maternal and paternal genomes. Because fertilization occurs before completion of female meiosis, some mechanism must prevent capture of the meiotic spindle by the sperm aster. Here we show that in wild-type C. elegans zygotes, maternal pericentiolar proteins are not recruited to the sperm centrioles until after completion of meiosis. Depletion of kinesin-1 heavy chain or its binding partner resulted in premature centrosome maturation during meiosis and growth of a sperm aster that could capture the oocyte meiotic spindle. Kinesin-1 heavy chain, light chain and a light chain binding protein were all concentrated in a shell surrounding the sperm DNA and centrioles during female meiosis. Microtubules were required for kinesin-dependent movement of the sperm DNA/centriole complex within the zygote but microtubules were not required for kinesin-dependent suppression of centrosome maturation. These results support a model in which kinesin prevents recruitment of pericentriolar proteins by coating the sperm DNA and centrioles and thus prevents triploidy by a non-motor mechanism.

Dynein

897

The 2.8- Å crystal structure of the dynein motor domain.

T. Kon[1], T. Oyama[1], R. Shimo-Kon[1], K. Sutoh[2], G. Kurisu[1]; [1]Institute for Protein Research, Osaka Univ, Japan, Osaka, Japan, [2]Research Institute for Science and Engineering, Waseda Univ, Japan

Dyneins are microtubule-based motor complexes that power a wide variety of biological processes within eukaryotic cells, including the beating of cilia and flagella, cell division, cell migration, and the intracellular trafficking. Most recently, structures of the dynein motor domain have been reported at 5-6 Å resolution, which have provided invaluable information at the secondary structure level. However, a higher resolution analysis is required to reveal complete atomic structure of the motor domain.

Here we report the crystal structure of the 380-kDa motor domain of *Dictyostelium* cytoplasmic dynein at 2.8 Å resolution. This atomic structure shows details of functional units constituting the motor domain, such as the ATP-hydrolyzing ring composed of six AAA+ modules, the long

coiled-coil microtubule-binding stalk, and the force-generating rod-like linker. Our analysis visualizes four ADP molecules bound to the first four AAA+ modules of the ring, among which three are active ATP hydrolysis site and one is a unique ADP/ATP binding site. The structure also uncovers how the linker and stalk interact with the ring unit, which should be critical for dynein's motor activity. This long sought atomic structure will open up new avenues for investigating and understanding how dynein produces force and movement.

898

In vivo 3D structural analysis of axonemal dynein in flagella/cilia by electron cryo-tomography.

T. Ishikawa[1], K. Bui[2], G. Pigino[2]; [1]Biomolecular Research Laboratory, Paul Scherrer Institute, Villigen PSI, Switzerland

Eukaryotic flagella/cilia are bending organelles to cause cellular motility or extracellular flow. They have a common “9+2” structure, in which nine microtubule doublets surround two single microtubules and adjacent doublets are connected by dynein motor proteins. There are a number of isoforms of dyneins and they form inner and outer arm complexes. Questions still to be answered are (1) mechanism of dynein power stroke, (2) cause of bending and (3) determination of waveforms. To address these questions, we employed the technique of electron cryo-tomography for structural analysis of dynein in flagella/cilia in vivo without purification. We revealed overall dynein arrangements in flagella/cilia (Bui et al. (2008) J. Cell Biol. 183, 923) and their conformational changes induced by ATP (Movassagh et al. (2010) Nat. Struct. Mol. Biol. 17, 761). Our analysis proved that the dynein ATPase head shift toward the distal end (plus end of the microtubule) at 8nm during power stroke, while there is no rotation of the ring detected (Winch mechanism). In the presence of ADP.Vi (non-hydrolysable ADP.Pi analogue), dynein molecules do not change structure in the synchronized manner: about half of the dyneins stay as non-nucleotide conformation, while the other half switch to the nucleotide-bound form. Interestingly these two structures coexist, forming clusters. This result suggests that torsion is generated at the boundary of the two clusters to cause bending. In this presentation, we will discuss the flagellar/ciliary bending mechanism based on the structure and mapping of dynein isoforms to discuss the determination of waveforms.

899

Submolecular structure of cytoplasmic dynein tail.

Y. Watanabe[1], M. Ichikawa[1], T. Murayama[2], T. Kobayashi[2], T. Kitai[3], T. Takahagi[3], H. Sakakibara[4], K. H. Bui[5], T. Ishikawa[5,6], Y. Y. Toyoshima[1]; [1]Graduate School of Arts and Sciences, University of Tokyo, Tokyo, Japan, [2]Juntendo University, [3]Hiroshima University, [4]NICT, [5]ETH, [6]PSI

Cytoplasmic dynein is a microtubule-based motor protein and plays important roles in vesicle transport, organelle positioning, neuronal migration and mitosis. Cytoplasmic dynein molecule is a homo dimer of heavy chains and has two headed structure. As for cytoplasmic dynein 1, the motor domain (the head) consists of C-terminal two third of heavy chains, while the tail region is composed of a N-terminal third of heavy chains as well as intermediate, light intermediate and light chains. Although dynein tail domain is important for the specific binding and the regulation of various cargos, the submolecular structure of the tail remains to be unveiled.

To investigate the molecular architecture of dynein tail, we observed the recombinant dynein molecules by negative staining electron microscopy using nanogold-labeling which is specific to the introduced tag. The position and the orientation of intermediate and light intermediate chains in the tail were determined. Notably, the relative position of these two chains and the orientation of intermediate chain were opposed to the previously advocated model. Furthermore, single

particle analysis of dynein tail region revealed that the tail consists of three globular domains. These findings provide important information for the cargo binding and targeting to the specific location in the cell, as well as the binding of regulatory proteins including dynactin complex, LIS1 and NDEL1.

900

Recombinant human cytoplasmic dynein heavy chain 1 and 2.

M. Ichikawa[1], Y. Watanabe[1], T. Murayama[2], Y. Y. Toyoshima[1]; [1]Department of Life Sciences, Graduate School of Arts & Sciences, The University of Tokyo, Meguro-ku, Japan, [2]Department of Pharmacology, Juntendo University School of Medicine, Bunkyo-ku, Tokyo

Cytoplasmic dynein is a microtubule (MT) motor protein and moves by the energy derived from ATP hydrolysis. Cytoplasmic dynein comprises two classes: dynein-1 and dynein-2. Dynein-1 is involved in various activities in cells, including cell division, cargo transport, and neural development. In contrast, cytoplasmic dynein-2 is reported to work exclusively in intraflagellar transport (IFT), which is a bidirectional transport of particles along axonemes in cilia and flagella. Dynein-2 is a putative retrograde IFT motor, which transports IFT particles from the ciliary tip toward the cell body.
To elucidate in vitro properties of dynein-1 and dynein-2, we have purified recombinant human dynein-1 and dynein-2 complex by expressing streptavidin-binding peptide (SBP)-tagged human dynein-1 HC and dynein-2 HC in HEK-293 cells. Both purified dynein-1 and dynein-2 showed minus-end-directed motor activities as shown in an in vitro MT gliding assay, and revealed two-headed structure by electron microscopy. These results are the first to describe the structure and motor activity of dynein-2 in vitro. Our results have also shown the structural and motile differences between dynein-1 and dynein-2. Firstly, human dynein-1 was able to drive robust gliding of MTs in an MT gliding assay, however, the MT gliding of dynein-2 was not robust, and MTs easily dissociated from the dynein-2 coated glass surface. The average velocity of dynein-1-driven MTs was 905 ± 152 nm/sec (mean ± SD, n = 120) and the average velocity of dynein-2 was 69.6 ± 41.0 nm/sec (mean ± SD, n = 53). Secondly, unlike dynein-1, which had the dense tail domain, the tail domain of dynein-2 was obscure and some of the dynein-2 molecules had thin tail structures. These results might reflect motile and structural diversity between the two classes of cytoplasmic dynein.

901

Studying Multiple Motor Ensembles using DNA Nanotechnology.

B. Goodman[1], N. Derr[1], W. Shih[2], S. Reck-Peterson[1]; [1]Cell Biology, Harvard Medical School, Boston, MA, [2]Dana Farber Cancer Institute, Boston, MA

*Brian Goodman and Nathan Derr contributed equally to this work.

In eukaryotic cells, many cargos are transported by groups of microtubule-based molecular motors. Some of these cargos move bidirectionally and can be observed switching directions during movement, but ultimately, cellular contents are sorted with spatial and temporal precision. The biophysical mechanisms that allow ensembles of same- or opposite-polarity motors to coordinate their behaviors are not known. The major technical challenge for dissecting this problem in vitro has been the inability to control the spacing, number, and type of motor present on individual cargo molecules. Using three-dimensional DNA origami, we have designed a synthetic cargo, to which precise numbers and geometries of DNA-linked dynein and kinesin motors can be attached in varying combinations of 1 to 7 motors. We find that synthetic cargo bearing multiple dynein motors can move farther, but not faster than single dynein molecules. Under physiological conditions, multiple dynein motors can move cargo

processively, while single dynein motors cannot. Our results suggest that dynein motors may coordinate to move cargo efficiently. Studies of "tug-of-war" scenarios are underway to determine whether cargos driven by both dynein and kinesin exhibit stochastic bidirectional movements.

