Generation of traction against the extracellular matrix by stress fibers (SFs) via focal adhesions (FAs) is critical to mechanosensing, motility, and tensional homeostasis. However, the spatiotemporal relationship between SF force generation and tension on individual FAs remains poorly understood. Here we directly measure the tension distribution of individual stress fibers in living cells by combining subcellular laser nanosurgery with a vinculin fluorescence resonance energy transfer (FRET) tension sensor. Our results demonstrate that the tension change in FAs following SF ablation is not restricted to the FAs that are in direct contact with the severed SFs but is exhibited by almost all the FAs in the cell: most FAs show a decrease in tension while a minority of FAs has slight increase in tension. This tension distribution evolves with time following SF disruption and varies with the spatial location of the SF, consistent with our previous finding that central and peripheral SFs exhibit different viscoelastic properties and contributions to cell shape stability (Tanner et al., Biophys J 2010). In addition, morphometric analysis reveals that there is a greater change in tension for the FAs aligned in a direction that correlates with the long axis of cell polarity or that of the severed SF. This study enhances our understanding of how cells couple SF contractility to tension on individual FAs, and to our knowledge represents the first combination of laser nanosurgery with a molecular FRET sensor.

Actin cap associated focal adhesions and their distinct role in cellular mechanosensing.

D-H. Kim[1], S. Khatau[1], Y. Feng[2], S. Walcott[3], S. Sun[3], G. Longmore[2], D. Wirtz[1]; [1]Chemical and biomolecular engineering, Johns Hopkins University, Baltimore, MD, [2]Medicine and Cell Biology and Physiology, Washington University School of Medicine, St. Louis, MO, [3]Mechanical engineering, Johns Hopkins University, Baltimore, MD

The ability for cells to sense and adapt to different physical microenvironments plays a critical role in development, immune responses, and cancer metastasis. However, how cells realize changes in mechanical compliance remains unclear. Here we identify a small subset of focal adhesions that terminate fibers in the actin cap, a highly ordered filamentous actin structure that is anchored to the top of the nucleus by the LINC complexes; these differ from conventional focal adhesions in morphology, subcellular organization, movements, turnover dynamics, and response to biochemical stimuli. Actin cap associated focal adhesions (ACAFAs) dominate early mechanosensing in human and mouse adherent cells, a ACAFA-specific function regulated by phospho-myosin and α-actinin content in the actin cap and by FAK, but not zyxin, talin, and paxillin in ACAFAs. LINC-mediated attachments of the actin cap to the nucleus are also critical to mechanosensing by ACAFAs. A computational model explains the more sensitive response of ACAFAs compared to conventional focal adhesions by the enhanced tension in actin cap fibers. These results establish the perinuclear actin cap and associated ACAFAs as mediators of early cellular sensing of substrate compliance and a critical element of the long-speculated physical pathway that can transduce extracellular mechanical cues all the way to the nucleus.

Isoform-specific Contributions of Non-muscle Myosin II to Viscoelastic Properties of Stress Fibers.

C-W. Chang[1], S. Kumar[1]; [1]Department of Bioengineering, University of California, Berkeley, Berkeley, CA

Stress fibers (SFs) are bundles of F-actin, actin-binding proteins, and non-muscle myosin II (NMMII) that enable cells to generate traction forces against the extracellular matrix. It has recently been shown that two isoforms of NMMII (NMMIIA and NMMIIB) play distinct roles in orchestrating cellular contractile forces, yet the specific contribution of each isoform to stress fiber viscoelastic properties remains incompletely understood. To address this open question, we used laser nanosurgery to disrupt single SFs in living cells in the setting of isoform-specific NMMII suppression. We used lentiviral shRNAs to knock down the heavy chains of NMMIIA and NMMIIB in U373 MG human glioma cells, severed individual mCherry LifeAct-labeled SFs, and tracked viscoelastic SF retraction kinetics. The retraction of the two severed ends of the SF was recorded and the retraction behavior was fit to a Kelvin-Voigt model described by a viscoelastic time constant (τ) and a plateau retraction distance (L_0). Our results demonstrate that NMMIIA and NMMIIB have different contributions to cell morphology and SF viscoelastic properties. NMMIIA suppression produced a dose-dependent morphology change characterized by the elucidation of spike-shaped processes and it also produced slightly faster SF retraction kinetics. By contrast, NMMIIB suppression did not dramatically alter cell shape but to a greater extent reduced the time constant associated with viscoelastic retraction, consistent with our previous findings with myosin light chain kinase inhibition (Tanner et al., Biophys J 2010). This may suggest a model in which NMMII isoforms provide different levels of resistance in SF retraction. To our knowledge, this represents the first attempt to resolve isoform-specific contributions of NMMII to stress fiber mechanics and provides new insight into the roles specific myosin II isoforms play in the mechanobiology of human glioma cells. Given recent observations that NMMII can promote glioma cell invasion through the brain parenchyma by generating high contractile forces, this study may also lend insight into the molecular biophysical basis of tumor invasion.

Signaling Networks Governing Cell Motility I

937

The scaffold Protein Grasp Interacts with Dock180 Bridging the Activation of ARF6 and Rac1 in Epithelial Cell Migration.

M. Attar[1], L. C. Santy[1]; [1]Biochemistry, Microbiology and Molecular Biology, The Pennsylvania State University, University Park, PA

Epithelial cells only exhibit migratory behavior under few conditions: developmental processes, wound healing and cancer metastasis. They normally form defined and polarized structures characterized by cell-cell and cell-substratum junctions. Small GTPases play a role in altering the cortical actin cytoskeleton and promoting epithelial movement. ARF6 and Rac1 are two of these GTPases that appear to cross-talk in migrating epithelial cells. We found that efficient ARF6 induced Rac1 activation happens via cytohesin2 and Dock180, the two respective GEFs of these GTPases. We proposed that the exchange factors interact within a larger multiprotein complex. Additionally data revealed that the scaffold proteins IPCEF and Grasp play a central role in the GTPases crosstalk (White D et. al. 2010). We have previously shown that Dock180 and Grasp interact with each other. We report here that Dock180 and Grasp bind to each other

via the SH3 domain on Dock180 and the proline-rich domain of Grasp. We found that the binding is disrupted when the SH3 domain is truncated and when we produced mutations in the proline-rich domain of Grasp. We confirm these results by coimmunoprecipitation and bi-molecular fluorescence complementation (BiFC) using the Venus split system. This study demonstrates that Grasp is the scaffold protein that bridges ARNO and Dock180 in migrating epithelial cells.

938

Multimodal visualization of motile glioma C6 cells and their response to P2Y2 nucleotide receptor induction.

J. Korczynski[1], D. Wypych[1], W. Klopocka[1], P. Pomorski[2]; [1]Nencki Inst Exp Biol, [2]NanoFun Laboratory of Multimode Microscopy of Cell Motility and Adhesion, Nencki Inst Exp Biol, Warszawa, Poland

While microscopy is crucial for development of live sciences from decades, the molecular biology revolution put this technique into the shade. From twenty years, however the real microscopy revolution take place. The revolution aims to put biochemical and molecular biology techniques from the glassware on the laboratory bench back into the living cell.
Our scientific interest focuses on the process especially suited for use of the live microscopic methods: cell motility. To address requirements of the real time subcellular studies of motile cell, we have decided to construct multimodal system allowing us to make parallel studies using both fluorescence and transmitted light methods. The system is organized around three main microscopy methods: long term DIC Nomarski cell observation, IRM (Internal Reflection Microscopy) and fast multiwavelength fluoresce microscopy. The fluorescence microscopy mode is optimized for fast Fura2 measurements yielding up to 30 frame-pairs per second in full camera resolution. This configuration allows overlay of calcium concentration maps on Nomarski contrast motility tracks and IRM adhesion measurements resulting in almost complete motility analysis.
Presented results show the influence of P2Y2 receptor induction by UTP and resulting calcium signal on motility of Glioma C6 cells and it substratum adhesion visualization. The signal parameterization showed previously on this conference (Poster 171, ASCB 50th Annual Meeting 2010, Philadelphia) as well as adhesion pattern is overlaid onto DIC images. While in the control, motile cells calcium signal is strongly polarized, our results show clearly how signal polarization disappears after cell actomyoisin contractility inhibition by Y-27632, a selective ROCK kinase inhibitor.
The main aim of the system is to put our previous results of nucleotide dependent signal polarization into cell motility context, however being financed from EU POIG founds, we are open for collaboration with all groups willing to put their biochemical results into imaging context but lacking microscopy expertise or equipment.

939

Silencing of DLC1 promotes PAI-1 expression and reduces normal cell migration.

Y-P. Shih[1], S. Lo[1]; [1]Biochemistry and Molecular Medicine, University of California-Davis, Sacramento, CA

Deleted in liver cancer (DLC1) is a GAP (GTPase Activation Protein) domain containing tumor suppressor that localizes to focal adhesion. One of DLC1¡¦s known functions is to regulate cancer migration. However, its role in normal cell migration has not been well studies. Here, we show that silencing of DLC1 (shDLC1) in normal prostates epithelial cells reduce cell migration. This migration defect is mainly due to up-expression of plasminnogen activator inhibitor 1 (PAI-1), since further silencing of PAI-1 rescues the shDLC migration phenotype. Re-expression of

DLC1 in shDLC1 cells suppresses PAI-1 protein level and rescues the migration defect. In contrast, DLC1-K714E (GAP inactive) mutant neither decreases the PAI-1 level nor rescues shDLC migration defect. Interestingly, re-expression of DLC1-Y442F (tesin-binding and focal adhesion-localizing defective) mutant is able to suppress PAI-1 expression but does not rescue the migration defect. Furthermore, PAI-1 upregulation in shDLC cells is EGFR-MEK pathway dependent and is able to promote in vitro angiogenesis. Together, our results demonstrate that at least two new mechanisms are involved in DLC1-mediated normal cell migration. (A) DLC1 modulates the expression of PAI-1, which is a negative regulator for cell migration, in a GAP domain and EGFR-MEK dependent manner. (B) Independent to PAI-1, the interaction of DLC1 with tensin members positively regulates cell migration.

940

Arpin, a Novel Protein that Inhibits the Arp2/3 Complex, Controls Lamellipodium Protrusion and Cell Migration.

C. Sousa[1], J. Linkner[2], I. Dang[1], C. Guerin[3], M. Nemethova[4], E. Derivery[1], G. Lakisic[1], J. Small[4], L. Blanchoin[3], J. Faix[2], A. Gautreau[1]; [1]Laboratoire d'Enzymologie et Biochimie Structurales, CNRS, Gif-sur-Yvette, France, [2]Institute for Biophysical Chemistry, Hannover Medical School, Hannover, Germany, [3]LPCV / iRTSV / DSV, CEA, Grenoble, France, [4]Institute of Molecular Biotechnology, Vienna, Austria

The Arp2/3 complex is a major actin nucleator of eukaryotic cells. It generates a branched actin network that generates a pushing force. This force powers the protrusion of the plasma membrane in a structure called the lamellipodium. The Wave complex is the major Arp2/3 activator in the lamellipodium, and the small GTPase Rac activates the Wave complex, when GTP-bound. Here we present a novel inhibitor of the Arp2/3 complex that regulates dynamics of lamellipodia and cell migration.

We interrogated public databases for proteins containing an acidic C-terminal domain and harboring a W at position -2. This characteristic motif involved in Arp2/3 binding allowed us to retrieve an uncharacterized human protein among known Arp2/3 activators. This protein indeed interacted with the Arp2/3 complex in a GST-pulldown, and inhibited its activation in a dose-dependent manner, as revealed by pyrene-actin assays and by actin filament branching monitored with TIRF microscopy. We call this protein 'Arpin' as a tribute to Monique Arpin, A.G. PhD supervisor, who retired earlier this year, and also because it is a good mnemonic for *Arp*2/3 complex *in*hibitor.

We found that Rac activity induces the interaction of Arpin with the Arp2/3 complex. Consistently, endogenous Arpin localized to the lamellipodium of migrating cells. Upon RNAi-mediated depletion of Arpin in human cell lines, lamellipodia protruded faster, consistent with its inhibitory role on Arp2/3 complex activity. Arpin depleted cells explored a larger territory than the controls, because of increased speed and directionality. A knock-out of the orthologous Arpin gene from *Dictyostelium discoideum* also resulted in faster and more directional amoeba, indicating that Arpin function is conserved from amoeba to man. Fish keratocytes are the best model for persistent migration. Microinjection of purified zebrafish Arpin into keratocytes resulted in cycles of suppression of the existing lamellipodium immediately followed by growth of a new ectopic one.

Together these results argue for an essential inhibitory role of Arpin in modulating Rac signalling toward the Arp2/3 complex. If the WAVE complex is the 'engine' of cell migration, Arpin would be a 'brake' and the 'steering wheel'.

941

RhoC is crucial to ensure proper protrusion formation through spatial location of cofilin activity.

J. Bravo-Cordero[1], J. Condeelis[1], L. Hodgson[1]; [1]Anatomy and Structural Biology and Gruss Lipper Biophotonics Center, Albert Einstein College of Medicine of Yeshiva University, Bronx, NY

The steps of invasion and intravasation during metastasis require tumor cells to migrate and degrade through dense basement membrane barriers. To accomplish this, tumor cells display actin-rich subcellular compartments, named lamellipodia and invadopodia, involved in leading edge protrusion and matrix degradation, respectively. Regulation of actin dynamics in lamellipodia as well as invadopodial protrusions is crucial to drive invasion. The actin severing protein cofilin is essential for directed cell migration and chemotaxis. Through its severing activity, cofilin increases the number of free barbed ends to initiate actin polymerization for actin-based protrusion in these distinct subcellular compartments. Cofilin severing activity is tightly regulated and multiple mechanisms are utilized to regulate cofilin activity. We have recently shown that RhoC regulates cofilin phosphorylation through a ROCK/LIMK pathway to control the ability of cofilin to generate actin barbed ends in invadopodia in invasive tumor cells. RhoC activity is spatially confined to a ring-like pattern surrounding the invadopodium that are formed during EGF stimulation. This has been shown to focus cofilin activity to the core of invadopodia. This spatiotemporal restriction of RhoC activity is controlled by “spatially distinct regulatory elements”, p190RhoGEF and p190RhoGAP.
Since lamellipodium formation also requires fine regulation of actin dynamics, we studied how RhoC contributed this process. In MTLn3 cells, RhoC is required for formation and elongation of EGF-stimulated protrusions. We have studied the spatiotemporal dynamics of RhoC during lamellipodium protrusion using a new RhoC biosensor. We found that RhoC is activated one micron behind the leading edge to focus the activity of cofilin toward the front of the cell. This spatial localization of RhoC activity appears necessary to place active cofilin at the very tip of lamellipodium to generate barbed ends, similar to what happens in the invadopodium core.
We propose a new model wherein areas of elevated RhoC activity form a barrier against the diffusion of active cofilin by enhancing the cofilin phosphorylation within this zone. This results in the restriction of elevated cofilin activity to only within the invadopodium core or within the very tip of the lamellipodium compartment to focus the protrusion and to increase cell migration and invasion.

942

Synergistic Interaction Between Cofilin and Arp2/3 Enhances Actin Barbed Ends Generations in a Spatiotemporal Model of a Lamellipodium.

N. Tania[1], J. Condeelis[2], L. Edelstein-Keshet[1]; [1]Department of Mathematics, University of British Columbia, Vancouver, BC, Canada, [2]Department of Anatomy and Structural Biology and Gruss Lipper Biophotonics Center, Albert Einstein College of Medicine of Yeshiva University, Bronx, NY

Rapid polymerization from the barbed ends of actin filaments generates protrusive forces at the cell edge, leading to cell migration. Two important regulators of free barbed ends, cofilin and Arp2/3, have been shown to work in synergy based on experiments on mammary carcinoma cells. Specifically, cofilin is found to sever older F-actin (with ADP bound monomers) generating new free barbed ends from which new ATP-F-actin polymerize. Arp2/3 complexes, which bind preferentially to these new filaments, can then nucleate new branch points, allowing for further growth of the actin network in the lamellipodium.

To further quantify the level of synergy between cofilin and Arp2/3, we build and analyze a mathematical model for the spatiotemporal distribution of actin filaments at the leading edge of a motile cell. The model incorporates spatial diffusion of cofilin and Arp2/3, membrane protrusion, F-actin capping and ageing, severing by cofilin and branch nucleation by Arp2/3. The level of synergy is quantified by calculating the ratio between the total barbed ends produced in the presence of both, to the direct sum of those produced by cofilin and Arp2/3 acting on their own.

By varying the level of cofilin and Arp2/3 activated at the cell edge, we found that each can generate a large pulse of barbed ends on its own. However, a high synergy is observed only under low cofilin and low Arp2/3 stimulation. We found that the synergy is larger, and results in greater protrusion in the spatially distributed system (compared to the well-mixed case). Further, the relative timing of the cofilin and Arp2/3 activation is important: a slight delay in the Arp2/3 peak can significantly increase the peak of barbed ends following cofilin activation. The synergy is maximized if Arp2/3 is introduced when the level of new F-actin is high following a burst of barbed end generation from an initial cofilin activation.

Note: See abstract submission 542 by Bravo-Cordero, et al., RhoC is crucial to ensure proper protrusion formation through spatial location of cofilin activity, for experimental work on a similar system. We ask to be included as a back-to back presentation/same poster session with the Bravo-Cordero et al presentation.

943

Cortactin Controls Cell Motility and Lamellipodial Dynamics by Regulating ECM Secretion.

B. Sung[1], X. Zhu[2], I. Kaverina[2], A. Weaver[1]; [1]Cancer Biology, Vanderbilt University Medical Center, Nashville, TN, [2]Cell and Developmental Biology, Vanderbilt University Medical Center

Branched actin assembly is critical for both cell motility and membrane trafficking. The branched actin regulator, cortactin, is generally considered to promote cell migration by controlling leading edge lamellipodial dynamics. However, recent reports indicate that lamellipodia are not required for cell movement, suggesting an alternate mechanism. Since cortactin also regulates membrane trafficking and adhesion dynamics, we hypothesized that altered secretion of extracellular matrix (ECM) and/or integrin trafficking might underlie motility defects of cortactin-knockdown (KD) cells. Consistent with a primary defect in ECM secretion, both motility and lamellipodial defects of cortactin-KD cells were fully rescued by plating on increasing concentrations of exogenous ECM. Furthermore, cortactin-KD cell speed defects were rescued on cell-free autocrine ECM produced by control cells but not on ECM produced by cortactin-KD cells. Investigation of the mechanism revealed that whereas endocytosed FN is redeposited at the basal cell surface by control cells, cortactin-KD cells exhibit defective FN secretion and abnormal FN retention in a late endocytic/lysosomal compartment. Cortactin-KD motility and FN deposition defects were phenocopied by KD in control cells of the lysosomal fusion regulator Synaptotagmin-7. Rescue of cortactin-KD cells by expression of cortactin binding domain mutants revealed that interaction with Arp2/3 complex and actin filaments is essential for rescue of both cell motility and autocrine ECM secretion phenotypes whereas binding of SH3 domain partners is not required. In conclusion, efficient cell motility, promoted by cortactin regulation of branched actin networks, involves processing and resecretion of internalized ECM from a late endosomal/lysosomal compartment.

944

CD11b regulates insulin-induced THP-1 cell migration and adhesion through PI3K/Akt1 pathway.

I. Jin[1], S. Yun[1], E. Kim[1], J. Ha[1], Y. Kim[1], D. Woo[1], H. Lee[1], C. Kim[1], S. Bae[1]; [1]MRC for Ischemic Tissue Regeneration and Medical Research Institute, Department of Pharmacology, College of Medicine, Pusan National University, Yangsan, Republic of Korea

Diabetes is risk factor for cardiovascular diseases and strongly associated with the incidence of atherosclerosis. During the pathogenesis of atherosclerosis, monocyte adhesion to vascular endothelium and subsequent migration across the endothelium has been recognized as key process. However, regulatory mechanism by which diabetic status promotes atherosclerosis is not clear. Here, we showed that high concentration of insulin (10uM)-induced human acute monocytic leukemia (THP-1) cell migration and phosphorylation of Akt in time and dose-dependent manner. However, insulin-like growth factor-1 (IGF-1), which is structurally similar growth factor, was not effective. Insulin-induced THP-1 cell migration was attenuated by pharmacological inhibition of phosphatidylinositol3-Kinase and Akt. In addition, silencing of Akt1 abolished insulin-induced cell migration and adhesion of THP-1 monocyte cells. We also found that both migration and adhesion of bone marrow-derived cells (BMDCs) isolated from mice lacking Akt1 was significantly attenuated. Finally, surface expression of CD11b/CD18 was strongly promoted by the stimulation with insulin. Enhanced surface expression of CD11b/CD18 was abrogated by silencing of Akt1 or in BMDCs isolated from mice lacking Akt1. Given these results, we suggest that insulin-induced THP-1 migration and adhesion is specifically regulated by PI3K/Akt1 pathway during the pathogenesis of atherosclerosis.

945

PAK regulates adhesion dynamics and membrane protrusion of the neuronal growth cone through its interaction with PIX.

M. Santiago-Medina[1]; [1]Neuroscience, University of Wisconsin - Madison, Madison, WI

Guidance of axons during development is critical to the establishment of a properly inter-connected nervous system. Targeting of axons requires growth cones at the tips of extending axons to navigate through complex environments by integrating signals generated though interactions with soluble and bound molecular cues. P21-activated kinase (PAK) is one intracellular signaling factor that may influence axon outgrowth and guidance downstream of extracellular matrix (ECM) proteins and growth factors. Here we examined the interaction of PAK with PAK-interacting exchange factor (PIX), in the regulation of growth cone motility. PIX functions as a guanine nucleotide exchange factor (GEF) for Rac1 and Cdc42, as well as an adaptor for other proteins that target PAK to adhesion sites known as point contacts. We find that PAK is expressed in the developing spinal cord and targets to both paxillin containing growth cone point contacts and the extending tips of filopodia. Additionally, we observe that acute disruption of the PAK-PIX interaction with a cell-permeable peptide called PAK18 leads to immediate acceleration of Xenopus spinal neurite outgrowth on laminin. Accelerated axon outgrowth in response to PAK18 is also associated with dramatic lamellipodial expansion of the growth cone. Immunocytochemical staining of the PAK targets, phospho-cofilin and phospho-myosin light chain II, paired with the corresponding changes in the cytoskeleton (increased actin depolymerization and decreased retrograde flow) suggest that disrupting PAK binding to PIX with PAK18 leads to less PAK kinase activity in growth cones. Furthermore, live imaging of paxillin-GFP adhesions shows that disruption of PAK-PIX interactions strongly regulates growth cone adhesion dynamics. While the number of adhesions increases markedly, point contacts formed in the presence of PAK18 are more rapidly disassembled. Interestingly we also find that Rac1 activity has a partial role in mediating the effect of PAK18 in neurite outgrowth suggesting

that PAK and Rac1 may be competing for PIX binding. Lastly, growth cones expressing a PAK-PIX binding mutant exhibit increased basal outgrowth and fail to respond to PAK18 stimulation. Together our data suggests that regulation of PAK-PIX interactions in growth cones controls neurite outgrowth by influencing the activity of several important mediators of actin filament polymerization and retrograde flow, as well as integrin-dependent adhesion to laminin.

946

Migrating fibroblasts reorient directionality by a metastable, PI3K-dependent mechanism.

E. S. Welf[1], S. Ahmed[2], H. E. Johnson[1], A. T. Melvin[2], J. M. Haugh[2]; [1]Chemical & Biomolecular Engineering, North Carolina State University, Raleigh, NC, [2]Chemical & Biomolecular Engineering, North Carolina State University

Mesenchymal cell migration as exhibited by fibroblasts is distinct from amoeboid cell migration and is characterized by dynamic competition among multiple protrusions, which determines directional persistence and responses to spatial cues. Localization of phosphoinositide 3-kinase (PI3K) signaling is thought to play a broadly important role in cell motility, yet the context-dependent functions of this pathway have not been adequately elucidated. By mapping the spatiotemporal dynamics of cell protrusion/retraction and PI3K signaling, monitored by TIRF microscopy, we show that fibroblasts reorient predominantly by *branching* of existing protrusions followed by *pivoting* of the two branches. Consequently, if the two branches propagate to their fullest extent, a 90 degree turn is achieved. PI3K inhibition does not affect the initiation of newly branched protrusions in fibroblasts, nor does it prevent protrusion induced by photo-activation of Rac. Rather, PI3K signaling is a dynamic response to, not a precursor to, local protrusion and is required for the lateral spreading and stabilization of nascent branches. Actin polymerization is required for the redistribution of the PI3K signaling pattern, but not its maintenance, suggesting a “passive” form of positive feedback. We further show that, during chemotaxis, the branch experiencing the higher chemoattractant concentration is favored, and thus the cell reorients so as to align with the external gradient.

947

A non-canonical role for Rgnef (p190RhoGEF) in integrin-stimulated FAK activation.

N. Miller[1], C. Lawson[1], S. Uryu[1], X. Chen[1], D. Schlaepfer[2]; [1]Moores Cancer Center, UC San Diego, La Jolla, CA, [2]Reproductive Medicine, UC San Diego

Rgnef is a Rho guanine exchange factor (GEF) for RhoA and RhoC that uniquely binds to focal adhesion kinase (FAK), a cytoplasmic tyrosine kinase activated by integrins. This Rgnef-FAK signaling complex promotes adhesion formation downstream of integrins and enhances colon carcinoma tumor progression. To investigate Rgnef function, we generated a knockout mouse model. Rgnef-null mice are born at a lower frequency than the predicted Mendelian ratio and Rgnef-null mouse embryo fibroblasts (MEFs) exhibit defects in integrin-stimulated adhesion formation on fibronectin (FN), RhoA GTPase activation, and cell migration. These phenotypes are rescued by Rgnef re-expression and are consistent with canonical models of Rgnef function with GEF activation occurring approximately 60 min after MEF binding to FN. However, Rgnef-null MEFs form fewer adhesions at 15 to 30 min on FN and early FAK activation is significantly decreased in Rgnef-null MEFs compared to wild type. Moreover, FN-stimulated FAK activation is inhibited by over-expression of the Rgnef-C-terminal domain but not Rgnef-C-Δ1292-1301 (FAK-binding domain deletion) in wildtype MEFs. Rgnef localizes to leading-edge cell projections and Rgnef (but not RgnefΔ1292-1301) re-expression facilitates FAK localization to and activation at nascent adhesions formed at 15 to 30 min on FN. These data support a new and non-canonical role for Rgnef binding to FAK in promoting early FN-stimulated FAK activation. Taken together, our studies indicate that Rgnef has two temporally distinct but

cooperative functions which contribute to the precise regulation of FAK activation and focal adhesion formation to control cellular contractility and migration.

948

The SH2-domain-containing inositol 5-phosphatase (SHIP) limits neutrophil motility and chemotaxis.

P-Y. Lam[1], S. Yoo[1], J. Green[2], A. Huttenlocher[2]; [1]Cellular and Molecular Biology, University of Wisconsin-Madison, Madison, WI, [2]University of Wisconsin-Madison

The recruitment and activation of neutrophils into sites of injury or infection is essential for host defense against invading microorganisms. However, excessive neutrophil recruitment or activation can be damaging to the surrounding tissues and cause unwanted inflammation leading to a delay in, or even prevention of healing. Hence, the responsiveness of neutrophils needs to be tightly regulated. It has been shown that SHIP hydrolyzes $PI(3,4,5)P_3$ to $PI(3,4)P_2$ and that $PI(3,4,5)P_3$ is an important regulator of cell migration. Here we investigated the role of Ship 5'-phosphatase activity on leukocyte motility and chemotaxis *in vivo,* using the zebrafish as an animal model. Using time-lapse confocal microscopy and ratiometric imaging of bioprobes specific for $PI(3,4,5)P_3$ and/or $PI(3,4)P_2$ in neutrophils, we show that $PI(3,4,5)P_3$-$PI(3,4)P_2$ accumulates at the front of neutrophils while $PI(3,4)P_2$ also localizes to the rear of neutrophils migrating *in vivo*, correlating with the observed localization of SHIP in neutrophils. Depletion of SHIP phosphatases using morpholino (MO) results in an increase in leukocyte recruitment to wounds. Time-lapse imaging of neutrophils randomly migrating in the head also reveals increased 3D velocity in SHIP-deficient larvae. The increase in the leukocyte recruitment in SHIP-deficient zebrafish is rescued by treatment with a low dose of a PI3 kinase inhibitor. Moreover, overexpression of the SHIP phosphatase domain specifically in neutrophils impairs neutrophil migration, suggesting that SHIP inhibits leukocyte motility through its phosphatase activity. Taken together, our results suggest that in an *in vivo* context, SHIP limits neutrophil motility and chemotaxis by modulating local sub-cellular pools of phospholipids.

949

Size and shape dependence of epithelial gap closure.

E. Anon[1,2], X. Serra-Picamal[2], P. Hersen[1,3], M. Sheetz[3,4], X. Trepat[2], B. Ladoux[1,3]; [1]University Paris Diderot, Paris, France, [2]Institute for Bioengineering Catalonia, Barcelona, Spain, [3]Mechanobiology Institute Singapore, [4]Department of Biological Sciences, Columbia University

Fundamental biological processes such as morphogenesis and wound healing involve the sealing of epithelial gaps. Epithelial sealing is commonly thought to be driven by two independent mechanisms: assembly and contraction of a supracellular actomyosin cable (purse-string model) and crawling of marginal and submarginal cells into the gap. Ample evidence supports the existence of each of these two mechanisms but their relative contribution to gap sealing remains unknown, mostly because of the complexity of the process and the high variability in the experimental approaches. Here, we present a new method to study systematically the sealing of gaps in an epithelial culture. Using masking strategies to block the surface available to the cells, we developed a pillar removal assay that allows us to finely control and standardize the size and shape of gaps within an epithelial monolayer. Upon pillar removal, cells actively respond to the presence of free space by extending lamellipodia and crawling into the gap. Cells at the gap edge polarize and elongate in the direction of migration. The decrease of gap area over time is strikingly linear and shows two different regimes depending on the size of the gap. For gaps larger than 15 µm in diameter, epithelial closure is dominated by lamellipodium-mediated cell crawling rather than actin purse-string assembly. Indeed, Rac inhibition (the main regulator for lamellipodial protrusion) induced a dramatic delay

in the collective migration of cells while inhibition of either MLCK or ROCK had no significant effect in gap closure. By contrast, for gaps smaller than 15 μm epithelial closure progressed independently of Rac, MLCK, and ROCK inhibition, suggesting a passive physical mechanism. By changing the shape of the gap, we observed that low curvature areas favored the appearance of lamellipodia, thus promoting a faster closure. Altogether, this study establishes that large epithelial gap closure is driven by lamellipodial-based migration whereas small gaps appear to close by adhesion forces, independent of active motility.