902

Structural Mechanism for Dynein Control by Lis1.

A. Roberts[1,2], J. Huang[1], A. Leschziner[3], S. Reck-Peterson[1]; [1]Department of Cell Biology, Harvard Medical School, Boston, MA, [2]Faculty of Biological Sciences, University of Leeds, Leeds, United Kingdom, [3]Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA

Cytoplasmic dynein, the large microtubule-based motor protein, is carefully controlled in cells, enabling it to be deployed to specific sites, collect cargoes, and transport them towards the microtubule minus end at set times. Dynein's "engine" is evolved from ring-shaped AAA+ ATPases, and its microtubule-binding domain lies at the tip of a coiled-coil stalk, but how these elements might be acted upon to achieve control remains unknown. Here, using purified proteins from *Saccharomyces cerevisiae*, we dissect how cytoplasmic dynein is controlled by two of its ubiquitous regulators: Lis1/Pac1 and Nudel/Ndl1. By single-molecule microscopy, we find that Lis1 slows dynein velocity, prolongs its encounters with microtubules, and is tethered to dynein by Nudel. High-precision analysis shows that dynein-Lis1 undergoes frequent "anchored" cycles, during which ATP is consumed without the usual microtubule release and forward motion. Unexpectedly, the structural basis for these changes involves Lis1 binding at the interface between dynein's ATPase domain and its microtubule-binding stalk. Lis1 is thus ideally situated to alter allosteric communication in cytoplasmic dynein, which could facilitate its control and function in cells. *J. Huang and A. Roberts contributed equally to this work.*

903

Inhibition of cytoplasmic dynein motility by a microtubule-binding protein, She1.

S. Markus[1], K. Kalutkiewicz[1], W-L. Lee[1]; [1]Biology, University of Massachusetts Amherst, Amherst, MA

She1 (sensitive to high expression-1) has been implicated in modulating cytoplasmic dynein function in *S. cerevisae* by regulating the association between dynein and dynactin at microtubule plus ends and the cell cortex. We find that overexpression of She1 in yeast severely compromises dynein activity and results in the mislocalization of dynein along the length of astral microtubules, suggesting that She1 affects the microtubule-binding behavior of dynein. To test the effects of She1 on dynein motility, we have produced a recombinant HALO-tagged variant of She1 from bacteria. She1-HALO binds directly to microtubules with high affinity and exhibits diffusive behavior along reconstituted microtubules. Using a GFP-tagged full-length dynein heavy chain (Dyn1-GFP) purified from yeast, we examined the ability of She1 to affect dynein motility in vitro at single-molecule resolution using time-lapse total internal reflection fluorescence microscopy. Remarkably, She1 reduced the velocity and increased the dwell time of Dyn1-GFP in a concentration-dependent manner. Using a motility-competent tail-less dynein construct (GST-Dyn1$_{MOTOR}$-GFP), we found that this effect is mediated via the motor domain, not the N-terminal tail domain where dynactin associates. We demonstrated that the effects of She1 are specific to dynein, since She1 had no effect on the motile behavior of either Kip2, a yeast kinesin-7 that walks along astral microtubules, or a human conventional kinesin (kinesin-1). The effects of She1 on dynein motility are unique from those previously described for Tau, which causes reversals of direction for dynein and dissociation of kinesin-1 from the microtubule track. Thus, She1 affects dynein activity in budding yeast by at least two distinct mechanisms:

1) regulating the association between dynein and dynactin, and 2) regulating the motility of the dynein motor along astral microtubules.

904

Rotation of microtubules driven by *Tetrahymena* 22S outer arm dynein and its sub-particles.

S. Yamaguchi[1], Y. Y. Toyoshima[1], J. Yajima[1]; [1]Department of Life Sciences, Graduate School of Arts & Sciences, The University of Tokyo, Meguro-ku, Japan

Axonemal dynein is the molecular motor that provides motive force in cilia and flagella. *Tetrahymena* 22S outer arm dynein, which is localized between the outer-doublet microtubules, consists of three different heavy chains, termed α, β and γ, and is decomposed into two-headed βγ sub-particle and one-headed α sub-particle by chymotryptic digestion. While motile activity of βγ sub-particle has been already reported, motile activity of α sub-particle has not been shown yet. In this study, we examine whether the α sub-particle has the motile activity, using three-dimensional tracking of a quantum dot attached to microtubules in an *in vitro* motility assay [1] to directly visualize the motion of the microtubule driven by α sub-particles. We found that surface-attached α sub-particles drove not only on-axis microtubule sliding, but also clockwise rotation of each microtubule around its axis. Rotational pitch determined by fitting the *xy*-position of a quantum dot with a sine function varied from 0.8 μm to 0.4 μm with increasing ATP concentration from 1 μM to 10 μM. Applying this method to intact 22S dynein, we also found that the 22S dynein induced rotation of sliding microtubules. The pitch varied from 1.7 μm to 0.7 μm with increasing ATP concentration from 1 μM to 10 μM. These corkscrewing motions of microtubules have not been seen previously for both 22S dynein and its α sub-particle, and it demonstrates that both 22S dynein and its α sub-particle produce torsional forces as well as axial sliding forces. Our results suggest that torque generation by the three-headed 22S dynein is not due to cooperation between each of the three heads, but due to the intrinsic property of individual heads. The relatively longer pitch caused by 22S dynein than by its α sub-particle may be attributed to the competition among three different heads. To comprehend regulation of cilia beating, it may be necessary to consider influence of the torsional forces generated by axonemal dyneins.

905

Neurodegenerative Mutations in Dynactin Disrupt the Initiation of Transport from the Distal Axon.

A. J. Moughamian[1], E. L. Holzbaur[1]; [1]Physiology, University of Pennsylvania, Philadelphia, PA

Dynactin is a required cofactor for the minus-end directed microtubule motor cytoplasmic dynein. Mutations in the CAP-Gly domain of the $p150^{Glued}$ subunit of dynactin cause two distinct neurodegenerative diseases, an inherited form of Parkinson's disease, Perry syndrome, and distal hereditary motor neuropathy 7B (HMN7B). The mechanism by which the CAP-Gly domain promotes dynein motor function remains unclear and how these distinct point mutations within the same protein domain cause two disparate diseases is unknown. Here, we report a novel function of the CAP-Gly domain of dynactin. We show that wild-type $p150^{Glued}$accumulates in distal neurites, while the N-terminal truncation construct, ΔCAP-Gly $p150^{Glued}$, does not. These data show that the CAP-Gly domain is necessary to enrich dynactin in distal neurites. Using live-cell imaging in primary neurons we show that the CAP-Gly domain is not necessary for sustained vesicle transport. Knockdown of $p150^{Glued}$ inhibits the motility of lysosomes while rescue with either wild-type or ΔCAP-Gly $p150^{Glued}$ completely prevents this disruption. However, using fluorescence recovery after photobleaching, we show that expression of wild-

type p150^{Glued} is necessary for efficient flux of lysosomes from the distal axon, as expression of ΔCAP-Gly p150^{Glued} decreases flux from the distal neurite by 65%. These data suggest that the CAP-Gly domain is critical to facilitate the initiation of transport from the distal axon. We studied the disease-associated mutations using biochemical and live-cell imaging assays to further investigate the function of dynactin in neurons. We show that the different mutations induce distinct disruptions in intracellular motility. We show that the HMN7B mutation destabilizes the CAP-Gly domain, preventing efficient incorporation of the mutant protein into the dynein-dynactin complex and effectively disrupts axonal transport by acting as a dominant-negative inhibitor of dynein motor function. In contrast, we show that mutations in dynactin linked to Perry syndrome cause a loss of CAP-Gly function that does not affect retrograde transport but results in a failure to localize p150^{Glued} in distal processes, leading to an inhibition of transport initiation. Together, our observations indicate that dynactin enhances dynein-mediated transport and the efficient initiation of axonal transport through distinct mechanisms. These distinct mechanisms provide the basis to explain the cell-type specific degeneration observed in these two diseases.

PKA phosphorylation of cytoplasmic dynein activates recruitment to adenovirus.

J. Scherer[1], R. B. Vallee[1]; [1]Pathology and Cell Biology, Columbia Univ, New York, NY

Adenovirus 5 (Ad5) enters the host cell after initial binding to cell surface receptors (e.g. CAR and α5 integrins), which increases intracellular PKA and p38/MAPK activity and leads to receptor-mediated endosomal uptake of virions. After endosomal escape, Ad5 relies on cytoplasmic dynein for transport from the cell periphery to the nucleus. We previously reported that Ad5 recruits dynein through direct interactions of the dynein IC and LIC subunits with the major adenovirus capsid protein hexon (Bremner et al., *Cell Host Microbe*, 2009). These interactions depended on short-term low pH exposure of hexon, suggesting that passage through the acidic lumen of the endosome primes the adenovirus capsid for dynein recruitment. We now find that exposure of the dynein complex to phosphatases substantially reduces the interaction of the motor protein with hexon and that phosphorylation of dynein with PKA rescues this effect. These data suggest that an important result of adenovirus-induced PKA activation (Suomalainen et al., *EMBO J*, 2001) is to promote dynein recruitment. The underlying molecular events accompanying this activity are under investigation.

Regulation of Cytoplasmic Dynein in T cell Activation-Induced Microtubule-Organizing Center (MTOC) Reorientation.

X. Liu[1], E. J. Quann[2], M. Huse[2]; [1]Immunology and Microbial Pathogenesis Program, Weill Cornell Graduate School of Medical Sciences, New York, NY, [2]Immunology Program, Memorial Sloan-Kettering Cancer Center, New York, NY

Upon activation, T cells rapidly reorient their MTOCs towards the immunological synapse (IS), the contact site with the antigen-presenting cell. This creates a target for directional transportation of cytokines and lytic factors towards the IS, ensuring the specificity of secretion and preventing bystander effects. Cytoplasmic dynein is recruited to the IS downstream of T cell receptor (TCR) stimulation and is involved in driving MTOC reorientation. However, how dynein is recruited and regulated at the IS remains unclear. In this study, we combined photoactivation of the TCR with total internal reflection fluorescence (TIRF) microscopy to analyze dynein recruitment dynamics and function during MTOC polarization to the IS in primary mouse T cells. Using fluorescently labeled dynein intermediate chain (IC), we found that dynein was recruited to the IS prior to MTOC reorientation. This recruitment was independent of the microtubule

network, as it could not be inhibited by the microtubule depolymerizing agent nocodazole. Silencing of dynein IC by shRNA greatly reduced MTOC reorientation in T cells, confirming a requirement for dynein in the process. In a subsequent screen to identify potential dynein regulators at the IS, we found that two dynein co-factors, dynactin and Lis1, were recruited to the IS at the same time as dynein. To determine the role of dynactin in MTOC reorientation, we used shRNA to silence the dynein binding subunit $p150^{Glued}$ and observed only a subtle defect in MTOC reorientation, suggesting that dynactin is not absolutely required for the process. Consistent with this result, we observed a substantial reduction in dynactin recruitment to the IS in dynein IC silenced cells, indicating that dynactin recruitment is dependent on dynein. To determine the role of Lis1, we transduced T cells homozygous for a floxed Lis1 allele with cre recombinase. We found that suppression of Lis1 dramatically impaired MTOC reorientation, indicating that it is functionally important for the process. Currently we are investigating the role of Lis1 in recruiting dynein to the IS. Taken together, our results suggest that dynein is involved in positioning the MTOC at the IS, and its function at the IS is differentially regulated by dynactin and Lis1.

Human T-cell Leukemia Virus type-1 Binds Microtubule-dependent Motor Protein, Cytoplasmic Dynein.

S. L. Ontiveroz[1], L. Caudillo[1], T. Gibson, Ph.D.[1]; [1]Univ Texas-Permian Basin, Odessa, TX

The Human T-cell leukemia virus type-1 (HTLV-1) affects an estimated 10-20 million people worldwide. It is believed to be the causative agent of adult t-cell leukemia (ATL) and HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP). To initiate a successful infection HTLV-1 must bind to the cell, penetrate into the cytosol, deposit its genome into the host cell cytoplasm and progress to the nucleus in order for the virus to replicate. Previous studies have shown HTLV-1 infection is dependent upon interactions between the virus and host cell cytoskeleton. Specifically, researchers have illustrated that HTLV-1 intracellular movement is dependent upon microtubules. Our laboratory proposes that HTLV-1 utilizes microtubule-based motor protein, cytoplasmic dynein, to translocate from the cell periphery to the nucleus. We have conducted immunocytochemistry and immunopreciptation experiments. Results from these experiments suggest that HTLV-1 interacts with cytoplasmic dynein two hours post infection. Our lab is embarking to understand how the recruitment of cytoplasmic dynein to human T-cell leukemia virus occurs. We have purified the HTLV-1cytoplasmic dynein from infected HEK 293 cells. Currently, we are investigating if dynactin, a cytoplasmic dynein-binding partner, is a component of the HTLV-1 cytoplasmic dynein protein complex.

Differential roles for NudE and NudEL in nuclear migration in the developing brain.

S. Kemal[1], R. Vallee[1]; [1]Pathology and Cell Biology, Columbia University, New York, NY

Radial glial progenitor cells in the developing neocortex undergo cell cycle dependent interkinetic nuclear migration (INM). We have found apical nuclear migration to be carried out by dynein, and basal nuclear migration by kinesin-3 (Tsai et al. *Nat. Neurosci.* 2010, 13:1463-71). A number of dynein regulatory factors are also involved in brain development, including LIS1 and its interactors NudE and NudEL. NudE has been found to recruit LIS1 to dynein to adapt it for high load transport (McKenney et al. *Cell.* 2010, 141(2):304-14). NudE and NudEL are closely related (55% identity; 70% similarity), but the brain developmental phenotypes of NudE and NudEL knockout mice are very different, either due to differences in expression or function. Using *in utero* electroporation followed by fixed and live cell imaging, we have tested the effects

of NudE and NudEL RNAi on INM. NudE RNAi resulted in strong early inhibition of INM with severe defects in apical nuclear migration and a complete failure to enter mitosis. NudEL RNAi, in contrast, had no effect on INM and cells divided as normal at the ventricular surface. Both NudE and NudEL RNAi, however, led to an accumulation of multipolar cells in the SVZ, whereas further migration through the IZ to the cortical plate appeared to be blocked, an effect rescued by RNAi-insensitive NudE expression. These results identify NudE as the isoform specifically required for INM, and identify both common NudE and NudEL functions as regulators of the multipolar to bipolar transition and migration of postmitotic neurons. Supp. by NIH HD40182.

Single-Particle Tracking of Dynein-mediated EGF transport through the endosomal system.

A. L. Zajac[1], E. M. Ostap[2], E. L. Holzbaur[2]; [1]Cell and Molecular Biology Graduate Group, University of Pennsylvania, Philadelphia, PA, [2]Pennsylvania Muscle Institute, University of Pennsylvania

Endocytosed cargo destined for degradation must be sorted through multiple compartments in the endosomal system before its arrival in perinuclear lysosomes. Cargo endocytosed at the edge of the cell may travel tens of microns on a complicated cytoskeletal network of actin and microtubules in order to reach lysosomes. Isolated endosomal compartments contain multiple types of actin and microtubule motors, suggesting the cargo coordinates motors for transport during its journey. To better understand how an endogenous cargo uses motors and the cytoskeleton for transport we used live-cell imaging of endocytosed epidermal growth factor attached to quantum dots (EGF-Qdots), a cargo that is destined for the lysosome. Low-angle oblique, simultaneous multicolor acquisition microscopy has allowed us to track EGF-Qdot movements in epithelial cells with high temporal (50 ms) and spatial (20 nm) resolution relative to endosomal and cytoskeletal markers. Tracking the path of EGF-Qdots from time of binding to cells to perinuclear accumulation shows that they are transported in short bursts of fast centripetal movement with very few anterograde runs. The fast movement is along microtubules and is punctuated by long pauses or bouts of diffusive motion. 79% of the EGF-Qdot track lifetimes were spent paused and 21% spent moving. The average speed during the runs was 2.5um/sec and the average run time was 4 seconds. Disruption of the dynein/dynactin complex, the major retrograde motor in the cell, leads to loss of these fast runs consistent with dynein driving centripetal movement of early endosomes to the perinuclear region for maturation and sorting. Dynein/dynactin disruption also results in dispersion of these static early endosomes throughout the cell. In contrast, lysosomes respond to dynein/dynactin loss by accumulating at the cell periphery and anterograde runs can still be observed, suggesting the highly biased centripetal early endosome movement might be due to the lack of competing anterograde motors seen on lysosomes. These observations suggest that high resolution tracking of single cargos moving through the endosomal system will provide new insights into the cytoskeletal and motor interactions that drive this process.

Microtubule Motor Proteins Drive Nuclear Rotation and Translocation in Developing Skeletal Muscle Cells.