950

Effects of p120 catenin and Rho GTPase interactions during zebrafish gastrulation.

M. A. Zepeda Rivera[1], C. Hsu[2], K. Depner[2], A. Knickerbocker[2], T. Cisneros[2], R. M. Walsh[2], M. Hille[2]; [1]Biology, University of Washington, Seattle, WA

Gastrulation is the process during which cells migrate and tissue layers differentiate during early embryo development. Such a process requires cell-cell adhesion mediated by cadherin-catenin interactions at adherens junctions. We study p120 catenin (p120ctn) in zebrafish. p120ctn stabilizes cadherins at the plasma membrane and interacts with various GTPases both in its membrane-bound and cytoplasmic states. These GTPases include Cdc42 and Rac, which stimulate filopodia and lamellipodia formation respectively, and RhoA, which stimulates stress fiber formation. Using an antisense splice morpholino we have shown that loss of p120ctn results in developmental deficiencies. In an amphibian model it was previously shown that Cdc42 and Rac in their constitutively active GTP-bound states could partially rescue similar developmental deficiencies due to loss of p120ctn. Our lab has shown that injection of mRNAs from Cdc42 and Rac in their wild-type states, which are able to cycle between GDP and GTP bound states, can more fully rescue the embryonic development caused by knockdown of p120ctn. We hypothesize that Cdc42 and Rac in their constitutively GTP-bound states activate filopodia and lamellipodia throughout the entire cell periphery resulting in undirected motion and thus a decreased rescue of developmental deficiencies as cells cannot differentiate into tissue layers efficiently. However, wild-type Cdc42 and Rac form localized filopodia and lamellipodia in response to chemokine signals thereby allowing directed mesodermal cell migrations. We are currently studying the potential of RhoA to rescue deficiencies by studying its role in mesoderm cell migration. It is known that RhoA becomes GTP bound and thus activated when near the plasma membrane and that GTP-bound RhoA acts by activating RhoA kinase increasing the activity of myosin. Since myosin cross-links and stabilizes actin filaments, RhoA indirectly strengthens the adhesion of migrating cells. Over-expression of constitutively active RhoA mRNAs disrupts normal gastrulation. By knocking down p120ctn we will test the potential of RhoA in different GTP and GDP bound states to rescue developmental deficiencies. We also hypothesize that p120ctn is additionally regulated via phosphorylation, with phosphorylation on serine and threonine sites increasing adhesion and that on tyrosine sites activating cell migration. We are currently studying the roles of phosphorylation at specific sites of p120ctn and their interactions with Rho GTPases.

951

Directional Cell Migration Regulates Tubule Morphogenesis.

G. Yao[1], X. Su[1], M. Plomann[2], J. Zhou[1]; [1]Harvard Med Sch/Brigham & Women's Hosp, Boston, MA, [2]Institute for Biochemistry 2, University of Cologne

Previous studies have shown that planar cell polarity (PCP), including orientated cell division (OCD) and convergent extension (CE), plays an important role in establishing and maintaining kidney tubule diameter in higher vertebrates. In the embryonic kidney, epithelial cells elongate perpendicularly to the axis of the tubule, which suggests that mediolateral cell intercalation

during convergent extension elongates the embryonic kidney tubules. Here we show that cell elongation is randomized in normal postnatal tubules. Genetic removal of PC1 in mice leads to the loss of this randomized cell elongation such that cells are elongated mostly parallel to the tubular axis, indicating abnormal directed cell migration (convergent expansion). We report the identification of a novel PC1-Pacsin 2-N-Wasp protein complex in kidney epithelial cells, and the finding that PC1 modulates directional cell migration through Arp2/3-dependent actin cytoskeleton organization. Analyses of mice lacking either Pacsin 2 or Pkhd1 suggest that neither convergent expansion nor OCD defect alone is sufficient to cause cystogenesis. We propose that directional cell migration and OCD cooperate to maintain kidney tubule diameter and that this process requires the integrity of PC1-Pacsin 2-N-Wasp complex.

Chromophore Assisted Laser Inactivation of ADF/Cofilin Demonstrates Its Function of Filament Severing and Depolymerization in Regulating F-actin Networks.

E. A. Vitriol[1], J. Q. Zheng[1]; [1]Department of Cell Biology, Emory University School of Medicine, Atlanta, GA,

There are numerous ways in which ADF/Cofilin effects actin dynamics: it can sever actin filaments, accelerate filament disassembly, act as a nucleation factor, recruit or antagonize other actin regulators, and control the pool of polymerization competent actin monomers. An issue with studying Cofilin has been that these rather straightforward biochemical activities have complex functional outputs in living cells. This has led to a number of reports showing conflicting roles for Cofilin in the same biological process. It has become evident that the timing and localization of Cofilin activity is carefully regulated within the cell, which means that global perturbations of Cofilin may not be sufficient to probe its true function. In an effort to better understand the spatiotemporal regulation of Cofilin, we have implemented fluorescent protein based Chromophore Assisted Laser Inactivation (FP-CALI) to knockdown Cofilin activity instantly with subcellular precision. We have combined FP-CALI with high resolution live-cell imaging so that changes to the actin network can be monitored in real time before, during, and after Cofilin inactivation. CALI of either wild-type Cofilin or a constitutively active mutant ($Cofilin_{S3A}$) decreases actin monomer mobility, indicative of a loss of the ability to sever actin filaments. Furthermore, CALI of $Cofilin_{S3A}$ has a number of effects on the lamellipodial actin network, these include: an increase in total F-actin, a broadening of the lamellipodia towards the cell body, lengthening of actin bundles, and a reduction of retrograde flow. We provide evidence that these phenotypic changes to actin are specifically due to inactivation of Cofilin and are not caused by collateral or non-specific photodamage. These findings not only continue to validate FP-CALI as an effective technique for instantaneous and specific knockdown, but also provide additional understanding into ADF/Cofilin's function in regulating actin dynamics.

953

Regulation of Nonmuscle Myosin II Assembly and Function through Heavy Chain PKC and Casein Kinase II Phosphorylation Sites.

V. Rai[1], T. T. Egelhoff[1]; [1]Department of Cell Biology, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH

Nonmuscle myosin-II is a hexameric complex comprised of two heavy chains (MHC), two essential light chains (ELC), and two regulatory light chains (RLC).There are three NMHC-II isoforms (NMHC-IIA, NMHC-IIB, and NMHC-IIC). Myosin IIA is enriched in leading-edge lamella during persistent polarized migration and RLC phosphorylation is known to play critical roles in regulating nonmuscle myosin II filament assembly during the migration, but the regulation and physiological relevance of myosin II heavy chain (MHC) phosphorylation is not well understood.

Myosin IIA can be phosphorylated on several C-terminal heavy chain residues, including a Protein Kinase C (PKC) consensus target site at position S1916 and a calcium-calmodulin-dependent casein kinase II (CK-II) consensus target site at position S1943.

S1943 phosphorylation has been established in earlier work as participating in regulation of myosin IIA filament assembly in leading edge protrusions. Mutation of S1943 impairs myosin IIA localization to lamellipodia during spreading of cells on fibronectin coated surfaces and during polarized migration/extension in response to the chemoattractant EGF. Although the involvement of myosin IIA phosphorylation on S1943 in assembly control is recognized, there have been few studies of phosphorylation on site PKC site, and virtually none in the context of live cells. The present study is focus on studying regulation of myosin IIA assembly by phosphorylation of PKC and CKII sites on the myosin IIA heavy chain (MHC). Using site-directed mutagenesis approaches coupled with expression GFP-tagged MHC IIA genes, we report here that the PKC target sites on MHC IIA are clearly involved in control of myosin IIA filament assembly in live cells. Initial studies suggest that phosphorylation at S1916 functions in coordination with phosphorylation at S1943 to control filament assembly during spreading and migration.

954

The distinct role of the Arp2/3 complex in 3D motility.

A. Giri[1,2], S. Bajpai[1,2], N. Trenton[1], H. Jayatilaka[1], G. Longmore[3], D. Wirtz[1,2]; [1]Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, [2]Physical Sciences-Oncology Center, Johns Hopkins University, Baltimore, MD, [3]Departments of Medicine and Cell Biology and Physiology and BRIGHT Institute, Washington University

Arp2/3 is a seven-subunit protein complex that nucleates actin filament assembly in adherent cells crawling on planar substrates. However, in physio-pathological situations, cell motility typically occurs within a three-dimensional (3D) environment and little is known about the role of Arp2/3 in 3D motility. Here we find that, for a wide variety of cells in 3D matrix, the Arp2/3 and associated proteins N-WASp, Cortactin, and Cdc42, mediate the formation of pseudopodial protrusions that branch off into multi-generation dendritic protrusions into the matrix. 3D cell speed in matrix correlates with the degree of side branching, not mother protrusion activity. This study shows that the Arp2/3 complex plays a critical role in 3D cell motility by mediating the dendritic topology of protrusions.

955

Myosin-IIA contractility is required for activated T lymphocyte trans-endothelial migration in vivo.

J. Jacobelli[1], M. Krummel[2]; [1]Immunology, National Jewish Health, Denver, CO, [2]Pathology, University of California San Francisco

To carry out their surveillance and effector functions, T lymphocytes must migrate from the vasculature into lymph nodes and tissues. We have previously shown that Myosin-IIA plays a role in T cell migration by modulating adhesion to the surrounding substrate and regulating the switch between fast amoeboid-like motility and slower mesenchymal-like motility. We have also shown that interstitial motility is affected in naïve T cells lacking Myosin-IIA leading to inefficient recirculation through the lymph nodes. However, the specific cytoskeletal requirements that underlie T cell trans-endothelial migration (TEM) and extravasation are not yet fully understood. Therefore, we sought to analyze the contribution of Myosin-IIA in TEM and in extravasation of T cells. Lack of Myosin-IIA in naïve T cells did not significantly impair their extravasation potential. However, Myosin-IIA depletion caused a significant defect in the ability of activated T cells to

complete TEM both in vitro and in vivo. Our data suggest that, in addition to the effects of Myosin-IIA on adhesion that we previously described, Myosin-IIA contractility provides the force necessary to squeeze the nucleus-containing body of the T cell through the endothelial cell layer. Furthermore, our results showed that Myosin-IIA plays a significant role in the ability of effector T cells to reach inflamed peripheral tissues in vivo. Overall, these results suggest a critical role for Myosin-IIA in promoting TEM and in migration through constrictive environments, as is necessary for the extravasation of activated T cells.

956

Dual Functions of p21-activated Kinase in Regulating Myosin Light Chain Phosphorylation.

J. Chu[1], K. Kislitsyna[1], C. Cox[1], K. Uray[1]; [1]Pediatric Surgery, University of Texas Health Science Center at Houston, Houston, TX

Intestinal edema and subsequent decreased intestinal contractile activity often occur under various pathologic circumstances. In an in vivo intestinal edema rodent model, our laboratory showed a significant decrease in intestinal contractile activity and corresponding decreases in both myosin light chain (MLC) and myosin light chain phosphatase targeting subunit (MYPT1) phosphorylation in edematous tissue. Our data also indicated in edematous tissue, P21-activated kinase (PAK) activity is increased while Rho kinase (ROCK) is decreased. Moreover, intestinal tissue contractility was rescued by inhibition of PAK activity in vivo.
To investigate the role of PAK in edema-induced intestinal contractile dysfunction, a human primary intestinal smooth muscle cell (hISMC) model was developed. HISMCs were subjected to either basal cyclical stretch (CCS) or an increasing cyclical stretch (ECS), mimicking pathologic changes in edematous tissues. ECS induced significant decreases in phosphorylation of both MYPT1 and smooth muscle myosin light chain (MLC) mimicking the in vivo intestinal edema findings. The role of PAK in regulating MLC phosphorylation has been investigated by transfecting hISMCs with two constitutively active PAKs (caPAK) or dominant negative PAK (dnPAK). In ECS group, transfection with caPAK induced further decrease in MLC phosphorylation while dnPAK produced the opposite effect. In contrast, in CCS group, caPAK transfection increased MLC phosphorylation and dnPAK decreases MLC phosphorylation. The PAK activator (BPIPP) and the PAK inhibitor (IPA-3) induced similar results as transfection with caPAK and dnPAK, respectively. While IPA-3 does not affect MYPT1 phosphorylation, BPIPP decreases MYPT1 phosphorylation in hISMCs. We conclude from this data that under physiologic environment, PAK is responsible for maintaining MLC phosphorylation; however, increased PAK activity under pathologic conditions switches PAK signaling to a pathway inhibiting MLC phosphorylation through decreased MYPT1 phosphorylation.

957

Transfection with fluorescent constructs impairs the mechanical behavior of cells.

N. Lang[1], N. Bonakdar[1], W. Goldmann[1], B. Fabry[1]; [1]Biophysics Group, Erlangen, Germany

To visualize cell movement and to analyze cytoskeletal and focal adhesion dynamics, the transfection of cells with fluorescently tagged protein expression vectors is a common method. Generally, cells are assumed to behave normally after transfection if their morphology remains unchanged, but this assumption has not been rigorously tested.
We investigated whether the transfection with fluorescently tagged cytoskeletal constructs (EGFP-actin and LifeAct) alters the mechanical behavior of invasive MDA-MB 231 breast carcinoma cells. Transfected cells showed unaltered morphology and spreading area, but their

ability to invade porous 3D collagen gels was strongly impaired. Cell stiffness measured with magnetically applied forces to 4.5 µm RGD-coated beads was reduced by 2-3 fold in transfected cells. Moreover, beads detached from transfected cells at pulling forces that were 5-fold smaller compared to control cells. These data demonstrate that transfection with fluorescently tagged cytoskeletal proteins strongly impairs the mechanical behavior of cells, without any visible changes in morphology. This behavior can only partly be attributed to the transfection procedure, as cell transfection with single tag pEGFP and to a lesser degree treatment with the transfection agent lipofectamine alone also resulted in a somewhat reduced cell stiffness and reduced bead binding strength. In summary, our data show that transfection in particular with fluorescently tagged cytoskeletal proteins may result in artefactual cell behavior and may strongly bias mechanical measurements.

958

Design and engineering of genetically encoded, high performance FRET biosensors of Rho GTPases.

T. Yin[1], Y. I. Wu[1]; [1]Center for Cell Analysis and Modeling, University of Connecticut Health Center, Farmington, CT

Genetically encoded, forster resonance energy transfer (FRET)-based biosensors are proven extremely valuable in elucidating the spatiotemporal dynamics of signaling proteins in living cells. However, current design strategies rely on empirical sampling of fluorescent proteins and linker sequences, resulting in suboptimal dynamic range of the sensors and thus limited application. Through rational design, we sought to improve the existing biosensors of Rho GTPases, in which interaction between Rho GTPases with their effectors is coupled to changes in FRET between two fluorescent proteins in a single polypeptide. Firstly, the high FRET state is improved by taking advantage of the dimeric nature of fluorescent proteins and their circular permutants. Secondly, a further decreased low FRET state is achieved via inserting repeats of a stable α-helix from the ribosomal protein L9, rather than an unstructured linker, between the fluorescent proteins to disrupt dimerization and therefore diminish FRET efficiency. Lastly, switching between these two FRET states is coupled to the interaction between GTPases and their effectors through modeling of the crystal structures of the fluorescent protein dimer and the GTPase/effector domain complexes. These engineering steps resulted in a set of genetically encoded, FRET-based biosensors for Rac, Cdc42 and RhoA that have markedly improved dynamic range. FRET/CFP emission ratios were increased by 4-6 folds in HEK293 cells expressing mutant sensors mimicking the bound state, comparing to ratios in cells expressing mutants mimicking the unbound state. Live cell imaging using these sensors revealed dynamic and distinct activation profiles of the individual Rho family GTPases in migrating cells. Because the high FRET efficiency is intrinsic to the engineered FRET module, we expect such design can be generalized to produce high performance biosensors for other signaling proteins.

Integrins and Cell-Extracellular Matrix Interactions

959

Cell Fate and Elasticity Dictates Cell-ECM Attachment Strength and Detachment Mechanism.

A. Fuhrmann[1], A. J. Engler[1]; [1]Bioengineering, University of California, San Diego, San Diego, CA

Cell attachment strength has been used as a metric to assess cell behaviors ranging from cell-ECM binding forces to matrix fiber strength. Shear force-induced detachment in these assays has typically been shown to be binary with the cell either attached with relatively normal morphology or absent at physiological or higher forces, but these assays have been limited to a relatively small number of cell types, e.g. fibroblasts, fibrosarcoma cells, etc. Using a spinning disc device that applies a radially-dependent shear force over a short duration, e.g. 5 minutes, here we investigate the attachment strength and detachment mechanism for a number of species and cell sources that vary in their degree of senescence from pluripotent and multipotent stem cells to cancer cells to common fibroblasts. While data from murine fibroblasts confirms binary adhesion states with relatively little cytoskeletal remodeling if any before detachment, tremendous remodeling was observed in mouse embryonic stem cells (mESCs) during this short shear exposure. Cells oriented themselves parallel to the applied shear and elongated up to aspect ratios of 4:1. Human bone marrow derived stem cells (BMSCs) also aligned with a shear up to an aspect ratio of 6:1. However after prolonged culture, BMSCs lost their ability to remodel under shear and detached in a binary fashion, perhaps indicating that a certain degree of pluripotency is required for the cytoskeleton to remain elastic and remodel. Since differentiation scales with cell stiffness, the ability of cells to rearrange under shear depends mostly on their elasticity. Softer cells such as undifferentiated BMSCs have an advantage to quickly adopt to the direction of shear and align themselves parallel to the force, reducing their total drag and consequently are able to withstand a higher shear force than their integrin density would let expect. Cell softness also correlates with cancer progression, an subsequent analysis could show that applying super-physiological shear could be used to select for cells with higher metastasis potential. Regardless, these data indicate that previous consideration for cell attachment strength, namely that it correlates to integrin density, may in fact be also dependent on cell state and its elasticity.

960

GEF-H1 and LARG regulate adhesion reinforcement in response to mechanical tension.

C. Guilluy[1], V. Swaminathan[2], L. Osborne[2], T. O'Brien[2], R. Garcia-Mata[1], R. Superfine[2], K. Burridge[1]; [1]Cell and developmental Biology, University of North Carolina Chapel Hill, Chapel Hill, NC, [2]Department of Physics and Astronomy, University of North Carolina Chapel Hill

Cells can “sense” and convert mechanical forces into specific biochemical signals that ultimately regulate cellular processes. Among all the structures involved in mechano-sensing, focal adhesion (FA) proteins and their matrix anchor, integrins, have emerged as important actors in mechanotransduction. Application of force on integrins triggers cytoskeletal rearrangements and growth of the associated adhesion complex, resulting in increased cellular stiffness, also known as reinforcement. Since this ability of FAs to respond to force is involved in various aspects of biology, from development to physiology and disease, many efforts have been directed recently to understand how mechanical forces regulate FA components and how they assemble.
We found that application of force on integrin triggered activation of the Rho GEFs LARG and GEF-H1 and their recruitment to the FA. Interestingly, we observed that LARG and GEF-H1 were activated by independent signaling pathways. We found that Fyn was required for LARG

force-dependent activation, while GEF-H1 was activated by Erk downstream of FAK. Using magnetic tweezers, we observed that depletion of LARG or GEF-H1 prevented the cellular stiffening in response to force, indicating that both Rho GEFs are necessary for the cellular response to force. More recently, we observed that GEF-H1 and LARG were activated when cells were grown on stiff substrates, suggesting that cell-generated contractility regulates LARG and GEF-H1 activity.

These data show that external force, as well as cell-generated tension, activates the Rho GEF LARG and GEF-H1, which in turn regulate adhesion reinforcement. Identification of Rho GEFs and/or GAPs modulated by force on other cell surface receptors is under investigation.

961

Mechanical tension promotes mast cell degranulation through an RGD-integrin dependent pathway.

V. Fowlkes[1], C. Wilson[2], W. Carver[1], E. Goldsmith[1]; [1]Cell Biology and Anatomy, University of South Carolina School of Medicine, Columbia, SC, [2]Center for Craniofacial Regeneration, University of Michigan School of Dentistry, Anne Arbor, MI

Mechanical forces applied to the extracellular (ECM) matrices of various tissues are essential in maintaining tissue homeostasis and physiology. Alterations in mechanical tension can result in a maladaptive response that includes induced cellular stress and activation of pathological signaling pathways. Mechanical forces applied to the extracellular matrix are largely transmitted to the cell via receptors of the integrin family. Specifically, RGD-specific integrins have been shown to act as mechanotransducers converting mechanical stresses into biological signals. Mast cells are immune cells that participate in several biological functions including wound healing, fibrosis, cell recruitment, asthma, inflammation and mediation of vascular permeability. In several pathological diseases where changes in the mechanical environment stimulate changes in the ECM, mast cell density and activation are increased significantly. The biological changes that occur to mast cells during mechanical tension have not been investigated. Our objective was to 1) examine the mechanosensitivity of the mast cell by subjecting it to cyclic mechanical load, and 2) determine the role of RGD-specific integrins in mast cell response to mechanical force. We applied 5% and 10% cyclic, uniaxial tension to three dimensional fibrin constructs seeded with RBL-2H3 cells (a mast cell line) and monitored the cellular response over a period of 24 hrs. Our results showed that at 5% and 10% cyclic mechanical load, RBL-2H3 degranulation, as measured by secretion of β-hexosaminidase, significantly increased (2.1 to 2.3 fold, respectively) in a load- and time-dependent manner when compared to the non-stretched controls ($p<0.003$). Furthermore, mechanical loading did not compromise cell viability or increase cell proliferation. To determine if RGD-dependent integrins mediated mast cell degranulation in response to mechanical tension, we inhibited cell-matrix interactions by treating the RBL-2H3 cells with Echistatin, a disintegrin that tightly binds RGD-specific integrins. Treatment with Echistatin attenuated load-induced degranulation (by ~50%, $p<0.0004$) without compromising cell viability. These results suggest a novel mechanism by which mechanical stretch induces mast cell activation via RGD-dependent mechanotransduction.

962

Substratum stiffness regulates switch control of cell proliferation and differentiation in primary cultures of mice proximal tubular cells.

W-C. Chen[1], H-H. Lin[1], M-J. Tang[1]; [1]National Cheng Kung University, Tainan, Taiwan

Differentiated renal tubular epithelial cells *in vivo* normally reside on soft basement membrane containing laminin-rich extracellular matrix and remain quiescent status. Accumulated studies indicate that substratum stiffness might regulate cell behavior, i.e. migration, proliferation,

differentiation, apoptosis and tumorigenesis. Our studies showed that mouse proximal tubular (mPT) cells in primary culture on stiffer substrate gradually lost their tubular morphology and differentiated properties with the increase of cell proliferation which could be alleviated when cells were cultured on softer substrate. Here we investigated how substratum stiffness regulates the switch of cell proliferation and differentiation in primary mPT cells. One of the possible candidates involved in mechanosensing machinery is β1 integrin. We showed that low substratum stiffness not only suppressed β1 integrin activation but also protein level via post-translational regulation. In addition, low substratum stiffness also downregulated Smad3, ERK and P38MAPK. High substratum stiffness-induced cell spreading, proliferation and dedifferentiation were alleviated by 4B4 (β1 integrin neutralized antibody) and UO126 (ERK1/2 inhibitor) treatment, but not affected by inhibition of Smad3 and P38MAPK pathways. Combination of the oligo-microarray data and bioinformatic prediction database revealed that hepatocyte nuclear factor 4α(HNF4α), a member of the nuclear receptor family of transcription factors, might play a critical role in regulation of a set of genes related to cell proliferation and differentiation in mPT cells. Interestingly, inhibition of ERK preserved-cell differentiation and inhibited cell proliferation induced by high substratum stiffness might due to the maintenance of HNF4αlevel. This study provides basic understanding of how substratum stiffness regulates the switch of cell proliferation and differentiation in proximal tubule by modulation of transcription factor HNF4α.

963

Cell volume decreases with increasing substrate stiffness.

M. Guo[1], K. Kasza[1], F. Mackintosh[2], J. Lippincott-Schwartz[3], D. Weitz[1]; [1]Department of Applied Physics, Harvard University, Cambridge, MA, [2]Department of Physics and Astronomy, Vrije Universiteit, Amsterdam, Netherlands, [3]Cell Biology and Metabolism Branch, NICHD/NIH, Bethesda, MD

Cell morphology and stiffness have been observed to change with their growing substrate stiffness. But whether they change their size due to substrate stiffness is not known. We measured the volume of cells that are grown on substrate with different stiffness with confocal microscopy. We find that both cell volume and cell nuclear volume decrease with the increasing substrate stiffness, and the volume changing is cell cortex contraction dependent.

964

Isolation and characterization of human dermal papillar and reticular fibroblasts.

M. Toutfaire[1], R. Boulgana[1], K. Lazou[1], J-H. Cauchard[1], E. Noblesse[1], S. Schnebert[1], E. Perrier[1], M. Dumas[1]; [1]LVMH RECHERCHE, F-45804 Saint Jean de Braye, France

The dermis of human skin is partitioned into histological and physiological distinct zones. The most superficial one, the papillar dermis and the deeper one, the reticular dermis contain papillar (Fp) and reticular fibroblasts (Fr) respectively. Little is known about these two sub-populations of dermal mesenchymal cells, their specific role and biological markers

Objectives: To isolate and characterize these two sub-populations of cells in terms of migration (healing), proliferation and clonogenic potential, differentiation, collagen remodeling and tensile strengths expression in response to neurotrophins (NTs), and genes expression profile.

Methods: dermis was sectioned with a dermatome (Fp 0-0.3mm and Fr >0.7mm) and cells obtained by explant culture and collagenase I digestion. Migration was evaluated by the ability of cell to colonize an articicial scar in vitro (healing) and by the number of explants producing cells. Growth potential of cells was determined by counting cells over 7 days and the ability of single cells to form colonies. Differentiation into myofibroblasts was analysed by the expression of alpha-SMA (Smooth Muscle Actin). Collagen remodeling ability of cells was evaluated by the

retraction of floating gels and tensile strengths by a GlaSbox device with and without treatment with neurotrophins (NTs). Transcriptional analysis of genes was performed by Taqman Low Density Array methods (TLDA).
Results: Fp have a higher migration potential than Fr according to the explant culture and healing test. We observed that the rate of growth and the clonogenic potential were higher for Fp than for Fr. Alpha-SMA expression was higher in Fr compared to Fp. At basal rate, collagen remodeling was more pronounced in Fr than Fp the later developing higher tensile strengths than Fr. Regarding NTs, and increase of tensile strengths was observed with NTs in both subpopulations of cells. The transcriptional analysis of genes expression showed that types I, III, V collagen are up-regulated in Fr as well as MMP-14, TIMP-1 and TIMP-2 whereas MMP-1 and MMP-4 are up-regulated in Fp.
Conclusion: Taken together these preliminary results showed a specific genes expression signature between papillary and reticular dermal fibroblasts. Papillary fibroblasts have a more proliferation and migration profile, since reticular ones are more involved in a tensile and differentiation process, both subpopulations of cells responding to neuroptrophins.

965
Differential Response of Arterial and Venous Endothelial Cells to Extracellular Matrix is Modulated by Oxygen.
L. Gomes[1], H. Miedl[1], B. Ebner[1], H. Hackl[2], G. Desoye[1], U. Hiden[1]; [1]Medical University of Graz, Austria, [2]Innsbruck Medical University; Austria

Adhesion of endothelial cell (EC) integrins to extracellular-matrix (ECM) components is one of the key events to trigger intracellular signaling that will ultimately result in proper vascular development. Even within one tissue the endothelial phenotype differ between arteries and veins. Here we tested the hypothesis that anchorage-dependent processes such as proliferation, viability, survival and actin organization of venous (VEC) and arterial EC (AEC) differently depend on ECM proteins. Moreover, because of different oxygen tension in AEC and VEC, we tested oxygen as a co-modulator of ECM effects. Primary human placental VEC and AEC were grown in collagen I and IV, fibronectin, laminin, gelatin and uncoated plates and exposed to 12% and 21% oxygen. Our main findings revealed that VEC are more sensitive than AEC to changes in the ECM composition. Proliferation and survival of VEC, in contrast to AEC, were profoundly increased by the presence of collagen I and fibronectin as compared to gelatin or uncoated plates. Focal adhesion kinase (Fak) inhibition studies demonstrated that these effects were dependent on Fak. They were also modulated by oxygen. VEC were more susceptible to the oxygen-dependent ECM effects than AEC. However, no differential ECM effect on actin organization was observed between the two cell types. These data provide first evidence that AEC and VEC from the same vascular loop respond differently to ECM and oxygen and this may be Fak dependent.