M. Wilson[1], E. Holzbaur[1]; [1]Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA

During development, dynamic interactions between the cytoskeleton and nuclear envelope proteins drive the movement and positioning of nuclei. In skeletal muscle, nuclei become

distributed evenly along the length of the mature syncytial myofiber. Here, we aim to understand the mechanisms driving nuclear movement in developing skeletal muscle cells. Using the well-characterized C2C12 mouse cell line as a model of myotubes, we show that nuclei actively translocate along the long axis of the cell. During translocation, we find that nuclei often rotate in three-dimensions; both the nuclear envelope and internal structures such as nucleoli rotate together. Within a single myotube, nuclei rotate independently with variable angular velocities and directions. To investigate the contribution of the microtubule (MT) cytoskeleton to nuclear dynamics, we performed live cell imaging of myotubes expressing either GFP-tubulin or GFP-EB3. While most MTs project along the long axis of the myotube in an anti-parallel arrangement, MTs can also polymerize between closely apposed nuclei, as well as along channels or invaginations on the nuclear surface. Depolymerization of the MT network abolishes nuclear rotation entirely, although some translocation persists. Immunofluorescence analysis reveals the presence of both kinesin-1 and dynein on the nuclear envelope. Knock-down of dynein using siRNA caused a ~50% reduction in sustained rotation of the nuclei (>30°/15min). Knock-down of KIF5B or overexpression of a dominant negative kinesin-1 tail domain construct also markedly inhibited rotation, indicating that both plus- and minus-end directed MT motors drive nuclear rotation in myotubes. Moreover, in cells with reduced dynein or kinesin-1 function, nuclei were abnormally clustered, suggesting that proper nuclear dynamics are required for normal distribution of nuclei. We hypothesize that the motors bind to the nuclear envelope through associations with LINC complexes, and that the competition between oppositely-directed microtubule motors is essential for effective nuclear positioning in myotubes.

912

Dynein affects muscle function through mechanistically distinct regulation of muscle size and myonuclear position.

E. S. Folker[1], V. K. Schulman[2], M. K. Baylies[1,2]; [1]Developmental Biology, Sloan-Kettering Institute, New York, NY, [2]BCMB, Weill-Cornell Medical Center, New York, NY

Each cell within an organism bears a distinct morphology that is defined by its size, shape and intracellular organization, all features that are regulated by the cytoskeleton. Muscle is an ideal system for studying morphogenesis because it displays a highly ordered and repetitive structure and the physiological output of its morphogenesis can be readily assessed. The impact of muscle size on function is clear, but defects in myonuclear positioning have also been correlated with muscle disorders, such as centronuclear myopathies and muscular dystrophies. Using Drosophila we have examined the mechanistic contributions of Dynein to embryonic morphogenesis and the impact of altered morphogenesis on muscle function. We have found that Dynein is essential for both muscle extension/growth and myonuclear positioning. Mechanistically, Dynein regulates muscle growth and myonuclear positioning through similar but distinct sets of factors. The Dynein light chain, Dlc90F (Tctex-1), and the Inscuteable/Pins polarity complex are necessary for both Dynein dependent muscle growth and Dynein dependent myonuclear positioning. However, Lis1 is necessary only for Dynein dependent muscle growth, whereas CLIP-190 contributes only to Dynein dependent myonuclear positioning. Moreover, CLIP-190 and Lis1 do not functionally interact illustrating that Dynein dependent muscle growth and Dynein dependent myonuclear positioning are indeed distinct pathways. These morphogenetic defects are maintained through larval development: Lis1 mutations affect muscle growth, CLIP-190 mutations affect nuclear spacing, and Dynein mutations affect both muscle growth and nuclear spacing. Finally, defects in muscle size, myonuclear positioning or both, result in larvae that crawl more slowly than controls, indicating that muscle function is also impaired. These data illustrate for the first time that Dynein regulates two distinct aspects of muscle morphogenesis, muscle size and myonuclear positioning, and that both processes are necessary for proper muscle function. Moreover, we

have shown that the contribution of Dynein to these two processes is mechanistically distinct and have identified CLIP-190 and Lis1 as the factors that specify Dynein activity in these contexts. The separation of function provides a system to further investigate the molecular mechanisms controlling growth and myonuclear positioning and evaluate their relative importance to muscle function.

913

Muscle differentiation and function require the interplay between microtubules and MAPs to correctly position myonuclei.

V. K. Schulman[1,2], E. S. Folker[2], T. J. Metzger[1,2], M. K. Baylies[2]; [1]Weill Cornell Graduate School of Medical Sciences, New York, NY, [2]Developmental Biology, Sloan-Kettering Institute, New York, NY

Proper cellular organization and morphogenesis are critical for cell function. Nuclear positioning is a poorly understood process that is particularly important in multinucleated cell types such as muscle. Within each syncytial myofiber, the nuclei are positioned to maximize internuclear distance. Disruptions of this organization, whereby the nuclei become clustered together, are associated with disease states. Nevertheless, little is known about the mechanisms underlying proper myonuclear positioning and whether mispositioned nuclei are a cause or consequence of muscle disease. To study this process, we used the genetically and optically tractable model organism, Drosophila melanogaster. In wild-type embryos, the nuclei in the lateral transverse (LT) muscles are evenly distributed along the length of the myofiber. Through mutational analysis, we have found that the spacing of nuclei is microtubule (MT) dependent, and we have identified Kinesin, cytoplasmic Dynein, and Ensconsin (Ens/MAP7) as necessary proteins for proper nuclear positioning. Because Ens is a MAP that can regulate interactions between the motor protein Kinesin and MTs in the ovary, we hypothesized that the interplay between Ens and motor proteins also regulates myonuclear positioning. We found that both cytoplasmic Dynein and Kinesin functionally interact with Ens during myonuclear positioning. These mutants had correct nuclear numbers and tendon attachments, suggesting that the effect on nuclear position is specific. Most importantly, we found that defects in myonuclear position tightly correlate with muscle weakness as mutant Drosophila larvae crawl more slowly than unaffected larvae toward a stimulus. Collectively, these data suggest that the process of myonuclear positioning is microtubule dependent, requiring the motor proteins Kinesin and cytoplasmic Dynein, and that proper myonuclear positioning is essential for muscle morphogenesis and function.

914

Identification of novel pathways that cooperate with kinesin-5 to drive bipolar spindle assembly.

R. van Heesbeen[1], J. Raaijmakers[1], J. Meaders[1], R. Medema[1], M. Tanenbaum[1]; [1]The Netherlands Cancer Institute, Amsterdam, Netherlands

Bipolar spindle assembly is an essential process during cell division. Spindle bipolarity is setup in two steps. During prophase, the two centrosomes migrate around the nuclear envelope (NE) to opposite sides. Second, during prometaphase the NE disassembles and the characteristic bipolar spindle assembles. It is known that the highly conserved homotetrameric microtubule motor kinesin-5 (also known as Eg5), which can slide microtubules apart, is absolutely essential both for centrosome separation in prophase and for bipolar spindle assembly. However, there is evidence suggesting that additional redundant pathways might exist as well. To identify additional pathways for bipolar spindle assembly, we performed a series of â€œdirected evolutionâ€ experiments in vitro in which cells were treated with increasing concentrations of

the kinesin-5 inhibitor STLC, to generate cells can form bipolar spindles independently of kinesin-5 activity. Strikingly, these cells not only form bipolar spindles in the absence of kinesin-5 activity, but also are able to separate their centrosomes during prophase. By characterizing these cells in more detail, we identified several redundant mechanisms that cooperate with kinesin-5 to drive centrosome separation and bipolar spindle assembly.

915

The MAP Kinase Pathway Regulates Cytoplasmic Dynein Binding to Endosomes.

D. Mitchell[1], K. Blasier[1], E. Jeffery[1], J. Trinidad[2], D. Hunt[1], K. Pfister[1]; [1]University of Virginia, Charlottesville, VA, [2]University of California-San Francisco

Dynein is the motor for vesicle trafficking toward microtubule minus-ends but little is known about how dynein binding to specific vesicles is regulated. PC12 cells and neurons recruit dynein to signaling endosomes formed in response to neurotrophin binding to receptor kinases (Trks). Using mass spectrometry, we identified a novel phospho-serine on the IC2 subunit of dynein isolated from neurotrophin-treated PC12 cells. In addition, the comparable phospho-IC1 site was found in dynein from cultured neurons. In both cell types, a phospho-IC specific antibody showed a time dependent increase in IC phosphorylation in response to neurotrophin. The MAP kinase, Erk1/2, a major downstream effector of Trk, was proposed to phosphorylate the sites by kinase prediction algorithms. The MAP kinase kinase (MEK) inhibitor, U0126, and the Trk kinase inhibitor, K252a, but not inhibitors of other downstream effectors of Trk, blocked the neurotrophin induced IC phosphorylation in both cell types. To investigate the role of the phospho-IC in living cells, we made mRFP-tagged IC-WT, S/A dephospho- and S/D phospho-mimic mutants. The S/A dephospho-mimic, but not the S/D, mutant had significantly less co-localization with endosomes relative to WT. In PC12 cells, IC2 S/A mutant co-localization with TrkA was reduced 50%. In cultured neurons, IC1 S/A mutant co-localization with TrkB and rab7 (late endosomes) was reduced by 70% and 40% respectively relative to WT. When neurons were treated with U0126 under conditions that significantly reduced the amount of IC1 phosphorylation (~50%), the motilities of TrkB, rab7, and IC1 in axons were comparably reduced. In addition, there was a 2.4 fold enrichment of the phosphorylation on ICs that co-purify with vesicles relative to cell lysates, and treatment of PC12 cells with U0126, before neurotrophin addition, reduced by 70% the amount of dynein that co-purified with signaling endosomes. Collectively these studies show that MAP kinase phosphorylation of the ICs is necessary for dynein binding to and transport of endosomes.

916

The Drosophila homolog of ARFAPTIN2 (DARFIP2) reveals a novel role for dynactin function at the golgi during presynaptic growth.

L. Chang[1], Y. Wu[1], A. Rothenfluh[2], B. Eaton[1]; [1]Physiology, University of Texas Health Science Center at San Antonio, San Antonio, TX, [2]Psychiatry, University of Texas Southwestern Medical Center at Dallas, Dallas, TX

Analysis of motor neurons in DCTN1/P150/Glued mutants in mice and flies have revealed a number of neuronal phenotypes including reduced synapse growth, reduced synaptic stability, impaired axonal transport, and disrupted Golgi structure. It is unclear whether these disparate phenotypes are the result of a singular mechanism or represent the combined effects of multiple dynactin-dependent mechanisms within the motor neuron. Previous studies suggest that individual dynactin-dependent processes including synapse growth and synaptic stabilization can be genetically separated but evidence for this is lacking. For example, we predict that there exists a unique set of genes that function to specify dynactin complex function during synapse growth independent of other dynactin-dependent processes such as synaptic stability and

axonal transport. To address this hypothesis, we have performed a large genetic screen to identify critical molecules responsible for specifying dynactin complex function during synapse growth at the NMJ. A motor neuron specific enhancer/suppressor screen of 3663 independent P-element insertion lines was performed to identify insertions that modified the viability of dynactin complex mutants. Secondary analyses isolated 40 individual enhancers and suppressors that were subsequently processed for synapse growth, synaptic stabilization, and axonal transport. This approach has identified mutations in the *Drosophila* homolog of *Arfaptin2* (*Darfip2*) that specifically impair dynactin-dependent synapse growth but not synaptic stabilization or axonal transport. The Darfip2 protein belongs to an interesting class of proteins that contain a BAR domain. BAR domains are protein sequences that mediate membrane binding and have been implicated to function during vesicle formation and membrane trafficking. Analysis of *Darfip2* mutants finds that Darfip2 is required presynaptically for normal synapse growth, but not axonal transport or synapse stability. Biochemical analysis demonstrates that Darfip2 is present in dynactin complexes isolated from fly brains. In addition, Darfip2 is able to mediate the association of the dynactin complex with isolated membranes. Localization studies in motor neurons find that Darfip2 is concentrated at the TGN and that this localization requires a functional BAR domain. Importantly, Darfip2 localization to the TGN is required for normal synapse growth. These studies of Darfip2 suggest a novel regulatory mechanism linking the coordination of dynactin complex function and vesicle formation at the TGN during presynaptic growth.

Mechanotransduction I

Understanding the Cooperative Interaction between Myosin II and Actin Crosslinkers Mediated by Actin Filaments during Mechanosensation.

T. Luo[1], Y. Ren[1], P. Iglesias[2], D. Robinson[1]; [1]Johns Hopkins School of Medicine, Balitmore, MD, [2]Johns Hopkins University

Myosin II is a central mechanoenzyme in a wide range of cellular morphogenic processes. Its spatial distribution is dependent not only on signal transduction pathways, but also on mechanical stress. In experiments, we found that myosin II and cortexillin (an actin-crosslinking protein) displayed cooperative accumulation at highly deformed sites in response to external forces and the extent of accumulation increased with the applied force. Additionally, the accumulation rate increased with time under constant mechanical stimuli. We suggest that this stress-dependent accumulation is the result of both the force-dependent binding to actin filament and cooperative interactions between bound myosin heads. The majority of the accumulated myosin comes in monomer form from other regions by diffusion and this kind of transport involves the turnover dynamics of basic functional unit of myosin II, the bipolar thick filament (BTF). For a quantitative interpretation of the in vivo cell behaviors, we developed a multi-scale model that integrates the cooperative interactions and the BTF turnover dynamics. By assuming that the binding of myosin heads causes local conformational changes in the actin filaments which enhances myosin II binding locally, we successfully simulated the cooperative binding of myosin to actin observed experimentally. In addition, we can interpret the cooperative interactions between myosin and actin-crosslinking proteins observed in cellular mechanosensation, provided that the same mechanism operates among different proteins. Finally, we present a scheme that couples cooperative interactions to the assembly dynamics of myosin bipolar thick filaments and accounts for the transient behaviors of the myosin II

accumulation during mechanosensation. This mechanism is likely to be general for a range of myosin II-dependent cellular mechanosensory processes.

918

Interplay between cytoskeletal forces, membrane tension, and hydrostatic pressure in rapidly migrating cells.

C. Gabella[1], C. Bottier[1], E. Bertseva[1], I. F. Sbalzarini[2], J-J. Meister[1], A. B. Verkhovsky[1]; [1]Ecole Polytechnique Fédérale de Lausanne, Switzerland [2]ETH Zurich

In motile cells, membrane pressure at the membrane/cytoplasm interface is balanced by the cytoskeletal forces and hydrostatic pressure. In particular, it is believed that protrusion of the lamellipodia is controlled by the balance of membrane pressure and the pressure generated by actin polymerization, while bleb formation results from the balance of membrane pressure and hydrostatic pressure. However, exact contributions of these forces to the cell shape and motion are not known. Membrane pressure is a product of tension and local curvature of the membrane; thus, to know the membrane pressure one has to know the exact three-dimensional shape of the cell. We have developed a simple approach to measure cell vertical profile and volume, which is based on the displacement of the fluorescent cell-impermeable dye dissolved in the medium. To get insight into the balance of forces at the membrane interface, we measure membrane tension (with tether assay), protrusion velocity, vertical profile, and volume dynamics in migrating fish epidermal keratocytes subjected to cytoskeletal drugs and volume perturbations. Inhibiting myosin-dependent contraction with blebbistatin resulted in irregular cell shape, and reduced protrusion velocity and membrane tension (variable and low tether forces as compared to a force distribution centered around 35-40 pN in control cells). Remarkably, hypoosmotic treatment normalized blebbistatin-treated cells by restoring their tension, protrusion velocity, and shape, and also increased tension and protrusion velocity in control cells. In general, treatments inducing increase in membrane tension and hydrostatic pressure also increased cell velocity, while treatments decreasing membrane tension decreased cell velocity. Vertical profile measurements showed that hypoosmotic treatment induced persistent cell swelling and substantial increase in the height of the lamellipodia. We propose that hydrostatic pressure that could be generated due to either myosin-dependent contraction or osmotic gradient helps to maintains optimal vertical profile of the lamellipodium and thus cooperates with actin-dependent protrusion. Supported by Swiss National Science Foundation, Swiss SystemsX and NCCBI.

919

Mechanotransduction response in corneal cells is mediated by YAP pathway.

V. Raghunathan[1], B. Dreier[1], P. Russell[1], C. J. Murphy[1,2]; [1]Department of Surgical and Radiological Sciences, School of Veterinary Medicine, University of California Davis, Davis, CA, [2]Department of Ophthalmology and Vision Science, School of Medicine, University of California Davis, Davis, CA

Corneal wound healing is influenced by the extracellular environment both through soluble signals and from biophysical cues such as substratum topography and matrix stiffness. These cues profoundly influence phenotypic characteristics of cells such as adhesion, migration, shape, size and proliferation. These changes are mediated by activation/inhibition of specific signaling pathways. Human corneal epithelial and stromal cells have been demonstrated to remodel their cytoskeleton and orient differentially on anisotropically patterned substrates possessing biological length-scale, accompanied by changes in nuclear height, volume, area and orientation. However, there still remains a considerable knowledge gap in understanding the role of cell signaling pathways in response to biophysical cuing and mechanotransduction.

YAP (Yes-associated protein) and TAZ (WWTR1; transcriptional coactivator with PDZ-binding motif), two important signaling molecules of the Hippo pathway, have recently been implicated as nuclear relays to mechanical cues sensed by cells. We investigated the effects of nano through micron scale topographic features and substrates of various elastic moduli in altering the YAP/TAZ pathway in human corneal epithelial and stromal cells.

Immortalized corneal epithelial cells (hTERT) and primary corneal stromal fibroblasts were cultured on planar or topographically patterned substrates with biologically relevant dimensions (pitch sizes of 400, 1400 and 4000 nm; pitch = ridge width + groove width) for 12 h, or on planar substrates of differing elastic moduli [Tissue Culture Plastic (TCP), acrylamide hydrogels of biomimetic elastic moduli (5 kPa, 25 kPa, and 75 kPa)] for 48 h. RNA was isolated and the expression of YAP, 14-3-3σ and Transforming Growth Factor beta-2 (TGFβ2) was determined by qPCR.

A cell dependent and differential response to topography was observed. Corneal epithelial cells were most responsive to 400 nm pitch topography with upregulation in YAP, 14-3-3σ, and TGFβ2. Alterations in YAP or 14-3-3σ were not detected in fibroblasts on any topographically patterned surface. TGFβ2 was upregulated in fibroblasts on 400, 1400 and 4000 nm pitches. While, YAP, WWTR1, and 14-3-3σ expression were significantly upregulated on 25 and 75 kPa hydrogels in epithelial cells, YAP remained unaltered in fibroblasts on all compliances. Interestingly, 14-3-3σ expression in fibroblasts was significantly down-regulated while TGFβ2 was up-regulated on 25 kPa hydrogels.