966
HIM-4/Hemicentin Links the Uterine and Vulval Basement Membranes during Anchor Cell Invasion in C. elegans.
M. A. Morrissey[1], D. R. Sherwood[1]; [1]Biology, Duke University, Durham, NC

Cell invasion across basement membrane (BM) occurs frequently during normal development and disease processes, such as cancer, but has been difficult to model *in vitro* and dissect *in vivo*. Anchor cell (AC) invasion is a genetically and visually tractable invasion process during *C. elegans* vulval development in which the uterine AC breaches two distinct BMs (uterine and vulval BM) to contact the underlying vulval epithelium. How the breaching of two BMs is coordinated during the invasion process is unknown. Previous work from the Sherwood Lab has

shown that mutations in a matricellular protein, HIM-4, the *C. elegans* ortholog of hemicentin, result in a 17% AC invasion defect. Transgenic worms expressing HIM-4::GFPdisplay distinct HIM-4 punctae specifically in the BM beneath the AC prior to invasion. As the AC invades, the HIM-4 punctae are pushed aside and accumulate around the edge of the BM hole. By imaging worms expressing LAM-1::GFP in the *rol-6(su1006)* background, we were able to obtain a ventral view of BM dynamics during AC invasion at a higher resolution than previous studies. Our results reveal that in 90% of wild type animals the AC invades simultaneously through the uterine and vulval BM, creating a single hole in both BMs. Strikingly, only 10% of *him-4(rh319)* worms breach the two BMs simultaneously, with 90% first opening up a hole in the uterine BM and subsequently penetrating the vulval BM in a delayed manner. By physically separating the uterine and vulval tissues, we have observed that the uterine and vulval BM become tightly linked specifically under the AC before invasion. Further, after AC invasion, the distinct vulval and uterine BM are fused into a continuous sheet at the edge of the AC. We hypothesize that HIM-4 functions in a novel process, adhering two distinct BM, to facilitate AC invasion. Interestingly, BM adherence and fusion have been observed in other developmental contexts, such as glomeruli formation and alveolar development, but the mechanisms underlying these BM changes remain unknown. BM remodeling during AC invasion may provide a tractable model to understand the molecular mechanism of BM adherence and fusion.

967

Fibroblast clustering on three-dimensional collagen matrices: Role of α5 integrin.

B. da Rocha-Azevedo[1], F. Grinnell[2]; [1]Cell Biology, UT Southwestern Medical Center, Dallas, TX, [2]UT Southwestern Medical Center

Cell organization and plasticity respond to diverse stimuli in the cellular microenvironment. Fibroblasts cultured in medium containing fetal bovine serum (FBS) or lysophosphatidic acid (LPA) on three-dimensional (3D) collagen matrices establish a procontractile phenotype that leads to the formation of cell clusters. The formation of clusters did not occur when cells were incubated with platelet-derived growth factor (PDGF), which activates a promigratory phenotype. The switch between clustering and dispersion phenotypes is reversible, indicating that signaling pathways can be turned on and off. To learn about the mechanism responsible for stabilizing cell-cell interactions when cells form clusters, we studied cluster formation by BR-5 human foreskin fibroblasts under conditions in which we used siRNA technology to modulate cell-cell and cell-matrix junctional complexes. Silencing N-cadherin expression interfered with formation of adherens junctions as detected by localization of N-cadherin and beta catenin. However, under these conditions cell cluster formation was unaffected. On the other hand, silencing alpha-5-integrin not only blocked cell adhesion to fibronectin (FN)-coated culture dishes, but also interfered with cell clustering on collagen matrices. Subsequent studies supported the idea that cell clusters were stabilized by integrin interaction with cell secreted fibronectin matrix. In cell clusters, alpha-5 integrin and fibronectin were observed in close proximity in cell clusters. Fibronectin matrix in the clusters was cell-derived since the FN distribution appeared similar regardless whether clustering took place in FBS-containing medium (which contains plasma FN) or in LPA (which lacks plasma FN). Once formed, the FN matrix appeared to be stable because addition of PDGF to clustered cells caused cell dispersion without causing disruption of the FN matrix. Our studies provide new insights in to the mechanism by which the growth factor microenvironment of cells on 3D collagen matrices can modulate changes in cell and matrix organization.

Sponsored by the National Institutes of Health GM31321.

SHARPIN is an endogenous inhibitor of beta1-integrin activation.

J. Rantala[1], J. Pouwels[1], T. Pellinen[1], S. Veltel[2], P. Laasola[1], C. Potter[3], T. Duffy[3], J. Sundberg[3], O. Kallioniemi[4], J. Askari[5], M. Humphries[5], M. Parsons[6], M. Salmi[7], J. Ivaska[1]; [1]Medical Biotechnology, VTT, Turku, Finland, [2]Centre for Biotechnology, University of Turku, [3]The Jackson Laboratory, [4]Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland, [5]Wellcome Trust Centre for Cell-Matrix Research, University of Manchester, [6]Randall Division of Cell and Molecular Biophysics, Kings College London, [7]MediCity Research Laboratory and Department of Medical Biochemistry and Genetics, University of Turku

Regulated activation of integrins is critical for cell adhesion, motility and tissue homeostasis. Talin and Kindlins activate β1-integrins, but the counteracting inhibiting mechanisms are poorly defined. Here we identified SHARPIN as an important inactivator of β1-integrins in an RNAi-screen. SHARPIN inhibited β1-integrin functions (affecting cell adhesion and migration) in human cancer cells and primary leukocytes. Fibroblasts, leukocytes and keratinocytes from SHARPIN-deficient mice exhibited increased β1-integrin activity (and increased cell migration) which was fully rescued by re-expression of SHARPIN. Mechanistically, SHARPIN directly bound to a conserved cytoplasmic region of integrin α-subunits and inhibited recruitment of Talin and Kindlin to the integrin. Therefore, SHARPIN binding to the cytoplasmic tail of α-integrins inhibits the critical switching of β1-integrins from inactive to active conformations.

Fibronectin promotes mesenchymal cell condensation and regulates Sox9 during chondrogenic differentiation.

P. Singh[1], J. E. Schwarzbauer[1]; [1]Molecular Biology, Princeton University, Princeton, NJ

Mesenchymal stem cells (MSCs) have potential as a therapeutic tool for joint repair due to their ability to differentiate into chondrocytes and deposit cartilaginous extracellular matrix. Fibronectin is abundant in growth plates at joints suggesting that this matrix protein may have a role in cartilage formation. Bone marrow-derived MSCs were induced to undergo chondrogenic differentiation in high-density micromass or pellet culture by addition of TGFβ3 and other factors. Cells condense into a compact aggregate during the first 24 hours followed by differentiation of condensed cells into chondrocytes, a process that requires changes in cell organization, gene expression, and matrix composition. Our results show that fibronectin production increased by day 3, remained elevated through day 9, and then decreased to a moderate level through day 21. Fibronectin matrix within the high-density culture also increased over time as detected by immunofluorescence. Type I collagen had a similar profile of secretion and matrix incorporation as fibronectin. We observed transient upregulation of the condensation marker N-cadherin at day 1. mRNA expression for Sox9, a major transcription factor required for chondrogenic differentiation, was increased after day 2 and remained elevated for an extended period during differentiation. Thus the increase in fibronectin level at day 3 corresponds with the increase in Sox9 which led us to hypothesize that fibronectin facilitates early chondrogenic differentiation. To test the requirement for fibronectin, we used siRNAs to knock down its expression in MSCs. Interestingly, we observed an early effect of reduced fibronectin, namely, impaired cell condensation, which was accompanied by a transient decrease in N-cadherin and a prolonged reduction in Sox9 mRNAs. Addition of exogenous fibronectin was sufficient to partially restore Sox9 mRNA expression. These results indicate that fibronectin-cell interactions facilitate condensation and regulate expression of an essential differentiation marker. To investigate potential mechanisms for the fibronectin effects, chondrogenesis was induced in the presence of excess fibronectin cell binding domain (CBD) fragment to disrupt integrin binding to fibronectin. Our preliminary results show that addition of the CBD fragment inhibited

condensation and reduced expression of Sox9. We propose that fibronectin has a dual role in chondrogenesis, participating in cell condensation and signaling through integrins to induce Sox9 expression.

971

An Antibody to the Lutheran Glycoprotein (Lu) Recognizing the LU4 Blood Type Variant Prevents LU Binding to Laminin α5.

Y. Kikkawa[1], T. Miwa[1], Y. Tohara[1], T. Hamakubo[1], M. Nomizu[1]; [1]Lab of Clin Biochem, Tokyo Univ Pharm/Life Sci, Hachioji, Japan

The Lutheran blood group glycoprotein (Lu), an Ig superfamily (IgSF) transmembrane receptor, is also known as basal cell adhesion molecule (B-CAM). Lu/B-CAM is a specific receptor for laminin α5, a major component of basement membranes in various tissues. Previous reports have also shown that Lu/B-CAM binding to laminin α5 contributes to sickle cell vaso-occlusion. However, since there are no useful tools such as function-blocking antibody and drug, it is still unclear how epithelial and sickled red blood cells adhere to laminin α5 through Lu/B-CAM. By studying several monoclonal antibodies that recognize Lu/B-CAM, we discovered a function-blocking antibody that inhibits the binding of Lu/B-CAM to laminin α5. It also suggested that the function-blocking antibody recognized an epitope of Lu/B-CAM involved in binding laminin α5. Therefore, to characterize the function-blocking antibody, we first identified the site on Lu/B-CAM recognized by this antibody. The extracellular domain of Lu/B-CAM contains five IgSF domains, D1-D2-D3-D4-D5. To narrow the region recognized by the antibody, we produced a series of truncated proteins with sequentially deleted Ig-like domains and chimeric proteins replaced with the analogous domain of melanoma cell adhesion molecule (Mel-CAM). The antibody epitope was localized to D2, but not to the D3 domain containing the major part of the laminin α5 binding site. Furthermore, mutagenesis studies showed that Arg^{175} was crucial for forming the epitope. Arg^{175} was also located at the LU4 blood group antigenic site. To examine if Arg^{175} was essential for forming the epitope, we also produced mutant protein substituted with Ala. However, although Arg^{175} was a part of the epitope recognized by the function-blocking antibody, it was not involved in the binding of laminin α5. The results suggested that the antibody bound sufficiently close to sterically hinder the interaction with α5. Inhibition assay using the antibody also showed that Lu/B-CAM served as a secondary receptor in the adhesion of carcinoma cells to laminin α5. This function-blocking antibody against Lu/B-CAM would be useful for not only investigating cell adhesion to laminin α5 but also developing drugs to inhibit sickle cell vaso-occlusion.

972

Role of IRSp53 in Cell-Extracellular Matrix Adhesion and Filopodia Formation in C2C12 Cells.

B. George[1], A. Misra[1], T. Thanabalu[1]; [1]School of Biological sciences, Nanyang Technological University, Singapore, Singapore

IRSp53 (Insulin Receptor Substrate) is an adaptor molecule which couples membrane-deforming activity with the actin cytoskeleton remodelling. Actin cytoskeleton plays a critical role in cell adhesion. Cell-extracellular matrix (ECM) adhesion is vital for many processes such as proliferation, differentiation and cell migration. Binding of integrin receptors to their respective ligands in the ECM lead to integrin clustering and activation that triggers the formation of large multiprotein complexes on the cytosolic face of the plasma membrane, referred to as Focal adhesions (FA). Vinculin is a component of cell adhesion complex that links actin cytoskeleton to integrins. Fibronectin, a major extra-cellular matrix protein, is one of the major constituents of endomysium (a layer of connective tissue that ensheaths a muscle fiber). Thus we sought to

determine the role of IRSp53 in adhesion to fibronectin in mouse muscle progenitor cells C2C12. We found a significant reduction in binding and spreading of C2C12 expressing IRSp53 as compared to control cells on fibronectin coated wells whereas knockdown of endogenous IRSp53 in C2C12 cells slightly increased the binding and cell spreading on fibronectin coated wells. We also investigated the effect of IRSp53 expression on localization of focal adhesion protein vinculin. Prominent vinculin patches were observed in control and knockdown cells, whereas IRSp53 expressing cells showed reduced vinculin patches. These results suggest that expression of IRSp53 inhibits adhesion of C2C12 cells on fibronectin and vinculin patches assembly. IRSp53 consists of three well-characterized domains an N-terminal IMD (IRSp53 and Missing in metastasis Domain) followed by a GBD (GTPase Binding Domain) motif and a SH3 domain. We further identified the role of the three domains of IRSp53 (IMD, GBD and SH3 domains) in localization and filopodia induction in C2C12 cells. We observed membrane localization and filopodia formation in cells transfected with IRSp53-EGFP expressing plasmid. Mutations in any of the three domains (IMD, GBD or SH3) impaired filopodia formation ability of IRSp53. Significant membrane localization was observed in IRSp53267N-EGFP (GBD mutant) expressing cells and less membrane localization in IRSp532A-EGFP (SH3 mutant) expressing cells while no membrane localization was observed in IRSp534A-EGFP (IMD mutant) expressing cells. This implies that IRSp53IMD domain is important for recruiting IRSp53 to the plasma membrane as well as for inducing membrane protrusions by IRSp53 in C2C12 cells.

973

Galectin-8 medium and long isoforms have opposite effects upon apoptosis in T cells and differential expression in lupus.

R. Doger[1,2], C. Metz[1,2], J. Urbina[2], F. Garay[1], S. André[3], G. Joanchin[3], A. González[1,2], A. Soza[1,2]; [1]Centro de Envejecimiento y Regeneración (CARE), Fac. Ciencias Biológicas. Pontificia Universidad Católica de Chile, Santiago, Chile, [2]Depto. Inmunología Clínica y Reumatología, Fac. Medicina. Pontificia Universidad Católica de Chile, Santiago, Chile, [3]Ludwig-Maximilians-University Munich, München, Germany

Galectins are a family of carbohydrate binding proteins (lectins) that are secreted through a non-conventional pathway and interact with beta-galactosides of cell surface and extracellular matrix glycoproteins, contributing to modulate a variety of cellular processes, including T cell homeostasis. Galectin-8 (Gal-8) consists of two different carbohydrate recognition domains (CRDs) joined by a linker peptide whose length variation gives rise to Medium (Gal-8M) and Long (Gal-8L) isoforms. Gal-8M has been the most studied. Previously, we showed that Gal-8M induces apoptosis on T cells through a pathway involving phosphatidic acid mediated ERK activation. Here we compared the effects of Gal-8L and Gal-8M on apoptosis and ERK1/2 and AKT signaling in Jurkat T cells and also assessed the expression levels in peripheral blood mononuclear cells (PBMC; 70% T cells) from normal individuals and patients with systemic lupus erythematosus (SLE), the prototypic autoimmune disease. Gal-8L does not induce apoptosis but instead counteracts the apoptosis, as well as the activation of beta1-integrin and ERK1/2, induced by Gal-8M. ERK1/2 activation is proapoptotic in T cells. Gal-8L also increases activation of anti-apoptotic AKT pathway. Strikingly, CRDs alone have similar anti-apoptotic effects, suggesting that Gal-8L might act as a monomeric CRD. RT-PCR shows an increased expression of Gal-8M in PBMC from SLE patients. These results are the first indication that isoforms of Gal-8 exert opposing effects on T cell homeostasis, with Gal-8L counteracting the immunosuppressor action of Gal-8M, and the changes in expression levels suggest a role in the pathogenesis of SLE.

Regulation of cell-cell and cell-ECM forces during the initial stages of epithelial cell scattering.

V. Maruthamuthu[1], M. L. Gardel[1,2]; [1]Institute for Biophysical Dynamics, University of Chicago, Chicago, IL, [2]Department of Physics, University of Chicago

Transition of cells from an epithelial to a mesenchymal phenotype is important during various stages of development and during disease progression. However, the role played by physical forces in orchestrating such a transition has been largely unclear. We have previously shown that cells exert significant tension at the cell-cell contact in an epithelial cell pair and that this tension directly increases with the level of cell-ECM force. This suggests that significant force redistribution must occur at the cell-microenvironment interface during epithelial to mesenchymal transition (EMT). Here, we use a classical model of EMT – the hepatocyte growth factor (HGF) induced scattering of MDCK cells – to determine the effect of growth factor induction on cell-cell and cell-ECM forces. In an epithelial cell pair with a single cell-cell interface, HGF induction leads to enhanced protrusive activity and marked expansion of cell area. Increased spread area, in turn, leads to a substantial increase in the total cell-ECM traction exerted on the substrate. Importantly, the tension at the cell-cell contact also increases in proportion to the total cell-ECM force. This suggests that enhanced protrusive activity dynamically modulates cell-ECM as well as cell-cell forces. Understanding how spatio-temporal regulation of cell protrusive activity impacts cell-cell and cell-ECM forces has direct implications for understanding morphogenesis and tumor metastasis.

975

Rigidity-dependent T Cell Costimulation.

E. Judokusumo[1], E. Tabdanov[1], S. Kumari[2], M. L. Dustin[2], L. C. Kam[1]; [1]Biomedical Engineering, Columbia University, New York, NY, [2]Skirball Institute of Biomolecular Medicine, New York University School of Medicine

T cells play a key role in mediating adaptive immunity. Activation of these cells occurs through engagement of the T Cell Receptor (TCR) complex with peptide-loaded MHC on the Antigen Presenting Cell (APC) surface, within a small area of contact termed the immune synapse. Costimulation through CD28, also a membrane-bound receptor, augments the TCR response and is needed for activation of naive T cells. The immune synapse is also characterized by an active and dynamic cytoskeleton which transports TCR and CD28 microclusters along the cell surface, posing the possibility that subsequnt signaling may be modified by the mechanical response of the extracellular environment. To explore such a possibility, this study examines activation of mouse CD4+ T cells by polyacrylamide gels presenting ligands to CD3 (activating component of the TCR) and CD28. IL-2 secretion, a high-level measure of costimulation, correlates directly with elastic modulus over a range of 10 – 200 kPa. Furthermore, this response can be divided into two regimes; on the stiffest surfaces, cell exhibit strong attachment and modulation of IL-2 secretion, while on the softest surfaces, cytokine secretion and attachment are both reduced. Phosphorylation of Lck and Zap70 were similarly reduced on the softest surfaces, suggesting that changes in early TCR signaling differentiate the two regimes. By presenting CD3 and CD28 ligands on different surfaces, we further demonstrated that mechanosensing is associated primarily with TCR signaling, although a minor and contrasting rigidity response was observed for CD28 signaling. This study presents the first evidence of cellular-level mechanosensing in T lymphocytes. Importantly, physical connections between the

cytoskeleton and TCR or CD28 have not been clearly delineated. Signaling through these receptors is thus a new realm of mechanobiology, and highly complementary to current understanding of similar responses to integrin and cadherin systems.

976

Fine mapping of the plakophilin-1 interaction with desmoplakin: Implications for desmosome plaque assembly.

R. Reddy[1], A. Pashaj[1], J. K. Wahl III[1]; [1]Oral Biology, Univ of Nebraska Medical Center, Lincoln, NE

Desmosomes are prominent cell-cell adhesive junctions in stratified squamous epithelial tissues, such as the skin and oral cavity, and are known to provide a point of continuity for the intermediate filament cytoskeleton throughout these epithelial tissues. The transmembrane core of the desmosome consists of the desmosomal cadherins (desmogleins and desmocollins) and is linked to the intermediate filament cytoskeleton through interactions with cytoplasmic desmosomal plaque proteins. These include plakoglobin, plakophilins and plakin family members. Plakophilins are armadillo repeat containing proteins that serve as scaffold proteins to cluster the desmosomal cadherins and recruit the IF cytoskeleton through interactions with desmoplakin. Over expression of pkp-1 in A431 cells resulted in increased desmoplakin recruitment to cell borders. We hypothesized that Pkp-1 interactions with desmoplakin play an important regulatory role in desmosome dynamics and disruption of this interaction results in decreased desmosome assembly. In order to study this interaction more closely, we sought to map the sequences of plakophilin-1/desmoplakin interaction. Previous studies have shown that the amino terminal domain of pkp-1 is important for binding to desmoplakin. Using a yeast two-hybrid approach; we mapped the interaction to a highly conserved sequence shared by other plakophilin isoforms. Point mutants were generated and shown to disrupt the plakophilin-1/desmoplakin interaction. Additionally, we demonstrated that plakophilin-1 mutants unable to interact with desmoplakin failed to promote desmosome assembly in A431D cells. Further characterization of plakophilin interactions reveal the ability of plakophilins to interact with one another, raising the possibility that plakophilins dimerize during desmosome plaque assembly. These studies extend our understanding of the role of plakophilin in desmosomal plaque assembly.

977

Plakophilin-3 interacts with 14-3-3 sigma (stratifin) independent of desmosome assembly.

B. J. Roberts[1], A. Pashaj[1], J. K. Wahl III[1]; [1]Oral Biology, Univ of Nebraska Medical Center, Lincoln, NE

Desmosomes are prominent adhesive junctions present in all epithelial tissues. Assembly and linkage of the desmosome to the intermediate filament cytoskeleton is dependent on a family of cytoplasmic proteins that constitute the desmosomal plaque. Plakophilin-3, a member of the armadillo family of proteins, is a component of the inner dense plaque of the desmosome and loss of plakophilin expression is known to affect junction assembly. Mechanisms regulating plakophilin-3 incorporation into the desmosomal plaque and overall junction assembly are poorly understood. In the current study we sought to identify novel plakophilin-3 interacting partners in an effort to identify mechanisms controlling desmosome assembly in epithelial cells. We identified stratifin (14-3-3 sigma) as a plakophilin-3 interacting protein using an affinity purification and mass spectroscopy approach. We confirmed this interaction in vivo by immunoprecipitation and we show this interaction is direct by yeast two-hybrid analysis. We mapped the domain of plakophilin-3 that is responsible for this interaction and found the

interaction to require a sequence not conserved in plakophilin-1 or plakophilin-2. Interestingly, the plakophilin-3/stratifin complex resides in the cytosol and is not incorporated into the desmosomal plaque. Interactions with stratifin in the cytosol may sequester a pool of plakophilin-3 in the cytosol and limit the pool of plakophilin-3 available to assemble the desmosome. These finding suggest that plakopihilin-3 may have unique and uncharacterized roles in the cytosol that may be distinct from its role in desmosomal adhesion.

978

Scribble and the Met receptor tyrosine kinase.

A. Spilker[1], G. Paliouras[1], M. Naujokas[1], J. Fawcett[2], M. Park[1]; [1]Goodman Cancer Center, McGill University, Montreal, QC, Canada, [2]Pharmacology, Dalhousie University, Halifax, NS, Canada

The activity or protein levels of Met, a receptor tyrosine kinase activated by hepatocyte growth factor (HGF), are frequently elevated in human cancers. In epithelial cells in culture, activation of the Met receptor induces a phenotype reminiscent of epithelial to mesenchymal transition (EMT), a process implicated in the formation of metastases. This includes the loss of cell-cell adhesion, remodeling of cell polarity, cell migration and invasion through matrix. However, how Met signaling elicits the changes in cellular morphology required for this metastasis-like behavior of cells is still largely unknown. We identified Scribble, a conserved scaffold protein previously shown to be required for cell-cell adhesion, cell migration and cell polarity as a physical interactor of the Met receptor. Scribble acts as a tumor suppressor in flies and mammalian systems and altered levels or mislocalization of the Scribble protein are observed in many human cancers. This makes it a promising candidate to execute Met-dependent remodeling of cellular architecture in order to facilitate cell migration or invasion and contribute to the oncogenic potential of the Met receptor.
By co-immunoprecipitations, we were able to show that Scribble and Met interact. Consistent with this finding, we observe partial co-localization of Scribble and the Met receptor at the basolateral cortex of polarized epithelial cells using immunofluorencence. Biochemical analysis indicates that the interaction between Scribble and Met is independent of maturation or kinase activation status of the receptor and does not require the Met scaffold protein Gab1. Importantly, preliminary data further suggest that abrogation of Scribble function leads to changes in cell migration in response to HGF, suggesting that Scribble modulates this process downstream of the Met receptor.
Given the role of Scribble in the organization of cell polarity, cell migration and as a tumor suppressor, we propose a role for Scribble in Met signaling, contributing to the changes in cellular organization observed during Met-induced signal transduction. We are currently analyzing whether the interaction between Scribble and Met is required for the cellular response to Met signaling, which subcellular compartments are important for the interaction, and which protein domains of Scribble and Met are involved in this process. Progress towards answering these questions this will be presented.

979

Regulation of Anoikis by the Discs Large 1 Tumour Suppressor.

P. Massimi[1], P. Zori[2], S. Roberts[3], L. Banks[1]; [1]Tumour Virology, ICGEB, Trieste, Italy, [2]ICGEB, Trieste, Italy, [3]Department of Cancer Sciences, University of Birmingham, Birmingham, United Kingdom

Human Papillomaviruses (HPVs) are the causative agents of cervical cancer, the second major cause of cancer related death in women worldwide. Most cervical cancers are caused by two HPV types, HPV-16 and HPV-18. These viruses encode two oncoproteins, E6 and E7, both of

which are required for the development and maintenance of the transformed phenotype. The oncogenic E6 proteins all possess PDZ binding motifs (PBMs) that confer interaction with cellular PDZ domain containing proteins. Through this PBM, HPV-16 and HPV-18 E6 both target two critical regulators of cell polarity, with HPV-16 E6 interacting with Scribble, whilst HPV-18 E6 interact with Discs Large 1 (Dlg1). We have been interested in understanding what aspects of the functions of Scribble and Dlg1 are relevant for the ability of HPV-16 and HPV-18 E6 to induce malignancy.
Using epithelial cells in which the expression of Scribble and Dlg1 have been ablated we demonstrate that loss of Scribble enhances cell invasion, reduces cell-cell contact and increases cell proliferation, characteristics that are favourable for HPV induced malignancy. In contrast, loss of Dlg reduces cell invasion potential and slows cell proliferation, effects that would seem at odds with a tumour suppressor potential. However we have found that Dlg is a powerful regulator of the apoptotic process of anoikis with loss of Dlg greatly increasing a cells resistance to this apoptotic response. Furthermore, HPV-18 containing cervical tumour derived cells have a high degree of resistance to anoikis: this is independent of the p53 status but dependent upon the presence of HPV-18 E6 and the absence of Dlg1. Using proteomic and microarray approaches we are now assessing the impact of the loss of Dlg1 upon gene expression profiles and identifying the relevant interacting partners of Dlg that might explain its anoikis regulating activities.
Taken together these results demonstrate that HPV E6 targeting of the Scribble/Dlg cell polarity regulating complex, can effect multiple levels of tumourigenesis, including, invasion, cell proliferation and anoikis.

980

Cell Adhesion Molecules Selection as Candidates for Differential Manipulation.

R. Martinez-Garcia[1], F. Carrero-Martinez[2,3]; [1]Department of Chemistry, University of Puerto Rico-Mayaguez, Puerto Rico, [2]Department of Biology, University of Puerto Rico-Mayaguez, Mayaguez, PR, [3]Department of Anatomy and Neuroscience, University of Puerto Rico-Medical Sciences Campus, Puerto Rico

Nanotechnology is a promising field that opens the possibility of minimally invasive in vivo manipulation in order to accomplish neuronal restoration. We propose that Cell Adhesion Molecules (CAM’s) can be used as targets for differential manipulation. CAM´s are essential at all developmental stages including those leading to a functional neuromuscular junction (NMJ). However, knowledge of how CAM´s organize spatiotemporally to facilitate assembly the NMJ network is limited. Differential manipulation can be achieved only with prior understanding of how CAM’s are normally organized in synaptogenesis through development. Immunocytochemistry assays and confocal microscopy enables three-dimensional visualization of CAM’s in the ventral somatic musculature of Drosophila embryos. Selected CAM´s (such as FasciclinII (FasII), Integrin and Dscam) are visualized from embryonic stages 12 to 18 in order to observe how they organize through development. This allows us to discern which CAM is ideal for manipulation. FasII, known for its role in axon guidance, is a candidate cell adhesion molecule for manipulation because it is expressed in axon bundles in the pattern that makes up ventral somatic musculature. Three dimensional localization of FasII in the anterior and posterior commisures of the ventral cord and the axon bundles in the ventral somatic musculature of stage 15 embryos has led it to be considered as a candidate for differential manipulation. My results, together with nanomaterial toxic assessment will bring us closer to achieve neuronal differential manipulation.

981

Effects of Cigarette Smoke Exposure on Expression and Function of the Adherence Junction Molecule CD146 in Pulmonary Endothelial Cells.

A. Kratzer[1], J. Salys[1], B. Gonzalez[1], H. W. Chu[2], M. Zamora[3], L. Taraseviciene-Stewart[1]; [1]Pulmonary Sciences and Critical Care, UC Denver, Aurora, CO, [2]National Jewish Health, [3]UC Denver

Cell adhesion molecule CD146 is a transmembrane glycoprotein constitutively expressed in all types of endothelial cells (EC). Two forms of CD146 have been found: the membrane-anchored form and the soluble form (sCD146). The plasma concentration of sCD146 is modulated in inflammatory diseases associated with endothelial alterations. We have investigated the role of endothelial CD146 in the cigarette smoke-induced emphysema *in vivo* and in pulmonary endothelial cells (EC) *in vitro*. Sprague Dawley rats exposed to cigarette smoke for 2 months developed significant emphysematous changes (as measured by mean linear intercept) and had increased levels of circulating and bronchoalveolar lavage fluid sCD146. CD146 is highly expressed in rat pulmonary microvascular endothelial cells (RPMVEC) and to a much lower extend in pulmonary macrovascular endothelial cells. Treatment with cigarette smoke extract (CSE) *in vitro* resulted in a decreased membrane-bound CD146 expression as well as reduced gene expression and increased sCD146 levels in the medium. Moreover, CSE-induced downregulation of CD146 expression increased vascular permeability of RPMVEC measured by EVANs Blue and macrophage migration assay. Similar results were found upon silencing of CD146 suggesting a role of CD146 in controlling tissue inflammation. Circulating levels of sCD146 were significantly increased in plasma of patients with COPD and correlated with the disease severity. In summary, CD146 plays an important role in pulmonary vascular EC function and its circulating form might reflect vascular endothelial injury.

982

Hydrogen Peroxide Produces A Selective Increase In Renal Epithelial Cell Paracellular Permeability To Large Solutes Via src Family Kinase Activation.