The biophysical attributes of the microenvironment of corneal cells cause changes in cell morphology and are capable of altering cell signaling. Our results strongly suggest that YAP, WWTR1, 14-3-3σ and TGFβ2 play fundamental roles in regulating how corneal cells respond to their biophysical microenvironment.

920

Netrin-1 Regulates Pak1-mediated Phosphorylation of Shootin1: Modulation of Clutch Activity of Shootin1 for Axon Outgrowth.

M. Toriyama[1], N. Inagaki[1]; [1]Laboratory of Neuronal Cell Morphogenesis, Nara Institute Science and Technology, Ikoma, Japan

Axon outgrowth is a critical process for neuronal circuit formation in developmental brains. The clutch system is thought to account for how neurons generate traction force at the growth cone for neurite outgrowth. The clutch system consists of three components: retrograde flow of treadmilling actin filaments, cell adhesion molecules, and clutch molecules which transmit the driving force of actin filament retrograde flow to cell adhesion molecules. Previously, we reported that shootin1 functions as a clutch molecule which links actin filaments and L1-CAM to promote axon outgrowth. It is assumed that spatial-temporal regulation of clutch activity by extracellular signals is one of mechanisms involved in directional axon outgrowth and cell migration, however, how the clutch activity is regulated is poorly understood.
In this study, we show that p21-activated kinase 1 (Pak1) phosphorylates shootin1. Netrin-1, an attractive axon guidance molecule, stimulated Pak1-mediated phosphorylation of shootin1 in cultured neurons. Single-molecule fluorescent speckle analysis revealed that the phosphorylation of shootin1 is required for its association with actin filament retrograde flow at axonal growth cones. Overexpression of wild type and phosphomimic form of shootin1 facilitated axon outgrowth, whereas overexpression of the nonphosphorylated form did not. Inhibition of Pak1 activity suppressed the localization of shootin1 at growth cones and axon outgrowth. These results suggest that an extracellular signal regulates shootin1 association with

actin filament retrograde flow through its Pak1-mediated phosphorylation, thereby modulating its clutch activity for axon outgrowth.

921

Modulation of mechanosensitive TRPC1 channels on filopodia activates calpain to guide spinal axons.

P. C. Kerstein[1], B. T. Jacques-Fricke[1,2], T. M. Gomez[1]; [1]Neuroscience, University of Wisconsin-Madison, Madison, WI, [2]Genetics, Cell Biology, & Development, University of Minnesota, Minneapolis, MN

Intracellular Ca^{2+} signals control the development and regeneration of spinal axons downstream of chemical guidance cues, but little is known about the roles of mechanical cues in axon guidance. Here we show that transient receptor potential canonical 1 (TRPC1) subunits assemble mechanosensitive channels on neuronal growth cones that regulate the extension and direction of axon outgrowth on rigid, but not compliant substrata. Reducing expression of TRPC1 by anti-sense morpholinos inhibits the effects of mechanosensitive channel blockers on axon outgrowth and local Ca^{2+} transients. Ca^{2+} influx through mechanosensitive TRPC1 activates the protease calpain, which likely cleaves Src family kinases and talin to inhibit adhesion turnover and outgrowth. This pathway may also be important in axon guidance decisions since asymmetric inhibition of mechanosensitive TRPC1 is sufficient to induce growth cone turning. Together our results suggest that Ca^{2+} influx through mechanosensitive TRPC1 on filopodia activates calpain to control growth cone turning during development.

922

Myosin-independent and Rac1-mediated ECM rigidity sensing in fibroblasts.

S. P. Winter[1,2], P. W. Oakes[2], M. L. Gardel[2,3]; [1]Interdisciplinary Scientist Training Program, University of Chicago, Chicago, IL, [2]Institute for Biophysical Dynamics and James Franck Institute, University of Chicago, Chicago, IL, [3]Physics Department, University of Chicago

Cells modulate their function and behavior based upon chemical and physical signals that they receive from their extracellular matrix (ECM). For instance, the mechanical rigidity of the ECM impacts cell adhesion, spreading, migration, and proliferation in culture, and has been strongly correlated to tumor progression in situ. ECM rigidity sensing is thought to be mediated by feedback between force generation in the lamellar actomyosin network, maturation of focal adhesions, and resistance by the ECM. Here, we identify a myosin-independent and Rac1-dependent rigidity sensing pathway in NIH 3T3 fibroblasts that plays a crucial role in mediating ECM stiffness-dependent changes in cell adhesion, spreading, and protrusion. We identify a threshold in ECM stiffness required for cell spreading and sustained lamellipodial protrusion in NIH 3T3 fibroblasts. When the shear elastic modulus of the ECM is less than 2 kPa, cells are poorly spread, exhibit small lamellipodial protrusions, and show less frequent nascent adhesion formation. Above this critical ECM stiffness, cell spread area, edge protrusive activity, and adhesion assembly are similar for all ECM stiffnesses ranging from 2.8 kPa – 51 kPa. This ECM rigidity sensing is independent of myosin II activity, as a similar threshold in cell spread area is observed in the presence of saturating concentrations of blebbistatin, a myosin II ATPase inhibitor, or Y27693, a Rho-kinase inhibitor. By expressing a constitutively active Rac1 construct, we can drive spreading of cells adhered to soft matrices to areas comparable to those observed on stiff ECM. Our data is consistent with a mechanosensation pathway occurring in the lamellipodia. This pathway would likely involve feedback between nascent adhesion signaling and Rac1-mediated actin polymerization to drive leading edge protrusion and nascent adhesion formation.

923

ICAP-1 and beta1 integrin modulate adhesion strength and traction force to sense matrix rigidity and control cell migration.

M. Regent-Kloeckner[1], A-P. Bouin[1], M. Balland[2], C. Verdier[2], V. Laurent[2], D. Bouvard[1], E. Planus[1], C. Albiges-Rizo[1]; [1]Institut Albert Bonniot UJF CNRS INSERM, Grenoble, France, [2]LiPhy CNRS/UJF UMR 5588, Saint Martin d'Heres, France

It is well known that cell mechanical properties modulated by extracellular matrix rigidity are crucial in regulating cell migration, cell differentiation and tumour progression. However, it remains unclear how forces are transduced through focal adhesions into biochemical activities and biological responses at the molecular and cellular level. To elucidate the mechanisms which drive cell migration, we examine the organization of adhesions, myosin II, and the actin network and determine adhesive strength and traction force in osteoblasts migrating on deformable substrates. We investigate the contribution of b1 integrin and its cytoplasmic regulator ICAP-1 in the adaptation of the cell to migrate on controlled environment thanks to cells deficient in beta1 integrin and ICAP-1. We show that the deficiency of beta1 integrin is associated with a round and small shape, a reduced number of focal adhesions, a slower migration, low traction forces and low adhesive strength. Surprisingly the additional loss of ICAP-1 rescues the migratory phenotype by increasing cell migration and traction forces without any change in adhesive strength suggesting a new signalling pathway controlled by ICAP-1 and independent on its interaction with beta1 integrin. This beta1 integrin independent signalling pathway seems to be important for extracellular rigidity sensing and ROCK activity control. On the whole our results are consistent with a role of beta1 integrin in adhesive strength and a role of beta1 and ICAP-1 in the control of traction forces. We show that quantitative changes in either adhesive strength or traction forces through a control by beta1 integrin and ICAP-1 can switch osteoblasts among qualitatively distinct migration regimes.

924

ICAP-1 monoubiquitylation regulates cell migration.

A-P. Bouin[1], A-S. RIBBA[1], M. Regent[1], E. Planus[2], C. Albiges-Rizo[1]; [1]Institut Albert Bonniot, Grenoble, France

Cell migration is a complex biological process that requires spatiotemporally regulation of integrin activation, assembly/disassembly of focal adhesion and dynamic organization of actin cytoskeleton. Extracellular matrix rigidity is an external factor influencing cell migration. ICAP-1, a beta1-integrin tail-binding protein, is essential for ensuring integrin activation cycle and focal adhesion formation by interfering with talin binding. In this study, we provide evidence that ICAP-1 function can be regulated by monoubiquitylation. We identified the monoubiquitylation site on ICAP-1. This modification is not involved in protein degradation via proteasome but rather might regulate the assembly and organisation of adhesion sites likely through modulation of protein interactions. Indeed, the monoubiquitylation of ICAP-1 prevents its beta1 integrin binding whereas the non-ubiquitinable form of ICAP-1 interacts with beta1 integrin. Expression of the non ubiquitinable form of ICAP-1 in ICAP-1 deficient cells impacts on beta1 integrin localisation and focal adhesion organization. By testing different matrix rigidities we show that cells expressing the non ubiquitinable form of ICAP-1 exhibit a modification in the matrix density and rigidity sensing which affect cell migration. The monoubiquitylation of ICAP-1 might play a key role in integrin-mediated cell migration through matrix rigidity perception. The using of ROCK inhibitor suggests that this specific role of ICAP-1 is linked to ROCK signalling pathway. Our results show that the ubiquitylation system is integrally involved in the process of cell migration acting as a nodal regulator between partners of beta1 integrin.