V. V. Rohring[1], D. Janosevic[1], S. Jaggi[1], D. Caswell[1], J. Axis[1], K. Amsler[1]; [1]NYCOM, Old Westbury, NY

Renal ischemia/reperfusion (I/R) injury is a significant cause of acute kidney injury and contributes substantially to patient morbidity and mortality, e.g., in renal transplant. Tubular backleak, due to breakdown of the renal epithelial cell paracellular permeability barrier, is a major component of renal I/R injury. Renal I/R injury is associated with increased tissue levels of hydrogen peroxide (H_2O_2). We have begun an analysis of the mechanism by which H_2O_2 produces increased renal epithelial cell paracellular permeability and the role of src Family Kinases (SFKs) in mediating the H_2O_2-induced increase. H_2O_2 produced a concentration-dependent increase in paracellular permeability of renal epithelial cell lines derived from both proximal (LLC-PK1) and distal (mIMCD3, and MDCK) nephron segments. “Leak pathway” permeability (low capacity, large solute size; measured using calcein and fluorescein-dextran4000) was selectively increased at H_2O_2 concentrations that did not produce cell death (Trypan Blue-positive nuclei). Data suggest an enhanced response with increasing solute size. In contrast, “pore pathway” permeability (high capacity, small solute size; measured as TransEpithelial Resistance (TER)) was only increased at H_2O_2 concentrations that also increased cell death. H_2O_2 produced a time-dependent, transient activation of SFKs. The H_2O_2-induced increase in leak pathway permeability was attenuated by SFK inhibitors, PP1 and PP2, but not by the inactive analog, PP3. H_2O_2 treatment did not produce changes in the cellular

contents of the tight junction (TJ) proteins occludin, claudin-1, ZO-1, or ZO-2. Under our extraction conditions (1% Triton X-100), the majority of all four TJ proteins was in the Triton X-100-soluble fraction. Moreover, our data indicate that the distribution of occludin and claudin-1 between Triton X-100-soluble and -insoluble fractions was unaffected by hydrogen peroxide treatment. However, the subcellular localization of occludin, but not claudin-1, to the TJ region was disrupted by H_2O_2 treatment. These data demonstrate that H_2O_2 selectively increases paracellular permeability via the leak pathway and that this effect is mediated, at least in part, by SFKs, possibly through modulation of occludin association with the tight junction structure.

983

Mitochondrial Translocation in Lymphocytes of Human Autologous Macrophage-Lymphocyte Rosettes.

I. T-C. Novak[1], A. D. Orquera[1,2]; [1]Natl Univ Cordoba Fac Med, Cordoba, Argentina, [2]Institute of Cell Biology

The phenomenon of multiple immunological synapses on macrophage-lymphocyte rosette (MLR) (Cabral and Novak, 1992, 99; Novak and Cabral 2008, 09) refers to cellular association between human blood monocyte-derived macrophages and lymphocytes from autologous cultures total leukocytes extracted from the blood, which bind selectively forming rosettes with central macrophage and lymphocytes adhered (MLRs). The contact area between a T cell and antigen-presenting cell is known as "immunological synapse" (Grakoui et al, 1999) and the multiple interactions that occur leading to a "signal" for T cell activation. The cells interact in the MLR phenomenon may present special features in their areas of contact or cell-cell interaction, and in the surrounding cytoplasm. Has focused attention on the organization of proteins in the contact area of the IS. Objectives: ultrastructural study to observe the location of mitochondria in the cells of the MLRs, taking into account the energy requirements for activation. Materials and methods: We used healthy human blood samples, anticoagulated with heparin (n = 10) (donated by the Blood Bank, UNC, anonymity, data serology). Autologous cultures in TC199 medium (SIGMA, St. Louis, MO). Samples: 48 and 144 h. MLR technique (Cabral y Novak, 1992, 99). Cell sediment samples of MLRs underwent electron microscopy. MET: Zeiss LEO-906E. Results: We observed redistribution of mitochondria in lymphocytes to the immune synapse area in MLRs. Conclusion: This distribution coincides with mitochondrial energy needs and opening channels of entry of Ca (2 +) for cellular activation.

984

Regulation of Intercalated Disc Formation during Postnatal Cardiac Development by the E3 Ubiquitin Ligase Wwp1.

W. A. Basheer[1], M. H. Abreha[1], R. L. Price[2], B. S. Harris[3], L. E. Matesic[1]; [1]Biological Sciences, University of South Carolina, Columbia, SC, [2]Cell Biology and Anatomy, University of South Carolina School of Medicine, Columbia, SC, [3]Regenerative Medicine and Cell Biology, Medical University of South Carolina, Charleston, SC

The developing postnatal heart maintains electrical and mechanical function while undergoing substantial changes in cardiomyocyte *architecture*. The electro-mechanical coupling between adjacent cardiomyocytes is tightly controlled by intercellular junctions localized at the intercalated discs (ICD) to ensure healthy and synchronized mechanical coupling (mediated by the fascia adherens and by desmosomes) and electrical conduction (via gap junctions). The spatiotemporal expression patterns of intercellular junction proteins are closely coordinated during postnatal cardiac development. During this period, which lasts about 8 weeks in mice, 90 days in rats, and 6 years in humans, there is a progressive and sequential accumulation of the intercellular junction proteins at the ICD. Several intercellular junction proteins have been shown

to be regulated via ubiquitination. Our recent data show that the E3 ubiquitin ligase Wwp1 is highly expressed in cardiomyocytes throughout this developmental window, and that Wwp1 can ubiquitylate the gap junction protein connexin 43 (Cx43). The objective of this study was to examine how modulating Wwp1 expression affects the structure and function of ICD during postnatal cardiac development. To achieve this objective, we created mice which either ubiquitously overexpress Wwp1 or completely lack Wwp1 activity. We found that all of the Wwp1 overexpressers died very suddenly around 2 months of age, while *Wwp1* knockouts were viable and fertile. Cardiac tissue derived from Wwp1 overexpressers was assessed by confocal microscopy and western blotting and showed mislocalization as well as diminished abundance of Cx43 at 4, 6 and 8 weeks of age. Consistent with loss of myocyte electrocoupling due to altered Cx43 expression, electrocardiogram abnormalities were noted in the Wwp1 overexpressers. The effect of Wwp1 on ICD formation seemed to be specific to Cx43 as the expression and localization of other ICD proteins such as N-Cadherin and Desmoplakin were not affected at any of the time points examined. In contrast to the transgenic mice, the *Wwp1* knockout animals showed an increase in the abundance of Cx43 protein in cardiac tissue at 2, 4, 6 and 8 weeks of age. Thus, this study highlights a new role of Wwp1 in regulating Cx43 protein levels during cardiac postnatal development.

985

Preparation of claudin-4 binder using C-terminal fragment of *Clostridium perfringens* enterotoxin and its application to mucosal vaccination.

H. Suzuki[1], S. Yamane[1], A. Watari[1], M. Kondoh[1], H. Uchida[2], K. Yagi[1]; [1]Osaka University, Osaka, Japan, [2]ASUBIO PHARMA Co., LTD.

Objective: Mucosal vaccines activate both mucosal and systemic immune responses, and are less painful, as they are needle free. Thus, mucosal vaccination appears to be an ideal vaccination strategy. The effective delivery of antigens to mucosa-associated lymphoid tissues (MALT) is a critical issue for the development of potent mucosal vaccines. Claudin-4, a tetra-transmembrane protein, is expressed in epithelial cells covering MALT (Tamagawa et al., Lab Invest, 2003). We previously showed that claudin-4-targeting is a promising strategy for mucosal vaccination using a claudin-4 ligand, the C-terminal fragment of *Clostridium perfringens* enterotoxin (C-CPE) (Kakutani et al., Biomaterials, 2010). In the present study, we determined the functional domain of C-CPE, and we subsequently attempted to prepare a novel claudin binder with higher affinity for claudin. We also applied the novel claudin binder to mucosal vaccination.

Methods: We genetically prepared alanine-substituted C-CPE mutants, and we determined their affinity for claudin-4 by BIAcore analysis. We also prepared a fusion protein of ovalbumin (OVA) as a model antigen with C-CPE mutants. Interaction of C-CPE mutant-fused OVA with claudin-4 was examined by ELISA using an immunoplate coated with claudin-displaying baculovirus. The titers of OVA-specific antibody in serum and mucosal washes were determined by ELISA. Production of interferon-γ and interleukin-13 in the splenocytes isolated from the immunized mice were measured using a commercially available ELISA kit. In an anti-tumor assay, female C57BL/6 mice (6-8 weeks) were nasally immunized with C-CPE mutant-fused OVA once a week for 3 weeks. Seven days after the last immunization, mice were subcutaneously inoculated with 1×10^6 EG7-OVA cells, and tumor growth was monitored.

Results: Substitution of some amino acids with alanine increased affinity of C-CPE for claudin-4, with KD values increasing from 455 pM to 46 pM. When mice were immunized with the C-CPE mutant-fused OVA, OVA-specific serum IgG and nasal IgA increased 10-fold when compared to mice immunized with C-CPE-fused OVA. Immunization with C-CPE mutant-fused OVA activated stronger Th1- and Th2-type responses than in mice immunized with C-CPE-

fused OVA. C-CPE mutant-fused OVA exhibited greater anti-tumor activity than C-CPE-fused OVA.
Conclusion: These results indicate that the alanine-substituted C-CPE mutant is a promising lead for claudin-targeted mucosal vaccines.

986
The Functional and Mechanical Consequences of Age in *Drosophila* Myocardium.
G. Kaushik[1], M. Nishimura[2], A. Fuhrmann[1], R. Bodmer[2], A. Cammarato[2], A. J. Engler[1]; [1]Bioengineering, University of California, San Diego, La Jolla, California(CA), [2]Development and Aging Program, Del E. Webb Neuroscience, Aging, and Stem Cell Research Center, Sanford-Burnham Medical Research Institute

Drosophila melanogaster is a genetically malleable organism with a short life span, making it a tractable system in which to study mechanical effects of aging and genetic modification on tissue, such as impaired heart function. We performed an micromechanical analysis on the heart tubes of juvenile and geriatric flies to investigate how heart stiffness may correlate with cardiac myopathies and explain the origin of dysfunction based on genetic screening with RNA-interference. Female *yellow-white* (*yw*) flies experience decreased diastolic diameter between 1 and 5 weeks of age (>20%) which we attributed to an increase in passive tension. Mechanical analysis revealed that cardiomyocytes stiffen more than two-fold between 1 and 5 weeks of age (1.0± 0.12 vs. 3.8 ± 0.30 kiloPascal, kPa, a unit of stiffness), but only at cell-cell junctions. Conversely, *white 1118* (*w1118*) flies showed no change in stiffness with position along the transverse axis of the tube (p = 0.7165 and 0.1035 between center and edge of tube in 1 and 5 week hearts, respectively) or age (p = 0.1923 and 0.8829 between 1 and 5 weeks at center and edge of heart tube, respectively) despite a drastic change in function; aged *w1118* were significantly more arrhythmic but had less diastolic dysfunction (<10% decrease in diastolic diameter between 1 and 5 weeks) than *yw* flies. Heterozygous deletion of the membrane-localized Integrin-linked kinase (ILK) dramatically reduces arrhythmia in *w1118* flies (>35% reduction in arrhythmia index, a measure of the standard deviation of heart period) though no stiffness change was observed. This may indicate that arrhythmogenesis more directly influences *active* tension produced during cross-bridge cycling rather than myofibrillar structure. To that end, *yw* flies were treated with RNA-interference against active tension producing myosin heavy chain (MHC), which resulted in severely impaired contraction and reduced stiffness after 1 week (1.0± 0.12 vs. 1.8 ± 0.13 kPa). These first *in situ* mechanical analyses of living myocardium have resolved differences in passive cardiac mechanics due to age and genetic modification and suggest that the aging phenotype and its mechanism differs significantly between *Drosophila* strains.

987
Effects of hematite nanoparticles on human intestinal cells.
M. Chakravadhanula[1], J. Faust[1], W. Zhang[2], Y. Chen[2], D. Capco[1]; [1]Arizona State University, Tempe, AZ, [2]Georgia Institute of Technology

The human body is constantly exposed to various nanoparticles used in commercial consumer products. One such nanoparticle is hematite which is used in commercial products such as pigments, catalysts, medical devices, sensors, and recording media. This may accumulate in the environment which can have a potential impact on the human intestinal system. In our study, we hypothesize that hematite nanoparticles at the sizes and concentrations tested will negatively impact Caco-2 cells the human intestinal epithelial cells, with increasing time. We have used various techniques such as trans-epithelial electrical resistance (TEER) measurements, immunocytochemistry and microscopic analysis (confocal and electron

microscopy) to support our hypothesis. Three sizes of nanohematite were used for the study namely, diameters of 17nm, 53nm, 100nm. Each of these nanoparticles was used at three concentrations namely, 1ppm, 10ppm, and 100ppm and the study was conducted at increasing time intervals. The results from our study show that the smallest and the largest nanohematite sizes affect the Caco-2 cells more than the intermediate sizes with increasing time. Also, our results show that nanohematite particles affect the cells at both physiological and non-physiological concentrations. Our results thus support our hypothesis that nanohematite at certain sizes and concentrations is detrimental to the human intestinal Caco-2 cells with increasing time.

988

Evaluation of Atrazine Permeation in Caco-2 Cells.

L. Hammonds-Odie[1], S. Mwongela[1], L. Mathew[1]; [1]School of Science and Technology, Georgia Gwinnett College, Lawrenceville, GA

Atrazine is a widely used and commercially available herbicide in the United States. Some studies have reported that human exposure to atrazine does not pose a health risk; while other animal model studies suggest that exposure can have profound effects, such as feminizing male frogs. Studies have been done on the impact of atrazine on intestinal epithelial cells focusing on changes in proliferative ability (*Environ Res,* 75: 85, 1997). If atrazine from farms and other agricultural locations is washing into our lakes, streams and aquifers, what impact could this have on drinking water and thus on freshwater aquatic species and on human health? Some studies have indicated that in heavily farmed regions of the United States significant levels of atrazine are present in drinking water. But is this drinking water laced with atrazine posing a health risk to those who drink it? Can the herbicide, atrazine, cross the epithelial monolayer of the human gastrointestinal tract? Our hypothesis was that atrazine will permeate across an epithelial monolayer of cells. We used the human intestinal cell line, Caco-2 cells, to determine the transepithelial transport of atrazine from the apical or luminal side to the basolateral or serosal side. Caco-2 cells are an established model system for measuring the permeability of chemicals that can be ingested and adversely impact human health.

NSF IGERT at UIUC: Training the Next Generation of Leaders in Cellular and Molecular Mechanics and BioNanotechnology (CMMB IGERT).

R. Bashir[1], M. L. Gillette[2], K. J. Hsia[3], T. A. Saif[3], M. Sheetz[4], L. A. Miller[5]; [1]Electrical and Computer Engineering, and Bioengineering, University of Illinois at Urbana-Champaign, Urbana, IL, [2]Cell and Developmental Biology, University of Illinois at Urbana-Champaign, Urbana, IL, [3]Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, [4]Biological Sciences, Columbia University, New York, NY, [5]Micro and Nanotechnology Lab, University of Illinois at Urbana-Champaign, Urbana, IL

The goal of the CMMB IGERT is to produce the next generation of leaders who will define the new frontiers of Cellular and Molecular Mechanics and BioNanotechnology. The living cell is the most fundamental building block of all biological systems. Recent discoveries show that mechanical signals play a critical role in cell functionality. How cells transduce mechanical signals to functionalities at different length scales presents a scientific grand challenge of our time. We have responded to this timely need and assembled a preeminent interdisciplinary

team of researchers across UIUC and partner institutions to train the next generation of engineers and biologists to address this grand challenge.

We are improving on traditional models of graduate education by (a) creating an integrated educational and research environment and support mechanisms to provide interdisciplinary experiences in biology, engineering, and bionanotechnology; (b) infusing critical thinking, leadership, communication, team building, ethics training, and other essential topics into the program; (c) recruiting and retaining a diverse set of trainees; (d) enabling the Student Leadership Council to shape strategic directions of the IGERT; (e) supporting international experiences; (f) assessing the value-add of the IGERT experience; and (g) broadening impact by permeating the IGERT's educational system to other programs at UIUC, UC Merced, NCCU, and other institutions. Our goal is to not only transform graduate education on our campus, but also to be an empirically validated model for other programs in this area.

We are bridging biology and engineering via three intellectual themes: (a) cellular-scale bio-mechanical processes driven by molecular motors in cells; (b) critical controlling mechanical phenomena at the micro- and nano-scale that underpin cellular-scale processes; and (c) mechanical and biochemical communication between cells and the extra-cellular matrix. The mechanochemical transduction processes behind these interconnected themes are poorly understood. Recent advances in micro/nanotechnology and molecular scale computational methodologies will catalyze this quantitative biological revolution through the unique capabilities of patterning, probing, imaging, and interpreting biological phenomena at a cellular and molecular scale. A real integration of these domains can make a revolutionary impact in many areas such as tissue/regenerative engineering, mechanobiology, biological energy harvesting, sensing/actuation, cells-as-a-machine, synthetic biology, etc. Cross-disciplinary training of a new generation of scientists is crucial to realizing the potential in these arenas.

990

Teaching critical analysis of scientific papers and scientific writing in a Molecular Biology for Master's students class.

E. Tour[1]; [1]Cell and Developmental Biology, University of California-San Diego, La Jolla, CA

Ability to analyze primary scientific literature and ability to communicate scientific ideas clearly are important skills for biology students. This report describes methods and preliminary results of practicing these skills in a Graduate Molecular Biology course taught to a small class of students enrolled in the contiguous BS/MS program in Biology at UCSD. During the course, figure-by-figure analyses of five primary research papers were conducted in small groups. In preparation to each discussion, students wrote a one-page report that contained their own analysis of the paper. At the end of the course, 70% of the students characterized their gains in scientific paper analysis as "high" or "very high". The average learning gain, calculated from average scores for Paper 1 and Paper 4 was 0.45. In another module of the same course, students practiced scientific writing by completing an Annotated Bibliography assignment and writing an Introduction to their own thesis. Close to 90% of the students evaluated the Introduction assignment as "Very useful" or "Useful" for such aspects as critical analysis of papers and practicing scientific writing.

991

Using Information and Science Literacy Instruction to Improve Student Performance on Laboratory Research Writing Assignments.

A. E. Kruchten[1], C. McCulley[2]; [1]Biology, Linfield College, McMinnville, OR, [2]Nicholson Library, Linfield College, McMinnville, OR

We tested the hypothesis that increasing students' understanding of how to ask scientific research questions, to use library resources for science, and to find and evaluate scholarly information on science topics would enhance students' understanding of the habits of mind of scientists and how they communicate scientific results. In this upper division microbiology course team taught by a science librarian and a biology faculty member, students were taught information literacy skills such as finding and evaluating primary literature during a beginning of the course library session. Students were asked to construct an annotated bibliography in which they found, summarized, and evaluated ten scientific sources related to an assigned microbiological topic. In a seemingly unrelated assignment, the students performed laboratory research in which they isolated and identified a microbiological unknown and reported their results in a manuscript format. In this study that included courses taught in 2008, 2009, and 2010, we tested our original hypothesis by evaluating whether instruction in information and science literacy enhanced students' abilities to write laboratory manuscripts in the style and sophistication of research scientists. We found increases in student confidence levels in the information literacy skills over the course of the semester. We also found that as we have improved our information literacy instructional methods over the three successive years of the course, students' scientific manuscript writing has improved and moved from a generic "lab report" style to a publishable research manuscript style. In summary, we have found that teaching information and scientific literacy skills and engaging students with the primary literature can help students become better scientific communicators. This technique is likely applicable across a broad range of scientific disciplines.

992

Using Graphic Novels to Engage the Modern Student.

S. K. Olson[1,2], C. Y. Okumura[1,2], R. S. Pozos[2]; [1]University of California, San Diego, La Jolla, CA, [2]San Diego IRACDA Program, San Diego State University, San Diego, CA

Bio100 at San Diego State University is a large introductory biology class for non-science majors, consisting of lectures given by NIH IRACDA postdoctoral fellows and supplemented by online reading materials. We are investigating the use of an alternative medium, an online graphic novel, to supplement the biological principles presented in the course. We hypothesize that an accessible storyline will allow students to better understand biological principles through connections to real-life situations. The graphic novel focuses on an independent story of a Mt. Everest climbing expedition. Hyperlinks embedded within the graphic novel connect students to online modules describing the biological bases of hypothermia, dehydration, muscle contraction, bacterial infection, and other relevant real-life processes. The graphic novel and the corresponding modules highlight important concepts students need to master to perform well on summative assessments. A pilot experiment showed students were engaged by this unique approach to learning biology, and we are currently analyzing student performance on exams to assess the effectiveness of this approach both as a supplemental teaching method and as an alternative method for presenting course material.

993

Communicating cell-biology research to the non-specialist: The “POPULAR” style poster.

J. Sanjeevi[1], H. Bryner[2], H. Waldenmaier[1], B. Porter[1], J. Fernandes[1], P. Callahan[1]; [1]Zoology, Miami University, Oxford, OH,

Miami University’s NSF-funded Undergraduate Research and Mentoring (URM) program is aimed at retaining underrepresented student groups in the Biological Sciences and to prepare them for graduate study. An activity that the students engage in during the Spring term is to develop a “popular-style” poster. The OBJECTIVE of this exercise is to enable undergraduates and their graduate student mentors to communicate cell biology research to a non-specialist audience, which we defined as high school students, their teachers and first year University majors. APPROACH: Students attended 3-4 workshops over a 4-week period to learn about effective communication of research projects and experimental outcomes to non-specialists, develop and present poster drafts, and peer-review of poster drafts. All students were asked to consider and articulate the following: (1) The biological process and why it is interesting. (2) The model organism used in the research and its relevance. (3) An overview of the research, including the questions addressed. (4) The techniques used, with a line or two describing the usefulness of the techniques. (5) Some visual depiction of results, e.g., pictures/graphs. (6) A short statement about the source of funding and why the agency is interested in the research. (7) A sampling of journals that the lab’s work has been published in, indicating undergraduate authors. (8) Photos of undergraduates at work in the lab. RESULTS: Seventeen undergraduate students and five graduate students developed posters in the past two years. They have been presented at multiple venues that include Miami University’s Annual Undergraduate Research Forum (held in April each year), Recruitment events held each Fall by the Office of Admissions, and in Teacher Professional Development venues. CONCLUSION: The process of creating popular posters enabled undergraduates as well as graduate students to better understand their projects, to become aware of the need to communicate science/research to multiple audiences, and to become confident in their ability to do so as a community of researchers.

994

Interdisciplinary Communication Laboratory for Undergraduate Biology (iCLUB).

J. Alonzo[1], H. Gaff[2], G. Watson[3]; [1]Communication and Theatre Arts, Old Dominion University, Norfolk, VA, [2]Biology, Old Dominion University, Norfolk, VA, [3]STEM Education and Professional Studies, Old Dominion University, Norfolk, VA

There is a growing awareness that major advances in research can be made through collaborations across traditional disciplines. Students and faculty involved in interdisciplinary research activities often confront obstacles to healthy collaboration. These obstacles may include: (1) Differences in personal and research values, (2) Differences in research practices and (3) Overall discomfort with the close interpersonal communication that is critical to any collaboration.

In the summer of 2010, two assistant professors (one from biology and one from theater) at Old Dominion University offered an eight-hour foundational communications workshop entitled "Let's Talk Research: Learning to Communicate in Collaboration.” The workshop provided hands-on training specifically focused on helping researchers better collaborate at the intersection of Math and Biology. Faculty and student participants were introduced to tools that actors use to foster healthy communication. The workshops were action-oriented. Participants immediately practiced the communication and collaboration skills that they learned by exploring existing problems in their research collaborations. Survey evaluations revealed that students and faculty

gained skill in (1) building rapport and (2) listening well. Participants most valued the development of (3) an increased comfort with communicating within conflict and (4) skills in identifying and communicating goals and values with potential collaborators. The original workshop groups now form the founding members of iCLUB, a recently NSF-funded RCN UBE-Incubator (DBI-1061935) for the development of communication skills in research scientists, graduate students, and undergraduates working at disciplinary intersections. We will present the structure of the workshops, the relationship of theater to communication and collaborative practice and overall structure of the iCLUB network.

995

Student Attitudes Toward Using Facebook as a Tool for the Dissemination of Laboratory Results in a Cell Biology Course.

H. G. Kuruvilla[1]; [1]Science and Mathematics, Cedarville Univ, Cedarville, OH

Facebook was used as a medium for disseminating laboratory results in a sophomore-level undergraduate cell biology course. Each week, at the conclusion of the laboratory period, digital photographs of laboratory results were taken and displayed as an album in Facebook. Students in the course were given access to all of the laboratory results, so that they could compare their results with other groups' results and use this information to write their laboratory reports. Students were expected to include a photograph of their data in their report. At the conclusion of the course, 40 of 52 total students enrolled (76.9%) participated in a voluntary survey which assessed their attitudes toward using Facebook for this purpose. Of the students surveyed, 100% selected “agree” or “strongly agree” in response to the following statements: “Having lab data on Facebook was convenient”, “Being able to look at data from the entire class was useful to me in writing my lab report”, and “I recommend that Facebook continue to be used for data dissemination in future cell biology courses, based on my experience this semester”. These data suggest that students perceive Facebook to be a useful tool for the dissemination of student laboratory results.

996

A structured approach to reading the primary literature that increases student critical thinking.

M. Segura-Totten[1], N. Dalman[1]; [1]Biology, North Georgia College & State University, Dahlonega, GA

Reading primary literature increases students' confidence, scientific literacy, and scientific process skills. Different approaches exist for analyzing primary literature: peer teaching, reporting on and writing journal-style articles, and linking articles to research projects. While previous studies highlight the importance of reading the primary literature in engaging students' interest in science and increasing their confidence, there have been few studies of how specific ways of reading the primary literature affect students' critical thinking (CT) skills. In this study, we compared the CT gains of students who follow a structured method for reading the primary literature to students who read and discuss the same articles after answering instructor-generated questions. We hypothesize that using the structured method will increase student CT skills beyond what is achieved through traditional discussion of research articles. The structured method we used compels students to analyze how and why a set of results is presented in a publication. We defined CT as student performance at the analysis, synthesis, and evaluation levels of Bloom's taxonomy. To determine gains in CT skills, we compared student performance at the start and the end of the semester in two different assessments: 1) exam questions at the analysis, synthesis and evaluation levels, and 2) an individual, in-class article critique exercise, which we scored by determining student performance at the analysis, synthesis and evaluation

levels. Mixed 3-way ANOVA of exam scores shows that CT skills of students who engaged in the structured method for reading primary literature increased significantly when compared to students who used the non-structured method (interaction of teaching method and pretest/posttest, $p = 0.034$). Mixed 3-way ANOVA of student performance in the article critique exercise showed that, while both groups had gains in CT skills, students who followed a structured approach for analyzing the literature had significant gains over those of students in the other group (interaction of teaching method and pretest/posttest, $p = 0.014$). Our results suggest that a structured method for reading the primary literature that compels students to dissect the "what, why and how" of scientific research leads to greater CT gains than merely having students answer discussion-generating questions prior to talking about a research article.

997

Journal Club: A four-year class to improve scientific literacy and outreach among undergraduate biology majors.

B. Dewsbury[1], A. Rosenblatt[1], A. Goldina[1], M. Lowenstein[1], O. Weeks[1]; [1]Biological Sciences, Florida International University, Miami, FL

Journal Club: A four-year class to improve scientific literacy and outreach among undergraduate biology majors

Leading institutions on education reform have called for the development of pedagogical practices that significantly improve scientific literacy of undergraduate biology majors. The QBIC (Quantifying Biology In the Classroom) program is an NSF and NIH funded program in the Department of Biological Sciences at Florida International University (FIU) developed specifically to address this call and other areas of biology instruction. As part of a larger pedagogical strategy called 'The Teaching Pentagon', we developed a seminar-styled readings class called 'Journal Club' which is a required class for all QBIC students during their tenure at FIU. This class has both horizontal and vertical structures. Horizontally, it contextualizes concepts introduced in lecture and laboratory classes by discussing scientific literature on the same topic. Vertically, each successive matriculation year represents a different stage in how students are taught to digest and communicate scientific literature. Students are introduced to literature in their freshman year using primarily review papers, but supplemented also by popular science writing. As sophomores students are taught to digest complex analytical articles and then as juniors, critique these papers and design new experiments based on the questions exposed by the conclusions. The seniors in our program learn to then communicate seemingly complicated scientific topics to non-scientific audiences.

We have found that Journal Club acts as a solid reinforcement to the major lecture with some students reporting that this class is their primary mechanism for truly understanding the worldly application of biological concepts. Exit surveys of our first graduating class also indicate that this class is a major platform for student training in science understanding and communication. This is a relatively new course and its goals are tied to the overarching instructional scheme as well as the more general goals of the program. Therefore, we have only just begun to apply more stringent assessment tools for this course and others. Student evaluations over the semesters have shown steady increases in both reported understanding of scientific literature, as well as the intellectual advantage provided by this class for their performances in lecture.

998

Information Literacy in a General Biology Laboratory: Developing Life-Long Skills.

J. Alvarez[1], V. Navas[2], A. Fernández-Troche[1], N. Diffoot-Carlo [2]; [1]General Library, University of Puerto Rico-Mayaguez, Mayaguez, Puerto Rico, [2]Biology Department, University of Puerto Rico-Mayaguez, Mayaguez, PR

In today's complex, information-rich society, it is vital to assist incoming biology freshmen to develop the necessary set of abilities and skills required to become effective users and producers of information. These skills are essential in their academic development and later in their professional life. Information literacy is most effective when it is embedded into the discipline-specific learning outcomes that tie into course goals and activities. Through a Howard Hughes Medical Institute initiative, the Biology Department at the University of Puerto Rico at Mayaguez in collaboration with library faculty designed an information literacy module to guide students in the use of library resources and teach them how to effectively search and evaluate appropriate information while emphasizing the importance of scientific primary literature in their field. The module was implemented in a laboratory exercise of the first General Biology course. It integrated an online tutorial and a complementary exercise for a lab research assignment. Students searched for references for their lab project and after viewing the online module evaluated their references. The reference discussion form was graded and evaluated by the lab teaching assistant. The module was initially pilot tested in a single laboratory section and was thoroughly assessed and modified prior to full implementation to the entire course population. Through this exercise, students improved their information literacy competency as evidenced by their reference evaluation exercise and other assessment results. They were able to better distinguish primary from secondary information as well as to better search the web and evaluate internet resources. Students evaluated the module as very effective, precise and easy to follow. Likewise, teaching assistants reaffirmed that this information was necessary and valuable. The module has now been modified to clarify misconceptions regarding reliable internet scientific resources and to include a citation instruction segment as requested by the students. Furthermore, students now have the opportunity to reinforce these skills throughout exercises in other courses that have also included information literacy activities. This repeated and progressive exposure to reliable scientific literacy will strengthen our students' skills and instruct them in up-to-date methods to obtaining scientific information and, thus, contribute to their becoming proficient scientists and lifelong learners.

999

Using a Model Systems Workshop to Teach Cell Biology.

T. W. Hendrickson[1], F. Norflus[2]; [1]Department of Biology, Morehouse College, Atlanta, GA, [2]Department of Natural Sciences, Clayton State University, Morrow, GA

Numerous schools have integrated active learning approaches into their biology classes to replace or enhance the traditional setting where the professor stands in front of the room and lectures. These new approaches are more student than faculty centered and have been shown to be more effective than passive learning. One such example of this type of approach is in having students participate in laboratory research experiences outside the classroom. In many cases, this can occur early on in the student career. These experiences enhance the development of critical thinking skills and communication skills. In addition, courses in laboratory research may stimulate students to become interested in science. These courses try to link the knowledge that students gain in traditional classes with the practice of performing laboratory research. At many schools, it is difficult to accommodate many students doing research due to a limited budget and resources of the school as well as faculty time. To overcome this obstacle, schools have been trying to incorporate laboratory research or the methods that researchers

use into the curriculum. In the present study, we have organized and held a workshop on model systems in cell biology. Our goals were to introduce students, even those in the beginning levels of their careers, to model systems. We hoped that this experience would build critical thinking skills in the students and we hoped to interest students in pursuing a career in cell biology research. To improve their communication skills, we taught the student how to present their work through posters and explained that this is how scientists present their work. The effectiveness of the workshop was assessed using pre- and post-tests. There were 17 participants in the 2-week workshop and although the average attendance was only four days, there was a 40% gain in knowledge.

1000

Developing laboratory activities using primary cultures that consolidate cell biology concepts and quantitative reasoning.

K. E. Marz[1]; [1]Biology, Gustavus Adolphus College, Saint Peter, MN

The use of mathematics is central to cell biology, but talented undergraduates sometimes shut down when encountering quantitative tasks in the context of a biology laboratory. They insist that they do not have the tools they need despite having had the relevant skills since high school and practice as undergraduates, such as work with concentrations in general chemistry. Also central to cell biology is primary cell culture, providing students opportunities to see how cells can be separated from the tissues in which they resided, how they respond to isolation, and what they need to survive. In an advanced undergraduate cell biology course, students have been isolating cells from chicken embryos and goldfish scales in experiments that incorporate practice in mathematics into activities that are novel and exciting to them, are relatively inexpensive to perform at a basic level, and can be expanded to incorporate available resources. In the chicken embryo laboratory, they are given powdered forms of chemicals that may influence the growth of dorsal root ganglion neurons they have dissected from embryos, choose concentrations to test and how to make them, and assess the treatments' effects. In the goldfish laboratory, they monitor scale keratocyte movement using ImageJ, compare methods of defining cell position, and compare rates of movement under different conditions. Protocols and opportunities for collaboration in further developing these activities will be shared.

1001

Achieving true teamwork in student course teams.

S. Wick[1], D. J. Matthes[2]; [1]Plant Biology, University of Minnesota, St Paul, MN, [2]Genetics, Cellular and Developmental Biology, University of Minnesota, Minneapolis, MN

The optimal value of team-based learning or other pedagogies that involve work by student teams can only be realized if teams function well. To avoid student frustration and the inefficiencies associated with laggards or overbearing or irresponsible team members, we have employed several strategies to set up effective teams and hold them accountable throughout the term. A key element of our approach is to create permanent (semester-long) teams with high diversity, including diversity of personal strengths. Each week team members list their specific contributions to all team activities of the week, from preparation for team quizzes and in-class activities to thoughtful contributions to elements of the semester-long major team project, and all team members must agree that the claims are accurate. Twice a semester each student evaluates the strengths and weaknesses of all team members and grades their contributions relative to each other; these evaluations are returned to students. The first time the exercise serves as a non-graded formative assessment, while at the end of the semester, these peer reviews by teammates account for about 6% of a student's final course grade. The vast majority

of students report that their team worked effectively with this framework for accountability and that they appreciated the varying talents that team members brought to their work as a team.

1002

Teaching Introductory Biology from a Historical Perspective.

C. Gaiser[1], A. Kruchten[1], M. F. Roberts[1]; [1]Biology, Linfield College, McMinnville, OR

Introductory biology courses usually consist of a survey of biological concepts from a compartmentalized point of view. Very often this approach focuses on levels of organization: molecules, cells, organisms, etc. We find this approach limited in at least two significant ways: 1) Often evolution and ecology are taught as distinct sections near the end of textbooks, which implies that they are only significant for the multicellular organisms covered near the end of the course. 2) This compartmentalized approach makes it difficult for students to develop an integrated understanding of biology. Here we describe a novel method of delivering a year-long introductory biology sequence. Our approach surveys the origin of biological processes, cells, and multicellular organisms in the historical sequence in which they actually occurred. Thus, the course begins with the chemistry of the early earth and moves to the origins of metabolism and the appearance of RNA as a catalyst and a hereditary molecule. This leads naturally into the first cells and the structural and metabolic characteristics of prokaryotes. The next step in the course is the endosymbiotic events that led to the eukaryotes, allowing us to explore for a second time cellular mechanisms such as replication, transcription, translation, and metabolism, now in eukaryotic cells. After discussion of sexual reproduction and phylogenetic analysis, we explore the diversity of single-celled and then multicellular eukaryotes, their physiological processes, and their interactions with the environment. Throughout each of these stages we emphasize how ecological niche and natural selection are the twin drivers of evolution on earth. We find that this method allows students to more effectively connect the vast amount of information presented in an introductory survey course. We present here our initial successes and challenges with this approach.

1003

Integrating Concepts in Biology for Introductory College Biology.

A. Campbell[1], L. Heyer[2], C. Paradise[1], P. Sellers[3], M. Barsoum[1]; [1]Biology, Davidson College, Davidson, NC, [2]Mathematics, Davidson College, Davidson, NC, [3]Political Science, Davidson College

We redesigned the first year college course (called *Integrating Concepts in Biology*) using the first principles of learning: students learn best when they construct their own knowledge and when new material is related to what they already know. Our redesigned approach emphasized data interpretation, the utility of mathematics in biology and deemphasized memorization. We divide biology into five big ideas (information, evolution, cells, emergent properties, and homeostasis) and address each of these big ideas at five levels of organization (molecules, cells, organisms, populations, and ecological systems). We compared our new course with two other traditional sections taught by two different instructors. Class time was traditional in format, similar to the other two sections. We hypothesized our students would: 1) score at least as well as the traditional students on content questions; 2) perform better on data interpretation questions; and 3) show significant changes in their perception of biology as a scientific discipline. Students participated in pre- and post-semester assessment of student perceptions. Our students performed significantly better on the data interpretation assessment than those in the traditional sections ($p = 0.04$) and demonstrated no significant difference in performance on the factual content assessment ($p = 0.91$). Our students exhibited significantly greater improvement in their ability to interpret experimental data over the course of the semester (p <

0.01). Several aspects of student perceptions were significantly different, indicating that students acquired a more realistic perception of biology as a discipline and may have developed a more accurate evaluation of their own scientific abilities ($p < 0.05$). *Integrating Concepts in Biology* improved critical thinking and disciplinary perceptions without compromising content knowledge.

1004

Exams Requiring Higher Order Thinking Skills Encourage Greater Conceptual Understanding in Introductory Biology.

J. Jensen[1], S. Woodard[1]; [1]Biology, Brigham Young University, Provo, UT

With the limited amount of time that instructors are afforded to spend with students during class time in an introductory biology course, instructors must often rely on individualized preparations done by students in preparation for exams. In order to encourage study processes that will enhance and solidify deep conceptual understanding, rather than rote memorization, the exams must be designed appropriately. In this study, students' biology conceptual understanding were compared for two exam formats: low-level regurgitation type exams demanding only recall of course materials verses high-level exams which test content knowledge, associated reasoning abilities, and the ability to transfer knowledge to novel situations. Subjects were taken from two introductory, non-majors biology courses taught in a guided-inquiry fashion by the same instructor. One course was given only low-level exams while the other course was given only high-level exams, based on Bloom's Taxonomy. Results show that students who prepared for high-level exams outperformed those who prepared for low-level exams on both knowledge/recall questions as well as advanced conceptual understanding and transfer questions. The effect was especially robust for students of lower reasoning ability and less prior content knowledge. Thus, it appears that exam design has a large impact on student learning despite identical in-class and homework experiences, with exams aimed at testing higher-order thinking skills encouraging greater gains in biological conceptual understanding.

1005

Bridging the Gap Between Concrete and Theoretical to Teach Gene Expression.

T. Kummer[1], J. Jensen[2], A. Banjoko[3]; [1]Brigham Young University, Orem, UT, [2]Biology, Brigham Young University, [3]Biology, Chandler-Gilbert Community College, Chandler, AZ

Gene expression is a highly theoretical concept that is often difficult for students to understand because many lack the necessary reasoning skills to comprehend it. As a consequence, teaching gene expression is difficult and misconceptions abound. In order to test the hypothesis that concrete analogies can help students overcome reasoning barriers and achieve theoretical conceptual understanding, a novel method of teaching gene expression utilizing concrete intermediates was designed and assessed. Results showed that this active learning approach was more successful than traditional lecture in achieving conceptual gains. In addition, students with lower reasoning ability and less prior conceptions experienced higher learning gains. Theoretical implications about the effects of reasoning ability and prior conceptions on learning as well as instructional implications for teaching theoretical concepts are discussed.

1006

Journey into HeLa Cells – Integrating Courses to Provide an Inquiry-Based Learning Experience.

A. Barrera[1], L. Hammonds-Odie[1]; [1]School of Science and Technology, Georgia Gwinnett College, Lawrenceville, GA

In the traditional classroom, the emphasis is *memory* of the material rather than *understanding* of how that material fits within the world. Content is important, but critical thinking, problem solving, and application of concepts, transforms facts into “usable knowledge” for the student, which leads to increased interest in the sciences [*How People Learn, pg 9*]. By demonstrating the interplay between several scientific tools, we hoped to provide students with a more holistic view of science. During the spring 2011 semester, we implemented a project to ascertain the effectiveness of an embedded cell biology focused research module in coordinated upper-division Biotechnology Lab and Bioinformatics course. The objective was to give a practical foundation in basic molecular biological techniques and a relevant scenario for exploring the power of bioinformatics. Another objective was to have students read and discuss the bestseller, *The Immortal Life of Henrietta Lacks* by Rebecca Skloot.

Twenty senior Biology majors concurrently enrolled in both courses participated in this research experience revolving around HeLa cells. This HeLa cell project formed the beginnings of an interdisciplinary experience for students, which clearly illustrated that science includes the ethical, legal and socioeconomic aspects. We assessed the effectiveness of the integration of the courses on student engagement, enthusiasm and interest using the Classroom Undergraduate Research Experience (CURE) survey as well as our own end of course questionnaire along with course evaluations and course assessments**.** Students enjoyed the collaborative work and felt a sense of meaning and purpose to their research projects. They also indicated that the coordination provided deeper comprehension of course material.

Typically in undergraduate Biology major courses, students study cell division using pre-made slides of onion root tip with the learning objective to be able to identify the key stages in mitosis. This traditional method of learning mitosis does not provide students with skills related to process-level thinking beyond memorization of the steps. Toward that end, this experience was designed to allow students to master several laboratory techniques and provided a platform for exposure to bioinformatics tools in context. The longer term vision for this project is to generate the reagents which would allow students to follow their gene of choice throughout cell division in real-time.

1007

Measuring Outcomes of Summer Research Experiences for Future Science & Math Teachers.

E. M. Stone[1], N. L. Nunes[1], S. A. Brady[2], S. Morgado[3]; [1]Cal Teach, University of California, Berkeley, Berkeley, CA, [2]Center for Science and Engineering Education, Lawrence Berkeley National Laboratory, Berkeley, CA, [3]Mare Island Technology Academy, Vallejo, CA

Summer programs have been put in place at a number of universities to provide research experiences for teachers so that they may gain an understanding of and comfort level with the process of research by engaging in in-depth, authentic research projects and subsequently engage their K-12 students in meaningful inquiry and problem-solving. We describe a summer research institute that we have designed for pre-service teachers in the Cal Teach secondary science and mathematics teacher credential program, and the instruments we developed for measuring outcomes of this program. A Knowledge Integration measurement tool specific for

the research process effectively measures conceptual understanding of research by analyzing responses from pre/post surveys and teacher interviews. We show that the opportunity to engage in research experiences provides participants with a deeper understanding of research methods, the nature of science and math, the process of experimentation, and science and math content. Moreover, such experiences also help future teachers develop their ability to guide their future K-12 students to develop skills in scientific thinking, designing and critiquing experiments, and solving problems.

1008

Fellowships in Research and Science Teaching (FIRST): A non-traditional post-doctoral training that generates effective researchers and educators.

J. L. Hurst-Kennedy[1], A. Eisen[2], J. K. Haynes[3], D. C. Eaton[4]; [1]Emory Univ Sch Med, Atlanta, GA, [2]Biology, Emory University, [3]Biology, Morehouse College, [4]Physiology, Emory University

Fellowships in Research and Science Teaching (FIRST) is a three-year post-doctoral program that combines traditional post-doctoral research training with intensive instruction in pedagogy. FIRST is supported by an Institutional Research and Career Development Award (IRACDA) grant from the National Institute of General Medical Sciences (NIGMS), a division of NIH. The goals of the FIRST program are 1) to generate faculty who are successful, independent researchers, as well as effective educators, and 2) to strengthen research-oriented teaching at Minority Serving Institutions (MSIs). To achieve these goals, FIRST fellows work under the direction of research mentors from Emory University, a nationally recognized biomedical research institute in Atlanta, GA. Additionally, fellows receive training in innovative pedagogical methods such as technology-based teaching and active learning and apply these skills at one of three top national MSIs within the Atlanta University Center (AUC): Morehouse College, Clark-Atlanta University, or Spelman College. A recent study indicated that FIRST fellows have the same publication rates and obtain the same amount of external funding as traditionally trained post-doctoral fellows. Furthermore, FIRST fellows were more successful than their peers at obtaining academic positions, demonstrating that FIRST effectively provides the training necessary for fellows to become successful faculty. Recently, in an endeavor to promote careers in the sciences among underrepresented minorities, FIRST has established a new undergraduate research program for AUC students. Undergraduate program participants spend one semester at Emory working directly with a FIRST fellow on an independent research project. These students receive a stipend, experience working in a top-tier research environment, and have opportunities to share their findings at national scientific meetings. FIRST fellows serving as mentors in the program gain experience mentoring undergraduates and managing research projects. Overall, this undergraduate research program offers both career development training for FIRST fellows and provides MSI students with high-quality, hands-on research experience.

1009

Pathways over Time: An Adaptable Project in Functional Genomics for Large Introductory Laboratory Classes.

C. M. O'Connor[1]; [1]Biology, Boston College, Chestnut Hill, MA

The explosion of genomic sequence information, particularly for microbial organisms, presents opportunities to engage large numbers of undergraduate students in authentic research projects within regular laboratory classes. The importance of undergraduate research on student learning and retention in science is already well-documented. The Boston College Biology Department has redesigned its introductory laboratory classes in molecular cell biology and genetics into a single-semester 3-credit course that incorporates original research on the

functional evolution of enzymes involved in methionine biosynthesis. Approximately 150 students, distributed between 10 sections, enroll in the course each semester. The project uses the budding yeast *Saccharomyces cerevisiae* to analyze gene function, because it is inexpensive to maintain, is easily cultured by undergraduate students, and has been extensively studied by yeast geneticists. Another key element in the selection of *S. cerevisiae* was the availability of deletion strains and overexpression plasmids for all of the *S. cerevisiae* ORFs. During two pilot semesters, students identified orthologs of S. cerevisiae Met proteins from the fission yeast, *Schizosaccharomyces pombe*. The two species are separated by close to a billion years of evolution, yet students were able to demonstrate the functional conservation of several genes by complementation of S. cerevisiae deletion mutants. Methionine biosynthesis in yeast involves several multi-enzyme pathways, which are subject to a variety of regulatory controls. This project topic was selected because it incorporates departmental learning goals, including student understanding of evolution, structure/function relationships, information transfer, energy transformation and systems biology. Other course goals addressed in the project include the application of the scientific process, quantitative analysis, the use of databases and bioinformatics tools and the ethical conduct of research. Students become "experts" on one *MET* gene and collaborate in 3-membered teams on wet bench experiments. Students working in parallel in the ten different sections communicate their results on a website hosted at Drupal Gardens. Assessment data from two pilot semesters indicate significant gains in student ability to conduct scientific research, to communicate research results, to use biological databases and to work with peers on experiments. The basic design of the Pathways over Time project can be easily adapted to other organisms and enzyme systems. The three elements required for course design are a multi-gene system to study, a genetically-tractable organism for complementation analyses, and a test organism with a sequenced genome.

1010

Implementation of inquiry-based plant tissue culture laboratory modules in minority undergraduate teaching laboratory.

D. Siritunga[1], N. Diffoot[1], V. Navas[1]; [1]Department of Biology, University of Puerto Rico Mayaguez, Mayaguez, PR

Recent studies have led to the conclusion that hands-on inquiry based research activities allow undergraduate students to feel the excitement and self-investment that is related to discovery of new knowledge and thus enhances their interest in pursuing a research career in the future. Here, we present a model for large-scale implementation of guided-research on a topic of broad interest, plant tissue culture, to increase interest in research at a 99% minority institution. Plant tissue culture is based upon the theory of totipotency, that is, the genetically based ability of a cell or a nonembryonic organ to form all the cell types in the adult organism. Multi-week laboratory module was implemented in the introductory botany course impacting 140 minority students per year by providing hands-on experience in using tissue culture tools. In this module the students use African violets (Gloxinia sp., Fam. Gesneriaceae) to gain experience in plant tissue culture techniques. The objective was for the students to learn how to take part of the plant from in vivo to in vitro by the establishment of aseptic techniques as well as to multiply plants under in vitro conditions by utilizing different media components. Assessment of the gain of content knowledge and learning perceptions revealed that our novel approach allowed the students to learn while increasing their self-perception of scientific methodology. In three semesters, at the completion of the lab module, the students reported an approximately 2.5-fold overall increase in the post-module assessment for content knowledge gained compared to pre-module assessment as well as an enhanced understanding of scientific process, increased proficiency of plant tissue culture methods and increase in confidence as researchers. Prior to

full-implementation, the laboratory module was pilot tested in a lab section and compared to a control lab section, with both section being taught by the same teaching assistant.

1011

Implementing an inquiry-based research module in a microbiology laboratory for minority undergraduate students.

R. Montalvo[1], N. Diffoot[2], V. Navas[2]; [1]University of Puerto Rico, Mayaguez, PR, [2]University of Puerto Rico

Participating in undergraduate research has been noted as one of the key elements for a successful career in science in the future. The Biology Department at the University of Puerto in Mayaguez has a population of 1,600 minority undergraduate students most of who do not have a chance to participate in research during their undergraduate years. In an effort to provide hands-on experience, an inquiry-based research module divided in three sections was designed and implemented in the general microbiology laboratory course. The impacted students were exposed to fundamental and modern molecular microbiology techniques for the characterization of bacterial strains that were isolated from extreme environments in Puerto Rico as part of a research project currently under way. These modules complement phenotype-based taxonomy with basic molecular methods and reinforced a research oriented approach to the characterization of unknown isolates and microbial communities. The assessment performed to the pilot sections reflected that the module had an impact on the students compared to the control section taught by the same teaching assistant. Answers to specific questions about techniques and scientific knowledge contained in the module were significantly improved in the post test. In questions about perception and scientific procedures, the students also showed that the module helped them to reinsure their confidence in developing an experimental approach through scientific methodology. The module also helped the students develop techniques in observing and collecting data. Eighty three percent of them were confident to perform this task after the module and 68% of them said that the module helped to develop this skill. Finally, 90% of the students in the pilot section felt confident in performing bacterial characterization experiments using molecular techniques compared to 39% of confidence reflected in the control section. Similar assessment results were obtained when the module was fully implemented impacting 217 undergraduate students, 7 teaching assistants and 1 laboratory coordinator. Overall, students demonstrated that they learned basic principles of molecular characterization of bacterial isolates by molecular techniques while increasing their confidence in learning scientific methodology.

1012

Teaching English Scientific Writing at the Undergraduate Level in Taiwan.

S. C. Schuyler[1]; [1]Chang Gung Univ, Taoyuan, Taiwan

Taiwanese undergraduate students in the biological and biomedical sciences have limited opportunities to practice English scientific writing. This leads to a great disadvantage when these knowledgeable, thoughtful, and talented students try to communicate about science in writing. A course that focuses on the structure and practice of writing a meeting abstract and a scientific paper has been designed and taught. The course is organized around the principle that practicing, coupled with feedback from the instructor, is the best way to improve a student's writing skills. The class emphasizes that writing is a process, and that sufficient thought and time must be invested in order to obtain a quality result. The concept that plagiarism is unacceptable and strictly forbidden is also noted throughout the course. Weekly lectures provide students with instructions about the specific grammar rules used in manuscripts and about the structures and organization of paragraphs, with an emphasis on executing the next writing

assignment. During the semester, students engage in several writing exercises. These assignments include writing a title and abstract, the first paragraph of an introduction, a paragraph of methods, a paragraph of results, and a paragraph for a discussion. Assignments are submitted via e-mail to the instructor as Microsoft Word documents. Feedback is provided to the students using the “track changes” feature in Microsoft Word. Initial experience revealed that several of the writing assignments required passage through multiple rounds of the “practice and feedback” process before the writing displayed significant improvement. During the semester, it was also observed that using examples from the student’s own work to highlight how improvements in the writing assignments could be made was very useful, as many students struggled with the same or similar problems. Colleagues in Taiwan have provided me positive feedback on the course, and the rating for the initial class by the students was 86.5%, which is considered very positive.

1013

Using video assignments in a 200-level Cell Biology class to promote student engagement.

J. Fernandes[1], E. Stoll[2], K. Jicinsky[2]; [1]Zoology, Miami University, Oxford, OH, [2]Office of New Student Programs, Miami University

Students in a 200-level Cell Biology class developed a series of video- assignments based on research being conducted in the biological science departments. The OBJECTIVE of this assignment was to promote student engagement with the course material using a non-traditional assignment. APPROACH: Each video assignment had two sections. One part focused on communicating an overview of each lab’s research topic and its relevance, emphasizing basic cell biology concepts and any relationship to health/disease. Students were also expected to include information about the model organism used by the lab. Interviews with the faculty member/graduate student and undergraduates were included in these videos, as were lab tours. The second section of the video assignment was designed to provide information about undergraduate research opportunities- how to find them, how to get started, what are the expectations and the benefits for students. Prior to making the videos, students had to complete “background” assignments to better understand the research topic. They then developed scripts which were edited, before the videos were made. Staff from the Office of New Student programs was consulted to provide a “real-world” perspective for students about the usefulness of these videos for incoming freshman. RESULTS: Surveys that assessed effectiveness of the project indicated that 80% of the class (n=62) identified the project as being beneficial. The perceived benefits included: awareness of ongoing research activities, better understanding/connection of course concepts, confidence in using scientific language, the importance of logical flow of information, and an opportunity to “teach” science. In the following semester, some students returned to serve as undergraduate assistants, and worked with the Office of New Student programs to develop videos for the incoming class of 2015. CONCLUSIONS: The video assignment in a cell biology class allowed students to develop an understanding of course material in the context of ongoing research programs at the institution.

1014

Undergraduate Associates as Peer Leaders in a 200-level Cell Biology Class.

K. Gaietto[1], K. Hawkins[1], K. Magee[1], A. Patel[1], P. Reddy[1], B. Romig[1], T. Simmons[1], C. Traner[1], J. Fernandes[1]; [1]Zoology, Miami University, Oxford, OH

BACKGROUND: In a 200-level Cell Biology course offered during the Fall 2010 semester, all students participated in a semester-long group assignment, Model Organisms in Research, which provided opportunities for students to understand basic cell biology concepts in the

context of ongoing research programs at Miami University. Students were required to read scientific literature, synthesize material from multiple sources, interview Miami University researchers who use model organisms, and collaborate with group members to compile a final paper and video. This integrative approach to learning cellular biology was facilitated by the use of Undergraduate Associates (UAs), students who had taken and excelled in the course the previous semester. The OBJECTIVE of this approach was to provide a class of 75 students with one-on-one instruction on the assignment, and for the UAs to develop peer mentoring skills. APPROACH: Each of the eight UAs worked with 2 groups of 4-5 students. They met with the instructor every other week to discuss the instruction, report progress, and to develop grading rubrics. RESULTS: UAs worked with students to accomplish the group assignment's major outcomes, which included: (1) Gain familiarity with research literature to explore the role of model organisms in health and disease, (2) Understand common themes in cell biology revealed through comparative analysis across organisms, (3) Gain an understanding of model organism research at Miami, and (4) Communicate model organism research to K-12 students and non-science majors. CONCLUSIONS: This integrative approach yielded many beneficial results for the instructor, UAs, and students. For the Instructor, the UAs' input into designing the assignment and providing one-on-one instruction in a large class was valuable. For the Undergraduate Associates, the project offered the unique opportunity to get first-hand curricular experience in designing, leading, and executing a collaborative group project from beginning to end. Students in the class had an opportunity to work with UAs who had taken the class before and to apply their cell biology concepts to develop a video assignment.

1015

Evaluation of Different Nutrient Medias on Population Growth of *Tetrahymena pyriformis.*

R. E. Heard[1], T. R. Carter[1], S. F. Revilla[2], J. M. Swann[3]; [1]Biology, Maryville College, Maryville, TN, [2]Biochemistry, Maryville College, Maryville, TN, [3]Maryville Coll, Maryville, TN

In the literature are reported various nutrient medias in which *Tetrahymena pyriformis* is grown; this study sought to determine which medium was most effective at supporting the most population growth while also resisting contamination. Multiple cultures were grown in four different media formulations with varying quantities of proteose peptone, yeast, glucose, iron chloride, and salt. Their populations were counted by hemocytometer over a period of 4 days. Three of the 4 medias were able to support a growing population with little or no contamination; the salt-containing media (PPYS, n=5) did not support culture growth by any measure. The media of proteose peptone, yeast, and iron chloride (PPY, n=5) appeared to support the most rapid growth, but there was no significant difference between populations when compared to populations grown in media that contained glucose (PPYG, n=5) instead of iron chloride (p=0.46) and populations grown in media (SSP, n=5) that contained both glucose and iron chloride (p=0.33). However, when the PPY media was compared to PPYS media, a highly significant difference was found (p=0.007). No media showed signs of contamination in the time frame studied. Therefore, it was concluded that the PPY, PPYG, and SSP medias each would be sufficient for supporting a growing population of *T. pyriformis* while also resisting bacterial contamination for acute or other short-term studies.

1016

Development of a monolayer cell-binding assay to quantify the time-dependent strengthening of cell-cell adhesion.

W. A. Thomas[1], J. Dyer[1], F. Wagnac[1], M. Cimpean[1]; [1]Department of Natural Sciences, Colby-Sawyer College, New London, NH

Cell adhesion plays a critical role in early development (e.g., the sculpting of tissues and organs), in daily maintenance of the body (e.g., wound healing), as well as in a number of aberrant conditions (e.g., tumor metastasis). A thorough understanding of cellular adhesion is thus a theme of broad importance in biomedical research. Results obtained using the dual pipette assay in the Dufour laboratory at Institut Curie demonstrate clearly that adhesions strengthen with time[1], and work continues there to determine how. The goal of the work presented here is to design a less expensive assay, readily employable at Colby-Sawyer, that yields data comparable to those obtained with the dual pipette assay, allowing us to contribute to the resolution of that basic question. We have chosen to explore the utility of a monolayer cell binding assay. The dual pipette assay measures separation forces between one pair of cells at a time; the monolayer assay provides less quantitative precision, but in addition to its considerably lower cost, allows us to observe the binding behavior of a much greater number of cells. Unlabeled cells are centrifuged in 4–well plates (Nunc) at 5000 rpm for 15 min to form a confluent monolayer, fluorescent probe cells are brought into contact with the monolayer, also by centrifugation (1000 rpm for 1 min), and after a fixed period of interaction (variable), the adhesion between the probe cells and the monolayer is quantified (% cells remaining bound) following disruption by a gyratory shear (100-200 rpm). This poster details the establishment of the parameters to make the assay functional. This project is supported by the New Hampshire IDeA Network of Biological Research Excellence (NH-INBRE) NIH Grant Number 1P20RR030360-01 from the INBRE Program of the National Center for Research Resources.

[1]Chu, Y-S, et al. (2004) Force measurements in E-cadherin–mediated cell doublets reveal rapid adhesion strengthened by actin cytoskeleton remodeling through Rac and Cdc42, JCB vol. 167 no. 6 1183-1194

1017

The Genomics Education Partnership (GEP): Undergraduate Student Analysis of the Evolution of Dot Chromosomes in Drosophila.