The Regulation of Traction Forces through Calpain 4 Mediated Secretion of Galectin-3.

S. Menon[1], C-M. Kang[1], K. A. Beningo[1]; [1]Department of Biological Sciences, Wayne State University, Detroit, MI

As a cell migrates it generates contractile forces. These forces, referred to as traction forces, are generated by the acto-myosin cytoskeleton and transmitted onto the external environment via integrins. However, the signaling mechanism for the production and regulation of these forces are still unclear and is an area of intense study. We have previously found that calpain 4, the small non-catalytic subunit of the proteases Calpain 1 and 2, is involved in the production of traction force. In this function, calpain 4 acts independently of the proteolytic activity of the larger subunits. We are currently working to define the mechanism used by calpain4 in the production of traction force. Using 2-D gel electrophoresis we have identified reduced levels of tyrosine phosphorylation of the protein galectin-3 in calpain 4 deficient cells, when compared to lysates from control and cells deficient in calpain 1 or 2. Galectin-3 is a lectin binding protein and a known regulator of migration and focal adhesion dynamics. Galectin-3 is localized within the cytosol and transiently within the nucleus, and it is also secreted by a currently unknown mechanism. Secreted galectin-3 has been shown to enhance cell adhesion through integrin clustering and focal contact formation. We have discovered that galectin-3 secretion is impaired in calpain 4 deficient cells, possibly due to its defective tyrosine phosphorylation. It is our hypothesis that calpain4 is regulating traction forces by mediating the secretion of galectin-3. Our current studies indicate that recombinant galectin-3 added externally to the media rescues focal adhesion turnover and maturation defects seen in calpain 4 deficient cells. Similarly, addition of recombinant galectin-3 to the media also enhances the adhesion strength of weakly adhered calpain 4 deficient cells. Migration studies performed by time-lapse microscopy with cells cultured on fibronectin coated cover glass also suggest that secreted galectin-3 alters linear speed and directional persistence during migration. Finally, using traction force microscopy, preliminary results further indicate that addition of extracellular galectin-3 can rescue the traction force defect observed in calpain 4 deficient cells. Our results suggest that calpain 4 and galectin-3 are key players in the production of traction force. Together these proteins regulate traction force by a novel mechanism involving internal signaling to strengthen the adhesion structures on the extracellular face of the cell.

A Direct Interaction between the Calpain Regulatory Subunit and an Inducer of Matrix-Metalloproteinases; A Potential Role in Cellular Traction Forces.

B. Hao[1], K. A. Beningo[1]; [1]Biological Sciences, Wayne State University, Detroit, MI

The Calpain family of cysteine proteases has long been implicated in the process of cell migration. Calpain 2 localizes to focal adhesions and functions in the turnover of focal adhesion proteins. To form a catalytically active holoenzyme, the calpain 2 and calpain 1 heavy chains heterodimerize with a common non-catalytic 28-kDa small subunit (calpain 4/*capn4*). Given the function of calpains in the turnover of focal adhesions, we previously investigated the role of calpain in the generation of traction forces and in the sensing of mechanical stimulation from the external environment. Traction forces are generated by the contractile machinery of a migrating cell as it crawls across a substrate. In previous studies we found that perturbation of either calpain 1 or 2 had no effect on the generation of traction force. However, we were surprised to find that traction forces generated by the cell were reduced when the small subunit calpain 4 was silenced. Furthermore, we found that silencing of either calpain 1, 2 or 4 resulted in the inability of the cells to sense changes in mechanical stimulation. These results thus suggest that calpain 4 plays a role independent of the large subunits in traction force production and together

with calpain 1 and 2 in mechanosensing. To gain further insight into how calpain 4 regulates traction force generation and mechanosensing, we performed a yeast two hybrid screen using *capn4* as the bait. A total of eight previously unknown binding partners of calpain 4 were identified. Of particular interest was the membrane protein basigin, also known as CD147 or EMMPRIN (extracellular matrix metalloproteinase (MMP) inducer). Basigin is a single pass transmembrane glycoprotein that contains two Ig domains one of which binds to caveolin-1. It has been found to effect the migration of both normal and cancer cells and the release of MMP's. We have confirmed the direct interaction of calpain4 with basigin through pull-down experiments. We are currently performing migration assay, traction force microscopy and mechanosensing assays on cells silenced for basigin. Preliminary data indicates that basigin deficiency results in a loss of the ability to sense mechanical stimulation just as seen in calpain 4 deficient cells. In addition, early results suggest an increase in traction force in embryonic fibroblasts when basigin is knocked down. In this study we have made the novel discovery of a previously unknown protein-protein interaction between the calpain small subunit and basigin. Further studies are currently underway to define how this interaction contributes to the regulation of traction force.

Endothelial Mechanotaxis in Vascular Remodeling.

E. Tkachenko[1], E. Gutierrez[1], A. Ablooglu[1], S. Saikin[2], C. Kim[1], H. Yang[1], N. Chi[1], A. Groisman[1], M. Ginsberg[1]; [1]Univ California-San Diego, [2]Harvard University

Migration and plasticity of venous endothelial cells (ECs) during development depend on hemodynamic forces and play an important role in vascular remodeling processes. Here, we examined the venous circulation of the zebrafish embryo and found that, in contrast to a widely-held view, venous ECs migrate against the direction of blood flow. Migrating venous ECs invaded intersegmental vessels of arterial origin, indicating that this novel form of mechanotactic migration is relevant to vascular remodeling processes. In a microfluidic in vitro model, we observed that confluent human venous ECs both migrate and polarize against the flow at shear stresses encompassing those in the venous circulation, from an unexpectedly modest 0.45 dyn/cm^2 to 14.5 dyn/cm^2. The polarization of confluent ECs against the flow can be explained by hydrodynamic drag pushing their nuclei downstream. This behavior is in sharp contrast with polarization and migration of non-confluent ECs in the direction of flow that can be due to confluence-dependent differences in the organization of the actin cytoskeleton. Specifically, non-confluent ECs have dense actin bundles in the lamellum preventing the downstream displacement of the nucleus by hydrodynamic forces. We found that in shear flow, disruption of lamellum actin structure in non-confluent ECs by inhibition of myosin II-dependent contractility or of actin polymerization resulted in rapid shift of the nucleus towards the downstream side of the cells and in their polarization against the direction of flow. This new mechanism of mechanotaxis was further confirmed in an experiment where rapid displacement of nuclei in confluent ECs caused their immediate polarization and subsequent directed migration under nearly zero shear stress.

3D Morphogenesis of Epithelial Cells on a Laminin-rich Soft Substrate Induced by Cellular Contractile Force.

M. Imai[1], T. Mizutani[1], K. Kawabata[1], H. Haga[1]; [1]Transdisciplinary Life Science Course, Graduate School of Life Science, Hokkaido Univ., Sapporo, Japan

Collective cell migrations are essential for many physiological events, such as embryonic development, wound healing and tumor invasion. It is known that epithelial cells form 3D

morphology like a cyst and a tube in 3D environment. Our previous studies revealed that MDCK cells formed 3D morphology on top of a laminin-rich soft substrate (Matrigel, BD Biosciences). The appearance of morphologies was like a tulip hat or a tube. Time-lapse observation showed that the cells tugged at the peripheral matrix and remodeled the gel surface morphology. However, the mechanism of the 3D morphogenesis on the soft substrate is unclear.

In the present study, we performed time-lapse imaging by interference reflection microscopy and confocal laser scanning microscopy to observe how MDCK cells form 3D morphology on top of the Matrigel. Fluorescence beads were embedded in the Matrigel to visualize cellular contractile force. Time-lapse imaging showed the 3D morphogenesis of MDCK cells seeded on the Matrigel accompanied with deformation of the gel surface. Furthermore, we focused on this multicelluar behavior with respect to the contractile force of stress fibers consisting of actin and myosin II filaments, dominant driving force of cell migration. Our recent study has revealed that diphosphorylation of myosin II regulatory light chain (MRLC) enhances the degree of traction force. To elucidate the spatial regulation of the traction forces, localization of diphosphorylated MRLC (2P-MRLC) and two isoforms of myosin II heavy chain (MHC-IIA and MHC-IIB) was visualized by immunofluorescence. 2P-MRLC localized along the periphery of the epithelial sheet, and MHC-IIA colocalized with 2P-MRLC, but MHC-IIB did not. These results showed that the contractile force was mainly induced by phosphorylation of MRLC binding with MHC-IIA. Treatment with Y-27632, to inhibit phosphorylation of MRLC and abrogate cellular contractility, stopped the 3D morphogenesis. These results indicated that the cellular contractile force and the deformation of the substrate are critical for 3D morphogenesis of epithelial cells.