S. C. Elgin[1], J. E. Bedard[2], G. E. Regisford[3], J. Roecklein-Canfield[4], M. L. Spratt[5], C. D. Shaffer[6], W. Leung[1], D. Lopatto[6]; [1]Washington University in St. Louis, St Louis, MO, [2]Adams State College, [3]Prairie View A&M University, [4]Simmons College, [5]William Woods University, [6]Grinnell College

An effective method for teaching science is to engage students in doing science. The GEP, a group of faculty from over 80 primarily undergraduate institutions, is using comparative genomics to engage students in research within regular academic-year laboratory courses. Using a versatile curriculum thathas been adapted to many different class settings (as the core of a laboratory course, within a lab for a broader course, or as an independent research project), GEP undergraduatesundertake projects to improve draft genomic sequences and/or participate in the gene annotation of these improvedsequences. GEP undergraduates have improved more than 2.4 millionbases of draft genomic sequence from several species of *Drosophila*and have produced hundreds of gene models using evidence-basedmanual annotation. Analyses of the Müller F elements (the dot chromosomes) of four Drosophila species (*D. melanogaster, D. erecta, D. grimshawi* and *D. mojavensis*) show that these genomic regions, which exhibit heterochromatic properties, are similar to each other and distinct from euchromatic reference regions. All dot chromosomes exhibit a high repeat density; the ~80 genes present show a

larger size and lower codon bias compared to genes in euchromatic domains. While there are major changes in the relative order and orientation of the genes, ~90% remain on the Müller F element. A subset of dot genes can be found in a euchromatic domain on another Müller element in at least one species; these "wanderer" genes exhibit the properties of the local environment in which they reside. A recent anonymous survey of GEP faculty showed that they are generally very happy with the core program and found teaching in this way to be a source of satisfaction. Institutional support has been positive. We find this approach rewarding for both faculty andstudents, and invite additional faculty to join us (see our website http://gep.wustl.edu; next workshop June 2012). Supported by HHMI grant # 52005780 and NIH grant R01 GM068388 to SCRE.

Cloning and characterization of a maize zmbrd1 gene.

I. Makarevitch[1], A. Thomson[2], G. Muehlbauer[2], N. M. Springer[3]; [1]Hamline University, Saint Paul, MN, [2]Agronomy, University of Minnesota, [3]Plant Biology, University of Minnesota

Brassinosteroids (BRs) are a group of plant steroid hormones that regulate growth and development. Plants defective in brassinosteroid biosynthesis and regulation exhibit dwarf phenotype and alteration of the cell structure and growth. To date, the role of brassinosteroids has not been investigated in maize. A maize mutant with severe dwarfing was identified and used for positional cloning of the causative mutation. A single base nonsense substitution in the Zea mais brassinosteroid-deficient (zmbrd1) gene was identified. This gene is a homolog of the rice OsDwarf and tomato Dwarf gene and encodes a BR6 oxidase enzyme that is responsible for the last step in the brassinosteroid biosynthesis. The maize genome contains only one homolog for BR6 oxidase. Maize plants homozygous for the mutation in zmbrd1 gene are sterile, exhibit severe dwarf phenotypes, no etiolation response, alterations in the structure of the leaf, and abnormalities of leaf cell morphology. The expression of zmbrd1 gene is negatively regulated by brassinosteroids such that low levels of brassinosteroids result in high gene expression. Supplementing of growth media with 10-6M brassinolide partially rescues the mutant phenotype and lowers down the expression of zmbrd1 in the homozygous mutant plants. Characterizing maize mutants defective in brassinosteroid biosynthesis will lead to better understanding of the brassinosteroid biosynthesis and biosignaling pathways might help in developing new semi-dwarf maize varieties.

The Internet Fosters Collaborations among College and Pre-College Students and Research Scientists.

C. Lo[1], N. Museles[1], M. Lu[1], A. Riddihough[1], Q. Weinberg[1], T. Hata[1], S. McRobert[2], C. Pierret[3], C. Dornack[4], J. Sonju[4], M. Fields[1]; [1]Sidwell Friends School, Washington, DC, [2]St. Joseph's University, [3]Mayo Clinic, [4]Lincoln K-8 Choice School

Students and scientists from four institutions--Lincoln K-8 Choice School, high school students from Sidwell Friends School, college students and a scientist from St. Joseph's University, and scientists from the Mayo Clinic--have worked together to develop research experiments that can be performed using the internet. In this collaboration, we utilized Fish Cam to develop a detailed shoaling analysis of the common goldfish. Fish Cam is an on-line tool that enables students to observe and collect data in real time from a shoaling test tank in the Biodiversity Lab at SJU. Shoaling, an aggregation behavior, provides fish with numerous benefits, including enhanced foraging success, access to potential mates, and protection from predators. Goldfish (Carassius auratus) have been utilized in shoaling studies (see Shinozuka and Watanabe, 2004), and it is known that they shoal; however, a detailed examination of shoaling behavior and shoalmate

choice has not yet been performed. In the laboratory, shoaling behavior is easily demonstrated in three-chambered tanks in which a solitary fish in the center chamber displays shoaling behavior by swimming near the side chamber containing a group of fish, as opposed to swimming near an empty chamber. At SFS, students in Introductory Accelerated Biology conduct Independent Research Projects in which they develop and conduct original scientific experiments, many involving zebrafish. Zebrafish are extremely helpful in classrooms because they provide an approachable method of learning science and cultivate a growing interest in young scientists. Previous experiments have included examining the effects of PBDEs on the development of zebrafish embryos, fin regeneration at different developmental stages, the inheritance and expression on the transgenic Glo gene, and the effects of light on sex differentiation in relation to pigment levels. We plan to expand this work to study shoaling behaviors in GloFish™ (transgenic zebrafish that express the Glo gene) of different colors. We have performed simple Mendelian crosses to learn the fundamentals of genetics and inheritance. Further studies will include genotypic analysis from these fish to determine which copy of the Glo gene that the fish have and how many copies of the gene are present. The identity of the different fluorescent genes present in GloFish and variations in the gene copy number can be detected by PCR and sequencing. Future experiments will be proposed by those students actively involved in this collaboration, allowing students from all levels of education to work together to conduct scientific research. Scientists could also utilize such on-line tools to perform behavior experiments, including genetic analyses, using the manpower provided by engaging other students in this process.

1020

AP Biology Students Make Significant Gains vs. Controls in the SUN (Students Understanding eNergy) Pilot Study.

A. Batiza[1], M. Gruhl[2], B. Zhang[3], T. Herman[1], D. Nelson[4]; [1]Center for BioMolecular Modeling, Milwaukee School of Engineering, Milwaukee, WI, [2]Gruhl Education Consultants, LLC, Washburn, WI, [3]Educational Psychology, UW-Milwaukee, Milwaukee, WI, [4]Biochemistry, UW-Madison, Madison, WI

The SUN (Students Understanding eNergy) Project is a new method for learning about biological energy transfer that depends upon: 1) the rationale for the directionality of spontaneous electron movement, 2) a one-to-one comparison of the hydrogen fuel cell and cellular respiration, and 3) physical models within nested trays that allow learners to configure and manipulate key components of the chloroplast and mitochondrion. Last year at this meeting we reported that regular and AP biology teachers who attended a SUN Workshop made significant gains in understanding photosynthesis, cellular respiration and the underlying energy principles; and that those significant gains were maintained a year later for the regular biology teacher group vs. their original scores and vs. cluster, randomized controls who had not yet attended the SUN Workshop. Here we report knowledge gains made by the students of teachers who participated in a concomitant AP pilot study. Seven AP teachers at seven different schools used “business as usual” methods during the 2009-2010 school year with one class of students. In the summer of 2010, they attended the SUN Workshop. Then six of these teachers used the SUN teaching materials in their classrooms the following school year (one was no longer assigned to teach AP biology). By necessity, these were different student groups. Comparison of student achievement during both years shows that students during the “control” year made a statistically moderate significant gain (.55 effect size) when measured with a 15-item multiple-choice exam at the beginning and end of the AP biology course. However, after the teachers attended the SUN Workshop and then used these materials in their classrooms, students made a statistically large significant gain (0.84 effect size) in content understanding on this assessment pre/post course. These results along with preliminary data regarding significant

student effects in regular biology classrooms vs. controls in the cluster, randomized controlled trial suggest that this program of professional development coupled with new teaching tools has promise for helping students understand these complex topics.

1021

Cell Biology is Learned Better when Combined with Art.

K. Clemenza[1], C. Lovati[2], S. Weisberg[1], T. Robinson[2], B. J. Dubin-Thaler[1], A. Laker[2]; [1]Cell Motion Laboratories, New York, NY, [2]Indianapolis Museum of Art, Indianapolis, IN

Is student learning enhanced through cross-disciplinary teaching of artistic expression along with cell biology? The Cell Motion BioBus, a mobile microscope lab housed on a retrofitted 1974 transit bus, has teamed up with the Indianapolis Museum of Art (IMA) to find out.

The pilot experiment was conducted in October 2010, when the BioBus and its team of cell biologists joined art educators at IMA. Students from four Indianapolis schools came to IMA's 100 Acres Art and Nature Park to participate in three activities over the course of 90 minutes: (1) a tour of the park, led by a museum docent, in which students were encouraged to look closely and articulate their observations about different pieces of art in the park; (2) an art-making activity, led by an IMA artist, using materials from the park; (3) hands-on science lessons aboard the BioBus, in which we collected samples from the park's lake and analyzed the physiology of single-celled organisms using on-board microscopes.

In post-visit evaluations, teachers described the program as "a great experience for [their] kids," and were especially positive about how combining "scientific, artistic and communication skills;" helped make science become less intimidating and more accessible to their students, because it showed them "that their observations are valid and everyday language can be used as the beginning of the scientific process."

The main complaint reported by teachers was not being well-prepared, and, as a result, it did not fit with their classroom teaching. To address this issue, we organized a three-day seminar in July 2011 to prepare for the October 2011 version of the program. At the end of this workshop, teacher's reported an increased confidence in their ability to use visual thinking strategies to encourage engagement with art as well as scientific exploration and discovery.

Here we present these results along with the results collected during the October 2011 school visits, revealing both the benefits of and challenges in designing a cross-disciplinary activity combining artistic and scientific expression.

Membrane Fission and Coat Proteins

1022

Functional studies of the retromer and WASH complexes.

M. Seaman[1], M. E. Harbour[2], S. Y. Breusegem[2]; [1]Cambridge Institute for Medical Research, University of Cambridge, Cambridge, United Kingdom, [2]University of Cambridge, Cambridge, United Kingdom

The retromer complex is a conserved endosomal protein sorting complex that sorts membrane proteins into nascent endosomal tubules. The recognition of membrane proteins is mediated by the cargo-selective retromer complex, a stable trimer of the VPS35, VPS29 and VPS26

proteins. We have recently reported that the cargo-selective retromer complex associates with the WASH complex, a multimeric protein complex that regulates tubule dynamics at endosomes. Here we show that the retromer-WASH complex interaction occurs through the long unstructured “tail” domain of the WASH complex-Fam21 protein binding to VPS35, an interaction that is necessary and sufficient to target the WASH complex to endosomes. Additionally the Fam21-tail interacts with FKBP15, a protein associated with ulcerative colitis, to mediate the membrane association of FKBP15. Inhibition of V-ATPase activity inhibits the endosomal association of FKBP15 and abolishes Snx1-tubule formation suggesting a mechanistic link between endosomal acidification and protein sorting. Overexpression of the Fam21-tail results in cell-spreading defects implicating the activity of the WASH-complex in regulating the mobilization of membrane into the endosome-to-cell surface pathway

Clathrin-mediated endocytosis is required for biogenesis of the contractile vacuole in *Dictyostelium.*

L. Macro[1], S. Simon[1]; [1]Lab of Cellular Biophysics, The Rockefeller University, New York, NY,

Clathrin-mediated endocytosis (CME) is the process by which eukaryotes selectively internalize receptors from the plasma membrane. Disruption of clathrin is lethal in multicellular organisms but unicellular organisms can survive indicating that CME may have evolved a more specialized function in higher eukaryotes. We have found that in the unicellular organism *Dictyostelium* the major components of CME, clathrin and AP-2, behave in a similar way to their counterparts in higher eukaryotes. Firstly, we labeled the *Dictyostelium* homolog of the alpha subunit of AP-2 with GFP and showed that it is incorporated into a heterotetrameric AP-2 complex homologous to that in mammals. Next, we observed the behavior of fluorescently tagged clathrin or AP-2 by total internal reflection fluorescence microscopy. Simultaneous imaging of clathrin and AP-2 showed that these proteins co-localize to membrane puncta and that they disappear together. We investigated the nature of the disappearing AP-2 and clathrin puncta by alternating between wide-field and evanescent field illumination. Using this technique we showed that AP-2 and clathrin disappearing puncta leave the plasma membrane and move into the cell, characteristic of CME. Furthermore, we show a plasma membrane cargo is internalized by CME. Dajumin is an integral membrane protein that is localized to the contractile vacuole in *Dictyostelium*. We show that dajumin also localizes to the plasma membrane where it is internalized by CME. In cells that lack clathrin no contractile vacuole is present and dajumin is trapped on the plasma membrane. We propose a role for CME in organelle biogenesis whereby membranes and proteins are trafficked via the plasma membrane. Furthermore these findings indicate that CME may play different roles in unicellular and multicellular organisms, explaining the different phenotypes seen with clathrin perturbations. Since *Dictyostelium* can transition between unicellular and multicellular states our findings can be extended to study the different physiological roles of CME during these stages of development.

1024

Regulation of clathrin coat assembly by Eps15 homology domain-mediated interactions during endocytosis.

J. Y.Toshima[1,2], R. Suzuki[1], J. Toshima[1,2]; [1]Department of Biological Science and Technology, Tokyo University of Science, Noda, Japan, [2]Research Center for RNA Science, RIST, Tokyo University of Science, Noda, Japan

Clathrin-mediated endocytosis involves a coordinated series of molecular events regulated by interactions between a variety of proteins and lipids through specific modules. One such module is the Eps15 homology (EH) domain, a highly conserved protein-protein interaction domain

present in a number of proteins distributed from yeast to mammals. Several lines of evidence suggest that the yeast EH domain-containing proteins (EHDPs), Pan1p, End3p and Ede1p, play important roles during endocytosis. Although genetic and cell-biological studies of these proteins have suggested a role for the EH domains in clathrin-mediated endocytosis, it is still unclear how they regulate clathrin coat assembly. To explore the role of the EH domain in yeast endocytosis, we mutated those of Pan1p, End3p or Ede1p, respectively, and examined the effects of single, double or triple mutation on clathrin coat assembly. We found that mutations of the EH domain caused a defect of cargo internalization and a delay of clathrin coat assembly, but had no effect on assembly of the actin patch. We also demonstrated functional redundancy between the EH domains of Pan1p, End3p and Ede1p for endocytosis. Interestingly, the dynamics of several endocytic proteins were differentially affected by various EH domain mutations, suggesting functional diversity of each EH domain.

1025

Clathrin Light Chain Regulates Endocytosis by Restricting the Attachment of the Yeast Hip1R Homologue, Sla2, to the Actin Cytoskeleton.

D. Boettner[1], H. Friesen[2], B. Andrews[2], S. Lemmon[1]; [1]Molecular & Cellular Pharmacology, University of Miami, Miami, Fl, [2]Banting & Best Department of Medical Research, University of Toronto, Toronto, ON, Canada

Endocytosis in *Saccharomyces cerevisiae* occurs in distinct stages: (1) an immobile phase, which is marked by accumulation of clathrin and clathrin adaptors at the site of invagination; (2) a slow mobile phase where additional factors are recruited, as actin assembly and membrane invagination occur; and (3) a fast mobile phase after scission when the nascent vesicle with associated actin moves deeper into the cell. We previously demonstrated that the disruption of clathrin causes delayed internalization and aberrant actin events, and found that overexpression of the N-terminus of clathrin LC, which binds Sla2 (the Hip1R homologue), suppresses the endocytic defects of clathrin deficient yeast. To understand the role of LC, we performed the first Synthetic Genetic Array analysis of clathrin, utilizing an N-terminal deletion of Clc1 (*clc1-Δ19-76*). This clathrin mutant was systematically crossed to the genome wide viable null collection and double mutant progeny were selected and scored for exacerbation or suppression of the growth phenotype. We identified the *clc1Δ19-76* allele as alleviating to the null mutation of verprolin (*vrp1Δ*). Vrp1 is known to interact with the Arp2/3 complex activators Las17 (WASp) and Myo3/5 (type-1 myosins) during the mobile phase of endocytosis. *vrp1*Δ yeast are endocytic deficient, display prolonged fluorescent lifetimes of early endocytic factors (Sla1 & Sla2), and have reduced inward movement of endocytic patches and these defects were suppressed by *clc1Δ19-76.* This suppression was dependent upon the talin-like domain of Sla2 and these LC residues are important for displacing Sla2 from actin, *in vitro*. We further tested the Vrp1 interacting actin nucleation promoting factors (NPFs), by combining each *las17*Δ or *myo3/5*Δ with *clc1-*Δ*19-76*. As expected, the LC-NT mutant suppressed both the endocytic and growth defects caused by loss of these major NPFs. Our work suggests that *clc1-Δ19-76* prolongs actin engagement by Sla2 leading stabilization of the membrane tubule over a longer period and concluding in eventual internalization despite suboptimal actin assembly. In wildtype cells LC binding Sla2 likely acts to maintaining directional tension during endocytosis.

1026

Measuring and modeling the lifetime of clathrin-coated structures.

F. Aguet[1], M. Mettlen[2], C. N. Antonescu[2], S. L. Schmid[2], G. Danuser[1]; [1]Department of Cell Biology, Harvard Medical School, Boston, MA, [2]Department of Cell Biology, The Scripps Research Institute

During clathrin-mediated endocytosis (CME), the assembly of clathrin-coated pits (CCPs) is a complex process regulated by interactions between structural and sorting proteins, receptors, and cargo molecules. Live-cell imaging of fluorescently-tagged CME-associated proteins via total internal reflection fluorescence microscopy has revealed a remarkable heterogeneity in CCP dynamics. Although many variables that contribute to this heterogeneity have been identified (i.e., cargo type/size, receptor concentration, local concentration of various accessory proteins), the hierarchy of molecular events that regulate CCP assembly is for the most part unknown. The distribution of CCP lifetimes is a powerful and widely used descriptive metric for the assessment of CME dynamics and identification of, or differentiation between, effects of molecular perturbation. Lifetimes are determined by detecting and tracking CCPs labeled with overexpressed fluorescent fusion proteins. High precision of the automated methods employed to this end is crucial, as any systematic error will introduce a shift towards shorter lifetimes in the estimated distributions. Here, we show that lifetime estimation is highly sensitive to signal-to-noise ratio (SNR) and, as a consequence, to the level of expression of the fluorescent fusion protein used as a fiduciary for CCP detection and tracking. In this context, we introduce a new set of tools designed for high sensitivity even at low SNR conditions, and show how the resulting lifetime distributions relate to the kinetics of CCP maturation. Finally, using a state-based kinetic model, we identify kinetically distinct subpopulations of CCPs based on the measured lifetimes.

1027

Dynamics of Clathrin Coated Pits.

A. Banerjee[1], R. Nossal[2]; [1]National Institutes of Health, Bethesda, MD

The early state of receptor mediated endocytosis involves the formation of transient structures known as clathrin coated pits (CCPs). Depending on the detailed energetics of protein binding and associated membrane transformations, the pits either mature into clathrin coated vesicles (CCVs) or regress and vanish from the cell surface. The former are referred to as “productive” CCPs and the latter as “abortive” CCPs. We build a simple model for CCP dynamics which includes the free energy of CCP formation and a related kinetic scheme, and demonstrate how the model can be used to describe various aspects of CCP dynamics. In particular, we carry out Monte Carlo simulations to investigate the time development of CCP size and explain the origin of abortive pits and features of their lifetime distribution. By fitting the results of the simulations to experimental data, we are able to estimate values of the free energy changes involved in formation of the clathrin-associated protein complexes that comprise the coat. We also show how the binding of cargo might modify the coat parameters and thereby facilitate CCV formation. Finally, we observe how variations in the lifetimes of pits that result in CCVs are linked to the stochastic associations and disassociations of the coat components.

1029

Regulating AP-2 interactions to control vesicle size and number during clathrin-mediated endocytosis.

B. Ritter[1], S. Murphy[2], M. Halin[1], J. Philie[1], K. Gehring[2], P. S. McPherson[1]; [1]Neurology and Neurosurgery, McGill University, Montreal, PQ, Canada, [2]Biochemistry, McGill University

The clathrin adaptor protein AP-2 is the core organizing element in clathrin-mediated endocytosis; it concentrates cargo and clathrin at the site of vesicle formation and it orchestrates a myriad of endocytic accessory proteins to control aspects of vesicle formation ranging from membrane deformation to vesicle fission. Thus, clathrin and accessory proteins need to interact with AP-2 in a temporally and spatially controlled manner, yet it remains elusive as to how access of these binding partners to AP-2 is regulated. Using knock down and functional rescue studies, we now demonstrate that the AP-2-binding protein NECAP 1 is a critical regulator of AP-2 interactions. In fact, NECAP 1 needs to be present in a complex with AP-2 to enhance the stability of FCHo2-marked vesicle nucleation sites, thereby controlling the number of clathrin-coated vesicles that form. During vesicle formation, NECAP 1 and AP-2 function cooperatively in the efficient recruitment of other accessory proteins that in turn control vesicle size. Moreover, we use binding assays and nuclear magnetic resonance studies to reveal NECAP 1 as the first known factor that competes with clathrin for access to the AP-2 beta2-linker, positioning NECAP 1 to regulate the ability of AP-2 to recruit and polymerize clathrin. Thus, our data demonstrate that NECAP 1 is a key modulator of the AP-2 interactome needed for productive vesicle formation and reveal a new layer of organizational control within the endocytic protein machinery.

1030

Regulation of dynamin-mediated fission by endocytic accessory proteins.

S. Neumann[1], S. Schmid[1]; [1]Cell Biology, The Scripps Research Institute, San Diego, CA

The large GTPase dynamin plays a dual role during CME: at early stages it monitors the maturation of clathrin coated pits (CCPs), whereas at late stages it assembles at the neck of deeply invaginated CCPs and mediates membrane fission. Dynamin consists of five functionally-defined domains. These include, the G domain, which mediates GTP hydrolysis, and a middle domain and GTPase effector domain that together are involved in self-assembly. The pleckstrin homology domain mediates lipid interactions, and the Pro/Arg domain (PRD) mediates interactions with dynamin's SH3 domain-containing partners. Structure-function analyses of a series of mutants have revealed that dynamin's ability to catalyze membrane fission depends on its interdependent abilities to a) bind and self-assemble onto membranes, b) generate high curvature on these membranes, and c) hydrolyze GTP.
Over the past 15 years a myriad of endocytic accessory proteins have been identified based on their interaction with clathrin, AP2 or dynamin. Here, we studied the effect of dynamin binding partners and their regulation of dynamin-mediated fission. We tested the major dynamin binding partners: SNX9, Endophilin and Amphiphysin, all of which contain membrane remodeling BAR domains.
Using an in vitro fission assay, we found that these effectors regulate dynamin mediated fission at multiple levels. 1) The interaction between the PRD and the SH3 domain of all three binding partners negatively regulates fission. 2) In the absence of this interaction fission is facilitated by amphiphysin and endophilin most likely supported by the BAR domain. 3) Our results imply that the SH3 domain in addition negatively regulates the BAR domain, perhaps in a manner similar to that recently identified for syndapin (Rao et al., 2010, PNAS 107:8213).
Fission is a stochastic process and requires multiple rounds of dynamin assembly, membrane squeezing, GTP hydrolysis and disassembly. Therefore we tested the GTPase activities in the

presence of these effectors. Our results imply that under conditions that facilitate fission, GTPase activities were reduced. This unexpected inverse relationship of GTPase activity and fission was not observed with dynamin mutants displaying decreased GTPase hydrolysis. We speculate that dynamin binding partners prolong the residence time of dynamin at the membrane by promoting self-assembly. This results in fewer rounds of assembly and disassembly and therefore in lower GTPase activity and increased membrane squeezing. To test our hypothesis, further assessment of the effect of dynamin binding partners on dynamin's multiple biochemical activities will be necessary.

1031

Dynamin's powerstroke.

J. E. Hinshaw[1], J. S. Chappie[1], J. A. Mears[2], S. Fang[1], M. Leonard[3], J. A. Heymann[2], S. L. Schmid[4], R. A. Milligan[4], F. Dyda[2]; [1]NIH, Bethesda, MD, [2]Case Western Reserve University, [3]The Scripps Research Institute

The dynamin family of proteins are large GTPases involved in membrane fission and fusion events throughout the cell. Our goal is to understand the dynamic structural properties of these proteins and correlate them with their diverse cellular functions. The founding member, dynamin, is crucial for endocytosis, synaptic membrane recycling, membrane trafficking within the cell, and associates with filamentous actin. Purified dynamin readily self-assembles into rings and spirals and forms similar structures on liposomes, generating dynamin-lipid tubes that constrict and twist upon GTP hydrolysis. Previously, we solved the three-dimensional structure of ΔPRD-dynamin tubules both in the non-constricted and constricted states to a resolution of ~20 Å. Recently, we have improved the resolution of ΔPRD-dynamin to 12 Å. The new map reveals additional density in the GTPase domain that would accommodate the bundle-signaling-element (BSE), which consists of the N- and C- terminal α helices of the GTPase domain and the C-terminal α helix of the GED domain. In addition, the new map resolves the middle radial density into two segments that twist and tightly interact. We have docked the GDP.AlF_4^- GG domain (GTPase domain-GED fragment) crystal structure and a new GMP-PCP GG crystal structure into our 3D map. Comparison between the GTP-bound state (GMP-PCP) and transition state (GDP.AlF_4^-) within the 3D EM map suggests that the conformational change induced by the GTP hydrolysis is driving a large swing of the BSE. We predict that the BSE movement is dynamin's power stroke that results in a significant twist and constriction of the underlying lipid bilayer leading to membrane fission. In addition to the ΔPRD-dynamin 3D map, we have calculated a 3D map of full-length dynamin in a further constricted state, with a resolution of ~15Å. The inner lumenal diameter of this structure is ~2-4 nm, a range that is compatible with spontaneous lipid fusion. Currently we are docking the GG domain crystal structures into our K44A-dyn map to identify changes within dynamin domains that leads to maximum constriction and ultimately membrane fission.

1032

The Structures of COPI-coated Vesicles.

M. Faini[1], S. Prinz[1], R. Beck[2], M. Schorb[1], J. Riches[1], K. Bacia[3], B. Bruegger[2], F. T. Wieland[2], J. A. Briggs[1,4]; [1]Structural and Computational Biology Unit, EMBL, Heidelberg, Germany, [2]Heidelberg University Biochemistry Center, Heidelberg University, [3]HALOmem, University of Halle, [4]Cell Biology and Biophysics Unit, EMBL, Germany

We used novel cryo-electron tomography methods to resolve the structure of the COPI coat *in situ* on COPI-coated vesicles derived from a budding reaction. We found that the repetitive unit of the coat is a triad of three coatomer complexes. We determined the location and arrangement of the triads on individual vesicles an discovered that the protein coat is not complete but

contains gaps. Structures of COPII and clathrin coats assembled *in vitro*, without membranes, have led to the current model where coat proteins assemble using essentially identical local contacts to form regular, geometrical cages. In this model, structural flexibility of the components allow formation of cages of different size. In striking contrast to this model, we revealed that COPI-coated vesicles are assembled through non-identical local contacts. By adopting different conformations and interacting with different stoichiometries, the coat forms vesicles with variable sizes and shapes. Regulating the relative frequencies of conformations in the same vesicle (for example stabilizing one interaction) would provide an avenue for cellular regulation of trafficking vesicle size.

1033

The role of cPLA2á in vesiculation of GPI-anchored protein-containing endosomes.

B. Cai[1], N. Naslavsky[1]; [1]Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE

The lipid modifier phospholipase A2 (PLA2) catalyzes the hydrolysis of phospholipids to inverted-cone shaped lysophospholipids that contribute to membrane curvature. Here we demonstrate a role for cytosolic PLA2-alpha (cPLA2á) in the vesiculation of glycosylphosphatidylinositol anchored protein (GPI-AP)-containing membranes. In this study, we used endogenous CD59 as a model for GPI-APs. Upon depletion of cPLA2á, CD59-containing endosomes become hypertubular. We further showed that accumulation of lysophospholipids, following the inhibition with lysophospholipid acyltransferase (LPAT) inhibitor, vesiculates CD59-containing endosomes. However, over-expression of cPLA2á does not increase the vesiculation of these endosomes, implicating other factors required in the fission of CD59-containing membranes. Indeed, we found that depletion of EHD1, a C-terminal Eps15 homology domain (EHD) protein, predicted to act as a “pinchase”, also induces the hypertubulation of CD59-containing endosomes. Furthermore, EHD1 interacts with cPLA2á. The results presented here provide evidence that the lipid modifier cPLA2á and EHD1 are involved in the vesiculation of CD59-containing endosomes. We speculate that cPLA2á induces membrane curvature, allowing recruitment of EHD1 to sever the curved membranes.

1034

ER export of GPI-anchored proteins requires COPII coat rigidity conferred by Sec13p.