Viscoelastic matrix elicits coordinated epithelial migration through actin reorganization.

Y-J. Chiu[1,2], P. Matsudaira[1,2]; [1]Mechanobiology Institute, National University of Singapore, Singapore, [2]Center for BioImaging Sciences, Department of Biological Sciences, National University of Singapore, Singapore

Collective cell migration, fundamental in embryonic development and adult tissue homeostasis, is governed by coordination of cell-cell and cell-matrix adhesions, but the mechanism that regulates reciprocal dynamics of adhesions is unknown. We have recently found that on a viscoelastic matrix of physiological relevance, highly correlated cell movement in an epithelial monolayer is induced, an E- cadherin-dependent phenotype as opposed to autonomous migration observed on stiff substrates. How cells convey mechano-signal from the matrix to adherens junctions and accordingly migrate in a concerted fashion is the main focus of current study. Twelve inhibitors have been used to screen cellular components that are essential for viscoelastic substrate-elicited phenotypes. Our results strongly argue that actin dynamics and actomyosin activity are indispensable for coordinated migration, while PI3K, Src family kinases, β-catenin stability, and microtubule dynamics are possibly involved. Actin organization has subsequently been studied by live-cell microscopy in epithelial sheets migrating on viscoelastic substrates. By imaging Lifeact-GFP, we have observed abundant stress fibers (SFs) and 2D morphology that are indistinguishable from cells on stiff substrates. Nevertheless, deconvolved 3D confocal images reveal distinct distribution of SFs with respect to surface-coated Rhodamine-fibronectin. Although fibronectin coating is essential for cell attachment, on viscoelastic substrates SFs make little connection to fibronectin but lie along the ventral surface, while the tips of SFs often colocalize with fibronectin on stiff substrates. Our study suggests that viscoelastic matrix-induced actin architecture may provide mechanical supports mainly to cell-cell contacts, and hence constitute the mechanistic basis for adherens junction-dependent coordinated migration.

930

Distinct regimes of mechanical propagation at the onset of collective cell migration.

X. Serra-Picamal[1], E. Anon[1,2], X. Trepat[1,3]; [1]Institute for Bioengineering of Catalonia, University of Barcelona, and Ciber Enfermedades Respiratorias, Barcelona, Spain, [2]Matière et Systemes Complexes laboratory, Université Paris Diderot, Paris, France, [3]Institut Català de Rercerca i Estudis Avançats (ICREA), Barcelona, Spain

A variety of fundamental processes in morphogenesis, health, and disease, involve the transition of cell sheets from a static to a migratory phenotype. While the biochemical events that regulate this transition are increasingly well understood under the rubric of the epithelial to mesenchymal transition, the physical forces that initiate and maintain collective cell migration remain unknown. By using polydimethylsiloxane (PDMS) cell micropatterning, traction microscopy, and monolayer stress microscopy, we provide dynamic maps of such physical forces and of the resulting cell velocities. Systematic analysis of these maps reveals an unexpectedly rich physical picture in which a velocity wave propagates away from and back to the leading edge. The direction of propagation defines two distinct mechanical regimes. During inward propagation, cells become motile under low levels of cell-cell stress. By contrast, outward propagation occurs under high and long-ranged levels of tensional stress. These distinct mechanical regimes are paralleled by a dramatic reorganization of stress fibers and cell-cell junctions. Our results demonstrate coupling between cell velocities, traction forces, and stress transmission between cells at the onset of collective cell migration.

931

Overcrowding of epithelia cells induces extrusion to maintain homeostatic cell numbers.

G. T. Eisenhoffer [1], P. D. Loftus[1], M. Yoshigi[2], H. Otsuna[3], P. A. Morcos[4], C-B. Chien[3], J. Rosenblatt[1]; [1]Department of Oncological Sciences, Huntsman Cancer Institute, Salt Lake City, UT, [2]Department of Pediatrics, The University of Utah, Salt Lake City, UT, [3]Department of Neurbiology and Anatomy, The University of Utah, Salt Lake City, UT, [4]Gene Tools LLC, Philmath, OR

For an epithelium to provide a protective barrier, the tissue must properly balance the number of dividing and dying cells to maintain homeostatic cell numbers. While cell division can be triggered by dying cells, how cell death may be utilized to relieve overcrowding due to proliferation is not known. After initiating apoptosis within epithelia, we have shown that dying cells are extruded to preserve a functional barrier. In order to extrude, apoptotic cells produce sphingosine-1-phosphate (S1P), which signals the cooperative assembly of an actin/myosin ring in surrounding epithelial cells that contracts to squeeze out the dying cell. Yet, what promotes cell death during homeostatic turnover in epithelial tissues is not clear. We show that overcrowding induces extrusion of live cells to control epithelial cell numbers. Extrusion of live cells occurs at sites where highest crowding occurs in vivo and can be induced by experimentally overcrowding monolayers in vitro. Like apoptotic cell extrusion, we find that live cell extrusion resulting from overcrowding also requires S1P signaling and ROCK-dependent myosin contraction but is distinguished by upstream signaling through stretch-activated channels. Moreover, we find that blocking stretch-activated channels in developing zebrafish prevents extrusion and leads to the formation of epithelial cell masses, indicating that stretch-activated signaling is critical for maintaining epithelial homeostasis via extrusion. Our findings reveal that during homeostatic cell turnover, division and growth of epithelial cells on a confined substratum causes overcrowding which leads to cell extrusion and subsequent death due to loss of survival factors. Taken together, these results suggest that live cell extrusion could be a tumor suppressive mechanism that prevents the accumulation of excess epithelial cells.

932

Automated Surface Tracking and Morphodynamics Quantification of Endothelial Cells in 3D Gels.

R. S. Fischer[1], H. S. Elliott[2], C. M. Waterman[1], G. Danuser[2]; [1]Cell Physiology, NHLBI/NIH, Bethesda, MD, [2]Cell Biology, Harvard Medical School, Boston, MA

Many non-amoeboid cell types migrate in 3D matrices with complex, branched morphologies. To better understand how these complex changes in 3D cell shape occur over time at both local and global levels, we sought to develop quantitative cell-surface tracking tools that would enable us to quantify cell shape changes in 4D in an unbiased manner. Spinning disk confocal 4D imaging of primary mouse aortic endothelial cells expressing tdTomato-CAAX, a membrane-targeted fluorescent tag, allowed visualization of the cell surface in 3D collagen gels over time. We have developed novel computational image segmentation and analysis tools that allow automated tracking and measurement of pseudopodial branch protrusion dynamics, local cell surface curvature, and branch topological complexity (branch order). To understand the role of myosin II contractility in regulating cell morphodynamics in 3D, we analyzed the effects of pharmacological inhibition of contractility. This revealed that inhibiting contractility increased cell branch number, as well as increased branch topological complexity and protrusion initiation rates from higher order branches. Local cell surface curvature measurements of the plasma membrane demonstrated that increased average surface curvature (both positive and negative) was correlated with decreased myosin II function, even in non-branched regions. These data suggest that not only does myosin II function to inhibit branch complexity and curvature of the cell surface, but also that the local surface curvature variability may be a useful metric in predicting cortical contractility of the actomyosin cytoskeleton. Automated surface and branch tracking algorithm enabled these quantitative observations that would have been difficult or impossible to achieve manually.

933

Mapping Protein Structure Changes in Live Cells by Cysteine Labeling and Mass Spec.

B. C. Chase[1], D. Pantano[2], J. Pajerowski[3], H-Y. Tang[4], D. Speicher[4], D. Discher[1]; [1]Bioengineering, University of Pennsylvania, Philadelphia, PA, [2]University of Pennsylvania, [3]Merck, [4]Wistar Institute

Protein unfolding, disassembly, and aggregation underlie many diseases, but detailed study of these processes in intact cells has been limited. Cysteine Shotgun labeling utilizes cell-permeable fluorescent dyes to label exposed cysteine residues and has been applied to study specific protein structure changes in response to mechanical stress on cells. We have expanded the technique to identify multiple protein changes in live red blood cells and mesenchymal stem cells as a function of mechanical stress and in whole-cell lysates in native versus urea-denaturing conditions as a function of time and temperature (20-45 deg-C). Labeling rate constants are calculated for any given Cys site by normalizing the protein labeling kinetics to the rapid labeling under denaturing conditions in lysates, or static conditions versus shear in live cells. Proteins can be identified and further analyzed by mass spectrometry to pinpoint specific, susceptible domains involved. This analysis has been done on a proteomic scale in cell lysates, on alpha and beta spectrin in mouse red blood cells, and Filamin A and B, Talin 1, Myosin 9 and lamin A/C in MSCs. Protein-specific results from these studies verify our results against previous literature.

934

Combining Laser Ablation and FRET to Measure the Tension Distribution of Individual Stress Fibers on Focal Adhesions.

C-W. Chang[1], S. Kumar[1]; [1]Department of Bioengineering, University of California, Berkeley, Berkeley, CA