A. Copic[1], C. Latham[1], M. Horlbeck[1], E. Miller[1]; [1]Biological Sciences, Columbia University, New York, NY

Eukaryotic secretory proteins are exported from their site of synthesis in the endoplasmic reticulum (ER) via transport vesicles that form when the proteins of the COPII coat assemble on the cytosolic face of the ER membrane. The hierarchical assembly of the five COPII subunits couples cargo selection with membrane deformation to generate and populate transport carriers. Despite a wealth of biochemical and structural information on the COPII coat, we still lack a mechanistic understanding of the biophysical processes that shape membrane deformation during genesis of these diverse transport carriers. We sought to probe this process by examining the molecular function of the outer coat component, Sec13. Although first characterized as a COPII coat protein, Sec13 is also a component of the nuclear pore complex, where its interaction with Nup145 is structurally analogous to its partnership with Sec31 and is thought to stabilize the curvature of the nuclear envelope much like Sec13-Sec31 imparts or stabilizes membrane curvature associated with COPII vesicles. Sec13 also binds in a structurally similar manner to Sec16, an essential but enigmatic regulator of COPII transport. It is therefore surprising that Sec13 is dispensable in the context of yeast mutants known as bypass-of-sec-thirteen (bst) mutants. The mechanism by which bst mutations permit secretion in

the absence of an otherwise essential coat component remains unknown. We sought to exploit the bst phenotype to further probe the function of Sec13. We undertook an exhaustive survey of the yeast genome to define novel bst mutants, identifying additional components with roles in biogenesis of GPI-anchored proteins. We propose that exclusion of an entire class of lipid-anchored proteins from COPII vesicles creates a locally altered membrane that is somewhat permissive in terms of membrane curvature and can therefore be bent into a transport vesicle in the absence of the rigidifying effect of Sec13. In support of our model, we demonstrate that a rigidified version of Sec31 supports viability in the absence of an additional bst mutation.

ER and Golgi Transport II

1035

Sedlin binds Sar1p and controls type II procollagen trafficking by modulating the cycle of COPII.

R. Venditti[1], M. Santoro[1], G. Di Tullio[2], B. Vertel[3], C. Wilson[1], A. De Matteis[1]; [1]Tigem, Telethon, Naples, Italy, [2]Consorzio Mario Negri Sud, [3]Cell Biology and Anatomy, Rosalind Franklin University, Chicago, IL

Genetic defects of sedlin, a conserved component of the TRAPP complex, cause spondyloepiphyseal dysplasia tarda (SEDT), a condition characterised by impaired chondrogenesis that results in short stature, flattening of the vertebrae and premature osteoarthritis. Prompted by the consideration that sedlin is ubiquitously expressed but that sedlin mutations cause cartilaginous-restricted dysfunctions, we hypothesized that sedlin might exert a role in the transport of chondrocyte-specific cargoes, such as type II procollagen (PCII). This hypothesis was reinforced by the fact that certain mutations in PCII give rise to autosomal dominant forms of spondyloepiphyseal dysplasia. We tested this hypothesis by analyzing the involvement of sedlin in the transport of different classes of secretory cargoes and found that sedlin is selectively required for PCII to exit the ER, while it is not essential for the ER exit of small soluble and membrane-associated cargoes. We have also identified the molecular mechanism underlying this role of sedlin in its ability to bind the GTPase Sar1 and to control the membrane-cytosol cycle of Sar1 itself and of the COPII coat complex at the level of the ER exit sites. Sedlin depletion and/or mutation in SEDT patients slows down the Sar1 cycle and prolongs the membrane association of Sar1-GTP at ER exit sites, thus inducing constriction and premature fission of nascent carriers which fail to incorporate the large PC protofibrils but are still competent for smaller secretory cargoes.

1036

The Role of Mammalian COPII Component SEC24D.

E. Adams[1], A. Baines[2], D. Ginsburg[3,4]; [1]Cell and Molecular Biology Program, University of Michigan, Ann Arbor, MI, [2]University of Michigan, [3]Howard Hughes Medical Institute, [4]Internal Medicine and Human Genetics, University of Michigan

Approximately one-third of all eukaryotic proteins transit the intracellular secretory pathway, exiting the ER in COPII-coated vesicles. Sec24 is the COPII component thought to be primarily responsible for the recruitment of transmembrane cargoes or cargo adaptors into newly forming vesicles. Mammalian genomes encode four Sec24 paralogs (*Sec24a-d)*, though little is known about their comparative functions and cargo-specificities. Co-immunoprecipitation experiments indicate that all four SEC24 paralogs interact with both paralogs of the SEC24 binding partner SEC23 (SEC23a/b) at relatively equivalent ratios. To address the *in vivo* function of the

SEC24D paralog, we generated two independent lines of SEC24D-deficient mice (carrying two distinct *Sec24d* gene-trap alleles). Mouse *Sec24d* is located on chromosome 3 and contains 23 exons. The first allele, carrying a gene-trap cassette insertion in intron 8, results in very early embryonic lethality (prior to the blastocyst stage of development) in homozygotes. Mice heterozygous for this *Sec24d* gene-trap allele have no apparent phenotype. The second allele contains a gene-trap in the more distal intron 20, with mice homozygous for this allele demonstrating delayed embryonic lethality (close to the expected number of *Sec24d-/-* embryos at E10.5, but none surviving to E18.5). The discrepancy between the two gene-trap alleles is likely explained by the ~1% residual normal splicing around the gene-trap in the second line. Finally, embryonic lethality in homozygotes for the first Sec24d allele is rescued by the introduction of a BAC transgene spanning the *Sec24d* gene. Current studies are examining the phenotype of SEC24C deficiency and the potential overlap in function between SEC24C and D by transgenic rescue experiments.

1037

COPII components SEC23A and SEC23B are required for normal murine development and survival.

L. Everett[1], B. Zhang[2], M. Vasievich[1], E. Adams[3], R. Khoriaty[4], X-W. Chen[5], D. Ginsburg[6];
[1]Human Genetics, University of Michigan, Ann Arbor, MI, [2]Molecular Medicine, Genomic Medicine Institute, Lerner Research Institute of Cleveland Clinic, Cleveland, OH, [3]Cell and Molecular Biology, University of Michigan, [4]Internal Medicine, Division of Hematology & Oncology, University of Michigan, [5]Life Sciences Institute, University of Michigan, [6]Life Sciences Institute, Department of Internal Medicine and Howard Hughes Medical Institute, University of Michigan

Approximately one third of all eukaryotic proteins transit the intracellular secretory pathway. COPII vesicles play a key role in transporting proteins from the ER to the Golgi. SEC23 is an essential component of the COPII vesicle coat, and two paralogs (SEC23A and SEC23B) are known in mammals. Human mutations in SEC23A and SEC23B are associated with cranio-lenticulo-sutural dysplasia and congenital dyserythropoietic anemia type II (CDAII), respectively. We recently generated mice deficient for SEC23A and SEC23B, as described in more detail by Zhang et al. Mice deficient for SEC23A die in mid-embryogenesis, and mice deficient for SEC23B exhibit massive pancreatic degeneration and perinatal lethality, but no anemia. Intercrosses between Sec23a+/- Sec23b+/- and Sec23a+/- Sec23b +/+ mice resulted in a statistically significant underrepresentation of Sec23a-/- Sec23b+/- embryos at E9.5 compared to all other genotypes (p=0.019), suggesting a significant genetic interaction between Sec23a and Sec23b. These findings indicate that humans and mice with mutations in Sec23a and Sec23b have disparate but tissue-specific phenotypes. Two independent Sec23a bacterial artificial chromosomes (BACs) and two independent Sec23b BACs were used to generate C57B6/SJL transgenic founder mice, which were crossed to generate a total of 8 Sec23a -/-, Tg+ and a total of 19 Sec23b -/-, Tg+ “rescue” mice. “Rescued” Sec23a-/-, Tg+ and Sec23b-/-, Tg+ mice are observed in expected Mendelian ratios; they are viable and grossly normal on autopsy and histological examination. RT-PCR and western blot analysis revealed differential endogenous tissue expression patterns for Sec23a and Sec23b in wildtype mice. Sec23b is expressed at a significantly higher level in the mouse pancreas as compared to bone marrow. These results confirm that the phenotypes we have observed are due solely to SEC23A and SEC23B deficiency, and not unintended effects of the gene targeting on a nearby gene. These findings also demonstrate that the Sec23a and Sec23b BACs contain the required regulatory sequences for sufficient physiologic expression of their corresponding genes in vivo. Ongoing studies utilizing BAC recombineering will determine whether Sec23a and Sec23b can functionally substitute for one another when expressed in the appropriate context in the mouse.

Mutations that allow formation of COPII vesicles in the absence of Sec13p.

A. Copic[1], M. Horlbeck[1], C. F. Latham[1], E. A. Miller[1]; [1]Biological Sciences, Columbia University, New York, NY

Secretory proteins are exported from the ER via COPII vesicles, which form when the proteins of the COPII coat assemble on the ER membrane. The outer layer of the COPII coat is thought to consist of a cage assembled from Sec31p-Sec13p heterotetramers. Whereas Sec31p and all other members of the COPII coat are absolutely essential, Sec13p is dispensable in certain yeast mutants, termed *bypass-of-sec13 (bst)* mutants (Elrod-Ericson and Kaiser, 1996, Mol Biol Cell 7: 1043). We conducted genome-wide screens in order to identify a full array of *bst* mutations in yeast. We find that the strongest *bst* mutants interfere with maturation of GPI-anchored proteins (GPI-APs) or disrupt the p24 complex, which is required for efficient export of GPI-APs from the ER. We hypothesize that because of their highly asymmetric distribution within the ER membrane, GPI-APs may make the membrane more resistant to introduction of positive curvature required for vesicle formation. Thus, a full COPII coat may be needed for deformation of a membrane enriched in GPI-APs, but under more permissive conditions Sec31p may be able to form the outer layer of the coat on its own.

An interesting new *BST* gene is *ERV29*, which encodes a receptor for soluble COPII cargo proteins. Whereas *erv29Δ* is a very weak suppressor on its own, its bst phenotype is greatly enhanced when we combine it with other weak *bst* mutants *erp1Δ* and *erp2Δ*. In addition, we identified many ribosomal and translational mutants as weak bst's. These
observations lead us to suggest that changing the bulk concentration of COPII cargo proteins at the ER may also influence the ease of COPII vesicle production.

1039

Regulation of COPII-dependent secretion of select extracellular matrix proteins in zebrafish skeletal morphogenesis.

D. B. Melville[1], M. Montero-Balaguer[1], D. S. Levic[1], W. Rybski[1], K. A. Zavalin[1], E. W. Knapik[2]; [1]Vanderbilt University, Nashville, TN, [2]Department of Medicine and Department of Cell and Developmental Biology, Vanderbilt University, Nashville, TN

The COPII machinery is the primary mediator of ER-to-Golgi transport and appears to be dynamically regulated, although the mechanisms of this regulation are only beginning to be elucidated. Using a positional cloning strategy, we identified a zebrafish mutant with a point mutation in the DNA binding domain of ER localized transcription factor creb3l2 that leads to a malformed head skeleton. The creb3l2 mutant phenotype is similar to those of previously identified zebrafish COPII mutants, and Creb3l2 directly regulates the expression of genes encoding select COPII proteins, suggesting that primary role of Creb3l2 is to modulate the availability of COPII components and the secretory capacity of the cell. The creb3l2 mutation is a hypomorphic allele that retains approximately 50% of its transcriptional activity, indicating that collagen secretion is sensitive to even modest changes in Creb3l2. Early patterning of creb3l2 mutant cartilage elements appears normal, and mutant chondrocytes begin producing type II collagen. However, mutant chondrocytes fail to secrete all of the collagen they produce, resulting in a backlog of collagen within the ER, a failure to maintain the ECM collagen, and aberrant chondrocyte maturation. Similarly, loss of Creb3l2 in the notochord leads to failure to secrete type II/IV collagens, while secretion of other cargos, including glycoaminoglycans and large ECM component laminin, is unperturbed. Creb3l2 is the first identified transcription factor to couple the secretory activity of cells to the progression of developmental programs. These

findings are likely to lead to better understanding of the etiology of human skeletal birth defects and adult-onset diseases linked to dysregulated ECM deposition.

1040

Luminal calcium regulates ER/ Golgi anterograde transport efficiency through ALG-2/SEC31 interactions.

M. Bentley[1], J. Helm[1], J. Klumperman[2], J. C. Hay[1]; [1]Univ Montana, Missoula, MT, [2]Department of Cell Biology, University of Utrecht, Netherlands

Luminal calcium released from secretory organelles has been suggested to play a regulatory role in vesicle transport early in the secretory pathway. In ER-to-Golgi transport, specific depletion of luminal calcium leads to unidentified enlarged clusters of intermediate compartment markers at ER exit sites. In vitro, blocking luminal calcium egress leads to release of residual (post-budding) COPII subunit sec31 and concomitant increased COPII vesicle fusogenicity, suggesting a role for residual coat retention in the calcium regulation of transport. The calcium sensor apoptosis-linked gene 2 (ALG-2) stabilizes residual sec31 on COPII vesicles in response to calcium and slows fusion, suggesting that it may be part of the signaling cascade by which luminal calcium exerts its effects on ER-to-Golgi transport (Bentley et al., 2010. Molecular Biology of the Cell 21:1033). Here we demonstrate using a kinetic morphological transport assay that specific luminal calcium depletion leads to a significant decrease in ER-to-Golgi transport rates for transmembrane cargo proteins. Furthermore, detailed ultrastructural analysis revealed that luminal calcium depletion is accompanied by an increase in numbers of COPII buds and tethered but unfused COPII vesicles at ER exit sites. Importantly, no accumulation of enlarged fusion structures was observed. Finally, in over-expression studies, we demonstrate that disruption of interactions between calcium sensor ALG-2 and sec31 cause severe defects in ER-to-Golgi transport. This work identifies for the first time a functional requirement for luminal calcium at a demonstrably post-protein-folding step in ER/Golgi transport in intact cells. The kinetic and ultrastructural analyses combined indicate that luminal calcium may be involved in promoting efficient post-ER sorting of transmembrane cargo between anterograde and retrograde directions of movement; in the absence of luminal calcium, the overall efficiency of anterograde transport decreases while anterograde vesicle formation is stimulated. Other possible interpretations are discussed. For the first time, ALG-2 interactions with sec31 are shown to posses a functionally critical role in anterograde transport, indicating that ALG-2 is at least one of the calcium sensors that effect luminal calcium's regulatory role in vesicle trafficking.

1041

Sec31p as a sole component of the COPII cage: Sec13p is dispensible under conditions influencing membrane rigidity.

C. F. Latham[1], A. Copic[1], J. G. D'Arcangelo[1], E. A. Miller[1]; [1]Department of Biological Sciences, Columbia University, New York, NY

Nascent proteins that enter the secretory pathway via the endoplasmic reticulum (ER) are packaged into vesicles for forward transport. Vesicles are sculpted from the ER membrane by the cytosolic COPII protein coat - the G-protein, Sar1p, Sec23/Sec24p and Sec13/Sec31p - in a process that is highly conserved in eukaryotes. In budding yeast, these COPII proteins are essential for viability, however, in mutants called bypass of Sec thirteen (*bst*), cells can survive without Sec13p. All strong *bst* mutations affect biogenesis or trafficking of GPI-anchored proteins (GPI-AP). We are exploring a model whereby that Sec31p can form the outer coat without Sec13p in *bst* mutants. This is supported by structural studies suggesting that Sec31p forms both the critical intermolecular contacts of the outer cage and the interactions with the

inner coat complex (Bi et al, 2007, Dev Cell, 13:635; Stagg et al, 2008, Cell 134:474). We have purified monomeric Sec31p and demonstrated that Sec31p or a Sec31p-β-blade mutant (where the Sec13p-interacting loop is replaced with an inert linker) can be specifically recruited to the COPII coat on synthetic liposomes in the absence of Sec13p. We have also demonstrated that Sec31p and the Sec31p mutant can form vesicles in the absence of Sec13p using an in vitro budding assay from microsomal membranes. We are also currently investigating the role of Sec13p in limiting the flexibility of the Sec13/31p outer coat during vesicle formation in wild type and *bst* mutant cells, where rigid GPI-APs could influence generation of membrane curvature. We have already defined one mutant, Sec31p-Δhinge, that lacks the entire inter-domain flexible region in order to mimic flexibility of the complex in the presence of Sec13p. Surprisingly, even though Sec31p-Δhinge does not bind to Sec13p, it allows for growth of yeast cells in the absence of *bst* mutations where the Sec13/31p complex is otherwise required.

1042

Sorting of ER-Golgi SNAREs by the COPII Coat in Saccharomyces cerevisiae.

H. Chu[1], D. K. Banfield[1]; [1]Division of Life Science, The Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong

Proteins that leave the ER via the secretory pathway are transported to the Golgi in COPII-coated vesicles. The selective and efficient recruitment of proteins into COPII vesicles is mainly achieved via signal-mediated or receptor-dependent sorting. In yeast cells, Sed5p (Qa-SNARE), Sec22p (R-SNARE), Bet1p (Qc-SNARE) and Bos1p (Qb-SNARE) form a SNARE complex that is essential for ER-Golgi transport and these SNAREs are known to be efficiently packaged into newly forming COPII-coated vesicles. Although Sec24p-binding sequences have been identified for Sed5p, Sec22p and Bet1p, via structural and *in vitro* biochemical approaches (Bos1p appears not to directly bind to COPII proteins), the physiological consequences of deficiencies in SNARE-COPII interactions have not been extensively explored. We have examined the physiological consequences of amino acid substitutions to SNAREs that knockdown their binding to the COPII coat in *in vitro* assays. We find that in the absence of a Sec24p-binding motif, Sed5p, Sec22p or Bet1p are inefficiently exported from the ER. Nonetheless, despite the profound transport delay of these SNAREs, cell growth and protein transport (in general) was not significantly affected in cells singly expressing these COPII binding-deficient SNAREs. Loss of both COPII binding motifs on Sed5p was, however, lethal to cells. In addition, we establish that a deficiency in the ER export of one member of the SNARE complex does not affect the transport of any other member, suggesting that the sorting and transport of Sed5p, Sec22p, Bet1p and Bos1p via COPII-coated vesicles is not co-dependent.

1043

Chlamydia trachomatis hijacks intra-Golgi COG complex-dependent vesicle trafficking pathway.

I. D. Pokrovskaya[1], J. W. Szwedo[1], A. Goodwin[2], T. V. Lupashina[3], U. M. Nagarajan[2], V. V. Lupashin[1]; [1]Physiology, UAMS, Little Rock, AR, [2]Microbiology and Immunology, UAMS, [3]UAMS

Chlamydia spp. are obligate intracellular bacteria that replicate inside the host cell in a bacterial-modified-unique compartment called the Inclusion. As other intracellular pathogens, chlamydiae exploit host membrane trafficking pathways to prevent lysosomal fusion and to acquire energy and nutrients essential for their survival and replication. The Conserved Oligomeric Golgi (COG) complex is a ubiquitously expressed membrane-associated protein complex that functions in a retrograde intra-Golgi trafficking through associations with coiled-coil tethers, SNAREs, Rabs and COPI proteins. Several COG complex-interacting proteins, including Rab6, Rab14 and Syntaxin 6 are implicated in chlamydial development. In this study, we analyzed the recruitment

of the COG complex and GS15-positive COG complex-dependent (CCD) vesicles to Chlamydia trachomatis inclusion and their participation in chlamydial growth. Immunofluorescent analysis revealed that both GFP-tagged and endogenous COG complex subunits associated with inclusions in a serovar-independent manner by 8 h post infection and were maintained throughout the entire developmental cycle. Golgi v-SNARE GS15 was associated with inclusions 24 h post infection, but was absent on the mid-cycle (8 h) inclusions, indicating that this Golgi SNARE is directed to inclusions after COG complex recruitment. Silencing of COG8 and GS15 by siRNA significantly decreased infectious yield of chlamydiae. Further, aberrant bacteria and membranous structures were observed inside inclusions by electron microscopy in cells depleted of COG8 or GS15. Our results showed that C. trachomatis hijacks the COG complex to re-direct the population of Golgi-derived retrograde vesicles to inclusions. These vesicles likely deliver nutrients that are required for bacterial development and replication.

1044

The Conserved Oligomeric Golgi (COG) Complex exists in multiple subcomplexes in HeLa Cells.

R. A. Willett[1], T. Kudlyk[1], I. Pokrovskaya[1], V. V. Lupashin[1]; [1]Cellular Physiology and Molecular Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR

The Conserved Oligomeric Golgi (COG) complex is a hetero-octameric peripheral protein complex that is proposed to function as a tether during intra-Golgi retrograde vesicle transport. The COG complex is composed of 8 proteins (COG's 1-8) that are predicted to assemble into two subcomplexes; lobe A, consisting of COG's 1-4, and lobe B, consisting of COG's 5-8. While the exact configuration of the COG complex has yet to be elucidated, the bi-lobed model appears to be an over simplification of the possible arrangements of the subcomplexes. We have shown that individual siRNA knockdown (KD) of COG subunits illustrates distinct phenotypes between lobe A and lobe B subunits, suggesting the two lobes to have separate jobs as trafficking machinery. In correlation with this theory, fluorescence recovery after photobleaching (FRAP), and fluorescence loss in photobleaching (FLIP) exhibited different kinetic profiles for lobe A and lobe B subunits. The lobe B subunit COG8-GFP cycled on and off Golgi membranes faster than the lobe A subunit YFP-COG3, suggesting a population of the COG8 containing lobe B that is absent of COG3 containing lobe A. Finally, gel filtration of separated HeLa cytosol and membrane illustrated a co-elution of COG's 3, 5, 6, and 8 in both the cytosol and membrane, which corresponded in size to an octameric protein complex. Furthermore, all tested COG subunits in the membrane fraction also co-eluted in a protein complex which corresponded to the tetramer. Uniquely, COG's 5 and 6 eluted in the cytosol in a slightly later fraction then the membrane bound subcomplex, suggesting that COG's 5 and 6 might exist in a cytosolic subcomplex that is smaller than the COG8 containing lobe B. Based on these data, we propose a model wherein the full octameric COG complex is present on both Golgi membranes and in the cytosol. Also in this model, we propose the existence of a previously uncharacterized third subcomplex containing COG's 5 and 6.

1045

Golgin-160 recruits the dynein motor to position the Golgi Apparatus.

S. Yadav[1], M. A. Puthenveedu[1], A. D. Linstedt[1]; [1]Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

Intracellular motility and organelle positioning depend on the recruitment of molecular motors by specific membrane receptors. Although ER-to-Golgi trafficking and Golgi positioning are the best-known examples of inward motility mediated by the microtubule minus-end-directed motor dynein, the dynein membrane receptor is unknown. Here, we show that the Golgi protein golgin-

160 is required and sufficient for recruiting dynein and for conferring centripetal motility to secretory membranes. Further, golgin-160 directly bound the intermediate chain of the dynein motor and this dynein/golgin-160 complex dissociated from membranes during mitosis allowing Golgi dispersal. These results identify the first physiologically regulated motor receptor in the early secretory pathway, and suggest a molecular basis for achieving dramatic changes in trafficking and organelle positioning during cell division.

1046

Intracellular Trafficking of the Amyloid β-Protein Precursor Regulated by PDZ domains of X11-Like.

Y. Saito[1], T. Suzuki[1]; [1]Hokkaido Univ, Sapporo, Japan

Amyloid β(Aβ), a causative peptide of Alzheimer's disease, is generated by intracellular metabolism of amyloid β-protein precursor (APP). In general, mature APP (mAPP, N- and O-glycosylated form) is subject to successive cleavages by α- or β-, and γ-secretases in the late protein secretory pathway and/or at plasma membrane, while immature APP (imAPP, N-glycosylated form) locates in the early secretory pathway such as endoplasmic reticulum or cis-Golgi, in which imAPP is not subject to metabolic cleavages. X11-like (X11L) is a neural adaptor protein composed of a phosphotyrosine-binding (PTB) and two C-terminal PDZ domains. X11L suppresses amyloidogenic cleavage of mAPP by direct binding of X11L through its PTB domain, thereby generation of Aβ lowers. However, how these functional domains of X11L do regulate APP trafficking and/or metabolism remains unclear. Here we performed a functional dissection of X11L. Using cells expressing various domain-deleted X11L mutants, intracellular APP trafficking and localization were examined along with analysis of APP metabolism including maturation (O-glycosylation). We revealed that X11L accumulates imAPP into the early secretory pathway by mediation of its C-terminal PDZ domains, without being bound to imAPP directly. With this novel function, X11L suppresses overall APP metabolism and results in further suppression of Aβ generation. Interestingly some of the accumulated imAPP in the early secretory pathway are likely to appear on plasma membrane by unidentified novel mechanism. Trafficking of imAPP to plasma membrane is observed in other X11 family proteins, X11 and X11L2, but not in other APP-binding partners such as FE65 and JIP1. We also revealed that conformational changes of X11L regulated APP metabolism and intracellular trafficking of APP. It is herein clear that PDZ domains and its conformation of X11L protein regulate APP metabolism at multiple steps in intracellular protein secretory pathways.

1047

Detection of in situ cleaved p115 in rapid protein inactivation.

M. Koreishi[1], Y. Honjo[1], A. Satoh[2]; [1]Okayama University, Okayama, Japan

Gene perturbation methods are commonly used in the study of gene and protein function. Therefore, we had recently developed a rapid protein inactivation technique utilizing the tobacco etch virus (TEV)-derived protease. The TEV protease recognizes the ENLYFQG amino acid sequence and specifically cleaves between Q and G. We developed antibodies that recognize the cleaved TEV (ENLYFQ) sequence, both in vitro and in vivo, but do not bind to uncleaved TEV (ENLYFQG). Using these antibodies, we successfully detected in situ protein cleavage of a vesicle tethering protein, p115 during its inactivation by the TEV protease. These antibodies used in combination with the TEV protease may be a useful complement to other perturbation methods.

1048

Cellulase Production in *Neurospora crassa.*

M. C. Reilly[1], N. L. Glass[2]; [1]University of California, Berkeley, CA

The filamentous fungus *Neurospora crassa* is a well-studied model organism that is frequently isolated from the environment in association with burned vegetation. Enzyme activities related to the metabolism of plant cell wall material have been observed in *N. crassa*, but the overall cellular response of the organism to such a recalcitrant carbon source remains poorly defined. In order to investigate the elements involved in fungal growth on cellulose, we utilized the near full genome collection of single gene knockout strains that has been generated under the auspices of the Neurospora Genome Project. Strains with deletions in loci thought likely to play a role in cellulase activity or production – including the known secretome of *N. crassa* when cultured on plant biomass, homologs of the *Saccharomyces cerevisiae* secretion apparatus, and proteins predicted to traverse the secretory pathway – were singled out for analysis. This subset of the *N. crassa* deletion collection was cultured on a cellulosic substrate and the levels of secreted protein and cellulase activity were compared to wild-type. A number of hyper- and hypo-secretion mutants have been identified. Sequence analysis suggests that while some of the deleted genes likely act in transcription, protein synthesis, and intracellular trafficking, many of the loci encode fungal-specific proteins of undetermined functions. The on-going characterization of these secretion mutants will enhance our understanding of the ability of *N. crassa* to utilize the complex carbon sources present in its natural environment.

1049

Characterization of Cellulase Secretion in the Filamentous Fungus *Neurospora crassa.*

T. Starr[1], L. Glass[1]; [1]Plant & Microbial Biology, The Energy Biosciences Institute at The University of California, Berkeley, Berkeley, CA

Many filamentous fungi survive in nature by secreting large amounts of hydrolytic enzymes that allow them to degrade and utilize lignocellulosic substrates for growth. Because of their inherent ability to secrete large amounts of proteins, filamentous fungi are used for high-level protein production in various industries, such as the textile, pharmaceutical, and biofuels industries. Although the basic conserved components of the eukaryotic secretion pathway characterized in yeast and higher organisms are also conserved in filamentous fungi, the highly polarized and compartmentalized growth mode of filamentous fungal hyphae mandates pathways of secretion that are specific to these fungi. Although certain aspects of filamentous fungal secretion are under active study, such as the terminal steps of polarized secretion at the hyphal tip, a basic characterization of the entire pathway from start to finish remains to be performed. Such a characterization may provide insights into how filamentous fungi are able to secrete large amounts of enzymes and how these fungi can be engineered to produce even more enzymes in the future. This is particularly of interest to the process of biofuels production, in which the inexpensive production of large amounts of cellulases is a major bottleneck to the efficient and cost-effective production of cellulosic biofuels. In nature the model fungus *Neurospora crassa* secretes a host of cellulases to allow it to grow on burnt vegetation. The tractability of *N. crassa* makes it an excellent model to characterize protein secretion in filamentous fungi, particularly the secretion of industrially relevant cellulases. To achieve this goal we are characterizing the pathway of cellulase secretion in *N. crassa* by following the trafficking of the fluorescently tagged endoglucanse 2 (EG-2) enzyme, a major secreted endocellulase. To determine the compartments through which cellulases traffic we are co-localizing EG-2-GFP with fluorescently-tagged markers of the ER, Golgi, endosomes, and the Spitzenkorper (a specialized secretion structure at the tips of filamentous hyphae). We are additionally assaying the consequences to EG-2-GFP trafficking of blocks to secretion imposed by pharmacological

or mutational insults. Our initial results suggest partial co-localization of EG-2-GFP with a marker of Golgi bodies, as well as the absence of obvious localization to the Spitzenkorper. These data suggest that cellulases traffic through the classical secretory pathway, but may be secreted at lateral regions instead of to the tips, which is traditionally considered to be the main site of secretion in filamentous fungi.

Establishing and Maintaining Organelle Structure

The B9 Complex Protects the Cilia as a Privileged Membrane Domain.

B. Chih[1], A. Peterson[1]; [1]Molecular Biology, Genentech, South San Francisco, CA

The primary cilium functions as cellular antenna that transduces extracellular signals to intracellular responses, such as Shh signaling1. The failure of cilia function leads to a multitude of human diseases, together termed ciliopathies2. How cilia are formed and how signaling proteins are selectively localized to cilia still remains unclear. Through the use of RNAi screening, proteomics, cell biological and mouse genetics approaches, we have identified a protein network at the base of the cilia that forms a barrier to membrane protein diffusion and thereby, promote cilia maintenance and selective receptor localization in the cilium membrane. The network contains all of the B9 domain proteins present in the mammalian genome, 4 proteins that are disrupted in human ciliopathies, including B9D1, MKS1, AHI1, CC2D2A and 3 previously uncharacterized proteins. The assembly of the B9 network at the basal body occurs before and independently of intraflagellar transport, demonstrating the fundamental role that it plays in formation and function of the primary cilia. siRNA disruption of the complex causes a reduction in cilia formation and a loss of signaling receptors from the remaining cilia. Strikingly, knockdown cells have increased amounts of plasma membrane proteins in the ciliary membrane and increased diffusion into the ciliary membrane. KO of either of two distinct components of the complex have identical defects in Shh signaling and ciliogenesis, providing the basis for understanding human ciliopathies with disruptions of the B9 network. Therefore, we propose that the B9-network is an essential complex for normal cilia function and acts as a diffusional barrier between the cilia and plasma membranes to maintain cilia as a compartmentalized signaling organelle.

1051

Reversibly changing directional flow in the plant endoplasmic reticulum.

L. Griffing[1]; [1]Biology, Texas A&M University, College Station, TX

Luminal and membrane proteins of the endoplasmic reticulum (ER) of plants flow directionally through the network. There is a possibility that the ER acts as a delivery nanopipe between organelles with which the ER is associated in plant cells. Flow at one particular ER-organelle subdomain, the chloroplast/ER nexus, is analyzed. This subdomain is of interest because it is the putative site of convergence of lipid traffic coming from the chloroplast's prokaryotic and the ER's eukaryotic lipid biosynthetic pathways. Photostimulation with a 405 nm laser at this site disrupts directional flow of proteins in the ER, producing aggregates (boluses) of luminal and ER membrane protein in the vicinity of the chloroplast/ER nexus. For several minutes following photostimulation, bolus formation propagates throughout the ER network and the rate and directionality of fluorescent ER protein diffusion at the nexus changes, as shown by quantitative assymetric fluorescence recovery after photobleaching (AFRAP). During recovery from

photostimulation, as boluses dissipate, directional diffusion is re-established, and the ER network is remodeled surrounding the chloroplast and at the nexus site.

1052

Proteasome-mediated degradation of ER membrane-derived cytoplasmic inclusions generated by the Amyotrophic Lateral Sclerosis-linked mutant form of VAPB.

A. Ruggiano[1,2], G. Papiani[1], M. Fossati[1,3], M. Francolini[1,3], A. Raimondi[4], R. Benfante[1], F. Navone[1], N. Borgese[1,5]; [1]Institute for Neuroscience, CNR, Milano, Italy, [2]Centre de Regulatio Genomica, Barcelona, Spain, [3]Department of Medical Pharmacology, University of Milan, Milano, Italy, [4]Neuroscience, IIT, Genova, Italy, [5]Pharmacobiological Sciences, University of Catanzaro, Catanzaro, Italy

VAP-B (Vesicle-Associated Membrane Protein-Associated Protein B) is a ubiquitously expressed, ER-resident tail-anchored protein that mainly functions as adaptor for lipid-exchange proteins. Its mutant form, P56S-VAPB, has been linked to a dominantly inherited form of amyotrophic lateral sclerosis (ALS8). P56S-VAPB forms intracellular inclusions, whose role in ALS pathogenesis has not yet been elucidated. We recently clarified the ultrastructure of these inclusions and their precise relationship with the ER, demonstrating that they are formed by profoundly remodeled stacked ER cisternae that appear to be held together by the mutated cytosolic domain of VAPB (Fasana E. et al., FASEB J. 24:1419, 2010). In the present study, we used stable HeLa TetOff cell lines inducibly expressing wild type and P56S-VAPB to investigate the dynamics of inclusion generation and degradation. Our results indicate that P56S-VAPB inclusions undergo turnover and that the rate of degradation of the aggregated mutant is faster than that of the wild type protein. At variance with other inclusion-forming mutant proteins, which are first ubiquitinated and then aggregate, P56S-VAPB becomes ubiquitinated after sequestration in inclusions. Degradation of the mutant protein involves the proteasome with no apparent participation of macro-autophagy. Involvement of the p97 ATPase in the extraction of poly-ubiquitinated P56S-VAPB from the ER membrane is suggested by the observation that transfection of a dominant negative p97 stabilizes mutant VAPB. Our results reveal surprisingly efficient poly-ubiquitination, extraction from the ER, and proteasomal degradation of a severely aggregated mutant protein. Furthermore, they suggest that the slow onset of P56S-linked familial ALS is not a consequence of the progressive accumulation of the mutant protein over time, and that the dominant inheritance of the mutant allele may rather be related to haploinsufficiency.

1053

Comparative Analysis of GOLPH3 Family Member Proteins.

M. Ng[1], M. Buschman[1], H. Dippold[1], S. Farber-Katz[1], M. Peterman[1], S. Field[1]; [1]Univ California-San Diego, La Jolla, CA

GOLPH3 is a Golgi-localized protein that is conserved from yeast to mammals. Previously, our lab has shown that GOLPH3 binds the phosphoinositide lipid phospatidyl inositol-4-phosphate (PI4P), connects the Golgi to the actin cytoskeleton through an interaction with Myosin 18A, and is required for anterograde trafficking functions as well as for maintenance of the characteristic Golgi ribbon morphology (H.C. Dippold, et al. Cell. 139(2):337-51. 2009). In higher vertebrate species there are 2 genes in the GOLPH3 family, GOLPH3 and GOLPH3L. Although GOLPH3 is known to have important roles at the Golgi and has also recently been identified as an oncogene, (K.L. Scott, et al. Nature. 459(7250):1085-90. 2009.) relatively little is known about GOLPH3L. Thus our objective was to characterize the relative functions of GOLPH3 versus GOLPH3L proteins in mammalian cells. The predicted sequence of GOLPH3L protein possesses a high level of homology with GOLPH3, particularly in the PI4P binding region, thus

we hypothesized that GOLPH3L may have similar activities in the cell to GOLPH3. First, we determined the relative expression levels of GOLPH3 versus GOLPH3L in various mouse tissues and various cell lines. Next, using an in vitro protein-lipid overlay assay, we compared binding of GOLPH3 and GOLPH3L to PI4P in vitro. Additionally, we expressed fluorescently-tagged versions of GOLPH3 and GOLPH3L in cells and determined whether they colocalized with each other or known Golgi markers using immunofluorescence microscopy. Finally we are knocking down GOLPH3 versus GOLPH3L to investigate their specific roles in cells. We expect to be able to discuss similarities and differences between the functions of GOLPH3 and GOLPH3L.

1054

Rapamycin-induced increase in vacuole size scaling in budding yeast is not due to macroautophagy.

Y-H. Chan[1], W. Marshall[1]; [1]Biochemistry & Biophysics, University of California, San Francisco, San Francisco, CA

The vacuole of *S. cerevisiae* is responsible for critical cellular functions including waste processing, and the morphology of this organelle is closely associated with these functions. For example, rapamycin treatment of cells induces many responses due to the inhibition of TOR signaling. Among these responses are a dramatic expansion of vacuole size, which we have quantified using novel size analysis methods based on 3-D fluorescence microscopy. Our measurements show that upon addition of rapamycin, vacuole surface area and volume scaling relationships with respect to cell size increase over a timescale of hours. Interestingly, these effects are not due to macroautophagy as has been suggested. To determine what is the cause, we have begun measuring vacuole size scaling in various known mutants of membrane trafficking. One such mutant is *fab1Δ* which affects lipid kinase activity, has enlarged vacuoles, and has previously been shown to affect TOR signaling. Vacuole size scaling in the *fab1Δ* mutant both in the absence and presence of rapamycin is very similar to that of rapamycin-treated wild-type cells, indicating that the *fab1Δ* phenotype is related to TOR signaling pathways. Furthermore, measurements on the *apl5Δ* mutant suggest that vacuole size scaling depends upon the flux of membrane through various trafficking pathways. One possible model to explain these observations, then, is that rapamycin treatment leads to increased trafficking to the vacuole independent of macroautophagy and/or decreased retrograde trafficking from the vacuole. Future experiments will continue to explore the role of membrane trafficking pathways in establishing vacuole size.

Eisosome filaments organize the plasma membrane in fission yeast.

R. Kabeche[1], S. Baldissard[1], J. Hammond[1], L. Howard[1], J. Moseley[2]; [1]Dartmouth Medical School, Hanover, NH

The cortical cytoskeleton interacts with the plasma membrane to mediate a range of cellular activities such as endocytosis, cell motility, and the maintenance of cell rigidity. Traditional polymers including actin, microtubules, and septins contribute to the cortical cytoskeleton, but additional filament systems may also exist. In yeast cells, cortical structures called eisosomes generate specialized domains to cluster specific proteins at sites of membrane invaginations. The BAR domain protein Pil1 organizes eisosomes, but the assembly mechanism and organizing principles have been unclear. Here, we show that purified Pil1 assembles into filaments in vitro and forms linear cortical filaments in fission yeast cells. Pil1 cortical filaments are excluded from regions of cell growth, and are independent of the actin and microtubule cytoskeletons. Upon increased expression, Pil1 forms cytoplasmic rods that are stable and span

the length of cylindrical fission yeast cells. In cells, Pil1 filaments assemble slowly at the cell cortex and appear stable by timelapse microscopy and FRAP. This stability does not require the cell wall, but Pil1 and the transmembrane protein Fhn1 co-localize and are interdependent for localization to cortical filaments. Consistent with its formation of cortical filaments, we find a role for Pil1 in generating spatial order and cortical rigidity of the plasma membrane. Our combined results indicate that Pil1 filaments form a cortical cytoskeleton in yeast, with implications for the role of filament assembly in the spatial organization and mechanical rigidity of cells.

New structural features of endoplasmic reticulum revealed by serial section electron microscopy.

M. Terasaki[1], N. Kasthuri[2], R. Schalek[2], K. Hayworth[2], J. W. Lichtman[2], G. Huber[1], T. Rapoport[3], M. Kozlov[4], T. Shemesh[5]; [1]Univ Connecticut Health Center, Farmington, CT, [2]Harvard University, [3]Harvard Medical School, [4]Tel Aviv University, [5]Weizmann Institute

New methodology for serial section electron microscopy using ATUM (automated tape-collecting microtome) and scanning electron microscopy has been developed for tracing neural connections but is also potentially very useful for cell biology. This technique allows reliable collection of very thin sections (~30 nm) through large volumes with well-defined staining of membranes. The structure of the endoplasmic reticulum (ER) was investigated in the neuron cell bodies, axons and dendrites in a 50 μm cube of mouse cerebral cortex layer 4/5.

The ER in the cytoplasm of neuronal somata is a mix of loosely organized sheets and tubules. The sheets have a sharp edge in cross section. This edge is likely to be enriched in curvature generating proteins such as reticulon (Shibata et al., 2010). Some regions of the ER consist only of interconnecting sheets. We believe that we have identified the fundamental structural motif of this type of ER. In series of serial sections through this structure, we could often find a single 30 nm thick section containing three sheets (e.g. #1, #2, #3) meeting at ~120°. As one views the serial sections on one side of this junction, only two of the sheets are connected (e.g. #1, #2) whereas the third sheet (#1) is separate, with its edge converging towards the junction. The situation is the same when approached from the other side, except that two other sheets are connected (e.g. #2, #3) and the third is separate and converging (e.g. #1). We propose that there is a single continuous sharp edge that runs through the junction (e.g. passing from #3 to #1) and that this is the key structural component of this three dimensional structure. Modeling using the concepts of membrane curvature elasticity shows that an initial U shape indentation of an edge of a two dimensional sheet transitions to this three dimensional structure in order to minimize the membrane bending energy.

In addition to this sheet structure, we also found very narrow (~20 nm), unbranched, and sometimes long (>1 μm) ER tubules which were very abundant in axons but are also present in cell bodies and dendrites. These may correspond to the 17 nm diameter tubules induced by recombinant YOP1 or reticulon added to artificial planar membranes (Hu et al., 2008).

A screen for microtubule-membrane linkers identifies LOM1, an endoplasmic reticulum protein required for nuclear envelope architecture.

A-L. Schlaitz[1], J. Thompson[2], J. R. Yates III[2], R. Heald[1]; [1]Department of Molecular & Cell Biology, University of California at Berkeley, Berkeley, CA, [2]The Scripps Research Institute, La Jolla, CA

Membrane-bound organelles exhibit a characteristic morphology and distribution within cells, and their regulated positioning and movement is key to the successful execution of fundamental cellular processes such as mitosis and cell polarization. The spatial internal organization of cells

is determined in part by interactions of organelle membranes with the microtubule cytoskeleton and concomitant with microtubule reorganization during mitosis, organelles undergo drastic morphological changes, suggesting that organelle-cytoskeleton contacts are also remodeled. However, a complete inventory of the molecular linkers between cell organelles and microtubules and an understanding of their regulation, e.g. during the cell cycle, are lacking. We developed an unbiased biochemical approach to isolate candidates for organelle-microtubule linker proteins from *Xenopus laevis* egg extracts based on their ability to bind both, cellular membranes and microtubules. Mass spectrometry of recovered proteins revealed several known organelle-microtubule linker proteins as well as a number of candidate LOM (**L**inker of **O**rganelles and **M**icrotubules) proteins that we are now investigating in tissue culture cells. We have found that LOM1, a previously uncharacterized endoplasmic reticulum- and microtubule-associated protein, plays an unexpected and critical role in nuclear envelope homeostasis. LOM1 depletion from HeLa cells by RNA interference (RNAi) resulted in irregularly shaped nuclei, apparently displaying deep invaginations of the nuclear envelope, defects that could be rescued by overexpressing an RNAi-resistant LOM1 construct. Remarkably, during mitosis in LOM1(RNAi) cells the endoplasmic reticulum displayed an aberrant association with the mitotic chromatin. We hypothesize that LOM1 functions to prevent premature access of the endoplasmic reticulum to the mitotic chromatin and thereby ensures correct post-mitotic nuclear envelope formation while in the absence of LOM1, endoplasmic reticulum membrane can get trapped between decondensing chromosomes leading to the irregularly shaped nuclei observed after LOM1 RNAi. These observations suggest that previously unappreciated microtubule-membrane interactions contribute to the generation of proper intracellular architecture during the cell cycle.

Assembly of an Algal Eyespot.

T. M. Mittelmeier[1], J. S. Boyd[1], M. D. Thompson[1], C. L. Dieckmann[2]; [1]Molecular and Cellular Biology, University of Arizona, Tucson, AZ

The eyespot of *Chlamydomonas* is a photosensory organelle required for phototaxis of the motile, single-celled green alga. The eyespot is assembled near the plus end of one of four bundled microtubule rootlets (D4) at the equator of the cell and comprises both plasma membrane and chloroplast components. Fluorescence microscopy with antibodies directed against acetylated microtubules, the rhodopsin photoreceptor ChR1, a chloroplast envelope protein EYE2, and a chloroplast pigment granule protein EYE3, in wild-type and a variety of mutant cells has led to the model that ChR1 is transported through the endomembrane system to the minus end of the D4 rootlet, and trafficked in the plasma membrane along the acetylated microtubules to the equator of the cell where it promotes assembly of the chloroplast envelope (EYE2) and pigment granule (EYE3) proteins to form the eyespot. The order of protein assembly into the eyespot is being investigated during cell division. In wild-type cells, the nascent D4 rootlet extends from the region of the daughter basal body toward the equator of the cell. Then, a small, oval patch of ChR1 accumulates near the plus end of the rootlet. The ChR1 patch remains near the equator of the cell while the acetylated rootlet extends temporarily to the posterior end of the cell, then regresses back toward the equator. In wild-type cells, EYE2 protein co-localizes with ChR1, but in *mlt1* and *cop3* (ChR1) mutant cells, EYE2 is observed in an oval shape at the proper location in the absence of ChR1. Experiments are under way to more precisely define the timeline of eyespot protein assembly, and to knock out or knock down both ChR1 and the highly similar ChR2 photoreceptor to test the hypothesis that the photoreceptors provide the master cue for eyespot assembly and location.

1059

GTP binding, but not hydrolysis, is required for the atlastin 'pre-fusion' to 'post-fusion' transition.

J. H. Morin-Leisk[1], S. G. Saini[1], T. H. Lee[1]; [1]Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

Formation of the branched endoplasmic reticulum (ER) network requires homotypic tethering and fusion of membrane tubules mediated by the membrane-anchored GTPase atlastin. Recent structural studies reveal two dimeric conformers of atlastin proposed to correspond to the tethered, ‘pre-fusion’ state and a ‘post-fusion state’. Though the structures suggest a fusion mechanism, how the ‘pre-fusion’ conformer transitions to the ‘post-fusion’ conformer and how the transition is coupled to GTP binding and hydrolysis are unknown. Here we identify a salt bridge specific to the ‘post-fusion’ conformer to be required. Charge reversal of each individual residue of the interaction pair blocked atlastin-mediated ER network branching, while a compensatory charge reversal to re-establish electrostatic attraction restored function. In vitro assays confirmed that GTP binding and formation of the identified salt bridge is essential for achieving the ‘post-fusion’ state. Surprisingly, nucleotide hydrolysis was not required. Together, these results suggest that GTP hydrolysis may drive the disassembly, rather than assembly, of the atlastin ‘post-fusion’ complex.

Electron Tomography Reveals that Rab6 Limits Golgi Cisternal Proliferation and the Accumulation of TGN Proximal Coated Vesicles.

B. Storrie[1], M. Micaroni[2], G. P. Morgan[2], N. Jones[1], J. A. Kamykowski[1], N. Wilkins[1], T. Pan[2], B. J. Marsh[2]; [1]Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR, [2]Institute for Molecular Biosciences, University of Queensland, Brisbane, Australia

We have shown previously that Rab6, a small trans Golgi localized GTPase, is critical to the maintenance of the juxtanuclear Golgi ribbon in mammalian cells. Rab6 knockdown or overexpression of GDP-Rab6 suppresses Golgi ribbon disruption in response to depletion of either ZW10/RINT1 or COG, structurally related tether complexes (Sun et al., MBoC, 2007). Based on the multiplicity of identified Rab6 effectors, e.g., TMF/ARA160 (cisternal adhesion), myosin IIA (Golgi tubule release), and Bicaudal D (vesicle transport), we hypothesized that an effector-by-effector, candidate protein approach was unlikely to reveal critical, upstream, suppressive effects of Rab6 on Golgi organization. Hence, we took the unbiased, high-resolution technique of electron tomography as a readout for the role of Rab6 in Golgi structure. We found that Rab6-depletion produced profound changes in HeLa cell Golgi cisternal organization including a 60% increase in cisternal number and a >3-fold increase in cisternal length. Consistent with previous observations that Rab6 facilitates anterograde trafficking (Grigoriev et al., 2009; Miserey-Linke et al., 2010), we found that the trans Golgi/trans Golgi network (TGN) was dilated. Unexpectedly, there was a pronounced TGN proximal accumulation of both coated vesicles and arrested budding/fusion structures that we term omega figures. Based on coat appearance and object size, the coated structures, be they free vesicles or omega figures, appeared to fall into two classes, clathrin- and COPI-coated. Omega figures were often located laterally along regions of non-adherent cisternae. The co-accumulation of coated omega figures and coated vesicles may have a common origin in delayed vesicle fusion. We failed to observe any accumulation of uncoated vesicles with Rab6 depletion. In striking contrast when cells were depleted of the Rab6-effector, myosin IIA, we did observe a marked accumulation of uncoated vesicles that were often trans Golgi linked. This outcome is important because it suggests that the role of Rab6 in Golgi organization is dominated by a critical subset of effectors. In addition to Golgi-specific effects, there was a significant accumulation of

multivesicular bodies, apparent autophagosomes, in Rab6 depleted cells. This may be an indirect effect; the S. pombe Rab6 orthologue has been linked to lysosomal stress responses through modulation of the TOR complex 2 (Tatebe et al., 2010). (Supported by a grant from the US National Science Foundation to B. Storrie and a grant from the Australian Medical Research Council to B. J. Marsh and B. Storrie)

1061

Calsequestrin-1 is required for association but not for targeting of triadin to the junctional sarcoplasmic reticulum membranes.

D. Rossi[1], C. Bencini[1], M. Maritati[1], F. Benini[1], S. Lorenzini[1], C. Paolini[2], F. Protasi[2], V. Sorrentino[1]; [1]Department of Neuroscience, University of Siena, Siena, Italy, [2]Dip. Neuroscienze e Imaging, Università "G. d'Annunzio", Chieti, Italy

Junctional membrane complexes (JMCs) of skeletal muscle cells are formed by two membrane compartments: the sarcolemma / transverse tubules (T-tubules) and the junctional region of the sarcoplasmic reticulum (jSR). These specialized domains, also called triads, are important for allowing the functional coupling between the voltage-operated Ca2+ channels, dihydropyridine receptors (DHPRs), on the sarcolemma / T-tubules and the ryanodine receptors / Ca2+ release channels on the jSR, in order to ensure proper execution of the excitation-contraction coupling mechanism. Different proteins are selectively localized at JMCs, however the specific molecular determinants leading to protein targeting and retention at JMCs are still unknown. To address these questions we expressed wild type and deleted GFP-tagged versions of triadin, a single transmembrane protein of the jSR, in rat primary myotubes. Three regions (named A, B and C) were identified as required for triadin targeting to the jSR. Analysis of protein mobility through FRAP experiments revealed that assembly of triadin into the jSR was accompanied by a significant decrease in protein mobility that was mediated by region C. GST-pull down experiments showed that region C was mainly able to interact with calsequestrin 1 (CSQ1), the major Ca2+ binding protein of the SR. These interactions were also supported by results from FRET experiments in myotubes and in non-muscle cells. Interestingly, experiments with myotubes from CSQ1 knockout mice revealed that, in the absence of CSQ1, triadin was properly localized to the jSR, although its mobile fraction was dramatically increased. These results suggest that CSQ1 is directly involved in retaining triadin to the jSR complexes, whereas protein targeting to the jSR is likely to be mediated by additional interactions with other proteins.

Trophoblast Cell-Cell Fusion and Dysferlin Expression is Mediated by the PKC Pathway.

W. Omata[1], W. E. Ackerman IV[2], D. D. Vandré[1], J. M. Robinson[1]; [1]Physiology and Cell Biology, Ohio State University, Columbus, OH, [2]Obstetrics and Gynecology, Ohio State University

Cell-cell fusion is a cardinal event in the formation of multinucleate syncytia and is part of the normal biology of the syncytiotrophoblast (STB) layer of the human placenta. The STB forms the interface between maternal blood and the placenta and is crucial for fetal development. The STB is formed by fusion of progenitor cells, the cytotrophoblasts (CTB). Dysferlin (DYSF) a putitive plasma membrane repair protein is expressed at high levels at the apical plasma membrane of the STB but not by the CTB. We have utilized the BeWo cell line as a surrogate for the CTB. These cells can be induced to fuse and form syncytia by forskolin (FK), which causes elevation of cyclic AMP (cAMP) and activation of cAMP/protein kinase (PKA). BeWo cells mimic the *in vivo* situation where the CTB does not express DYSF while the STB expresses DYSF. Thus control BeWo cells have little, if any, DYSF, while FK-treated cells fuse and express DYSF. We now show that treatment of BeWo cells with 4β-phorbol 12 myristate 13-acetate (PMA), an activator of protein kinase C (PKC) but not PKA, also induced BeWo cells

to fuse and up-regulated DYSF in a dose and time-dependent manner. These effects were largely blocked by the PKC inhibitor bisindolymaleimide I. An inactive analog of PMA, 4α-phorbol 12-myristate 13-acetate, did not induce BeWo cell fusion or DYSF expression. PMA induced BeWo cell fusion was not dependent upon DYSF expressions, since BeWo cells that do not express DYSF upon cell fusion (DYSF knock down cells) fused when treated with PMA. Interestingly, when BeWo cells were treated with PMA and FK simultaneously there was a synergistic enhancement of DYSF expression. These results indicate that multiple signaling pathways may be involved in regulating both cytotrophoblast fusion and the expression of DYSF in the syncytiotrophoblast.

Serial Block Face Scanning Electron Microscopy is a novel approach that extends 3D reconstruction of the endoplasmic reticulum to the cellular level.

I. Belevich[1], M. Puhka[1], H. Vihinen[1], M. Joensuu[1], E. Jokitalo[1]; [1]University of Helsinki, Helsinki, Finland

In addition to electron tomography (ET) that is effective on subcellular level, other alternative methods that extend the imaging to the cellular level have been developed. New scanning electron microscopy (SEM) techniques are based on automated sequential imaging of a freshly cut block face of resin-embedded specimens using a back scatter detector yielding images resembling TEM images of thin sections. A fresh block face is created by an ultramicrotome inserted in the imaging chamber (SBF-SEM) or by focused ion beam (FIB-SEM). In this work we utilized SBF-SEM technology to study the ER of interphase and naturally mitotic metaphase Huh-7 cells. The use of SBF-SEM allowed us to image and model large portions, up to the whole cell, of ER with the slice thickness of 25-50 nm, which is more than sufficient to resolve all morphological entities of the ER including 60-80 nm fenestrations on sheets and branch points connecting ER sheets and tubules. Progression of early mitotic cells to metaphase showed both dramatic rearrangement of the ER network and structural transformation of ER sheets to smaller and more fenestrated units. As result the mitotic ER forms numeric fenestrated sheets and short tubules arranged as concentric ER layers in the cell cortex. In addition, modeling of the middle parts of the cell revealed the existence of long tubular ER profiles originating from the cortical ER layers and extending towards the center of the cell in alignment with the mitotic spindle.

1064

A role for Rab10 in Endoplasmic Reticulum network assembly.

A. English[1], G. Voeltz[1]; [1]Molecular, Cellular and Developmental Biology, University of Colorado at Boulder, Boulder, CO

The Endoplasmic Reticulum (ER) is a continuous membrane bound organelle that composes the nuclear envelope and the peripheral ER. The structure of the ER is quite dynamic; during interphase, the ER continuously rearranges its structure while maintaining continuity in a process that requires an active fusion machinery. Very little is known about how homotypic ER fusion is regulated. Recently, the atlastin family of proteins was shown to regulate ER fusion and integrity. Our studies aim to identify additional components that regulate ER fusion and dynamics.

To isolate novel ER fusion machinery components, we used an ER rich *in vitro* system derived from *Xenopus laevis* egg extract. In this system, ER vesicles fuse to form tubular networks in a GTP-dependent manner. We then used this system as a starting material to identify ER derived

GTP-binding proteins that may regulate ER fusion. The purified GTP-binding proteins were identified by Mass Spectrometry. Of the thirteen GTP-binding proteins identified, eleven were Rab proteins. Rab proteins are known to have GTPase functions and have been implicated in membrane fusion of vesicles and organelles. Indeed, previous studies have shown that *in vitro* ER formation is disrupted by the addition of a Rab GDP-dissociation inhibitor (GDI); indicating a Rab could be involved in the GTP-dependent fusion mechanism required for ER network formation. Of the eleven Rab GTPases identified, only one, Rab8/10, had no previously identified function.

We determined that Rab8/10 is tightly associated with ER membranes *in vitro* and can be dissociated from ER membranes by addition of purified RabGDI. In humans there are two *Xenopus* Rab8/10 homologs, Rab8 and Rab10. Rab10 has 99% identity to *Xenopus* Rab8/10, whereas Rab8 has 95% identity. We localized fluorescently tagged Rab8 and Rab10 in mammalian COS cells, and found that Rab10 is unique in its ability to localize strongly to ER membranes. To test a role for Rab10 in ER morphology, we overexpressed mutant constructs of Rab10 in Cos-7 cells. A dominant negative mutant of Rab10 (T23N) changes peripheral ER morphology by converting the tubular ER into sheets. We observed a similar altered ER morphology when endogenous Rab10 was depleted by siRNA from Cos-7 cells. Together, these data suggest a role for Rab10 in the maintenance of tubular ER morphology. Current studies are aimed at identifying the factors that regulate Rab10 binding to the ER.

1065

Reticulon 4b modulates mammalian Endoplasmic Reticulum.

O. Rämö[1], E. Gucciardo[2], I. Belevich[2], H. Vihinen[2], E. Jokitalo[2]; [1]Institute of Biotechnology, University of Helsinki, Helsinki, Finland

Endoplasmic Reticulum (ER) hosts multiple essential cell functions including protein and lipid synthesis, regulation of intracellular calcium concentration and cellular trafficking. Morphologically ER can be divided into peripheral tubules and sheet-like nuclear envelope and perinuclear ER.

Reticulons are a large family of membrane associated proteins sharing a common C-terminal Reticulon Homology Domain (RHD). Previously it has been shown that Reticulon proteins are required to maintain the tubular morphology of ER. Reticulons are inducing membrane curvature by insertion of wedge-shaped RHD to outer ER membrane leaflet and by forming oligomers with each others and several other membrane proteins (DP1/Yop1p/Atlastins). The earliest results demonstrating these events were obtained by expressing neuro-specific exogenous Reticulon 4a in cultured mammalian cells.

Here we show that ubiquitously expressed Reticulon 4 splice variant Rtn4b has similar role in mammalian fibroblast cells. We have used both light microscopy and high resolution electron microscopy to study these morphological changes of ER upon manipulation of Rtn4b expression levels. Depletion of the endogenous Rtn4b via siRNA treatment leads to formation of large peripheral ER sheet structures in Huh-7 cells whereas overexpression of the protein produces long, unbranched tubules. Notably the siRNA treatment does not affect the fenestrations typical for the Huh-7 ER sheets. To better outline these subtle morphological changes we have used electron microscopic 3D data acquisition methods electron tomography and serial blockface scanning electron microscopy.

1066

Role of Triadin in the Organization of Reticulum Membrane at the Muscle Triad.

A. Fourest-Lieuvin[1], J. Rendu[1], A. Osseni[1], K. Pernet-Gallay[1], J. Brocard[1], D. Rossi[2], V. Sorrentino[2], I. Marty[1], J. Fauré[1]; [1]Grenoble Institute of Neurosciences - INSERM - CEA, Grenoble Cedex 9, France, [2]University of Siena, Interuniversity Institute of Myology, Siena, Italy

Calcium release from the sarcoplasmic reticulum (SR) triggers skeletal muscle cell contraction and takes place in highly organized membrane structures, called triads, distributed along the muscle fiber. A triad is composed of two SR terminal cisternae surrounding a plasma membrane transverse-tubule. This architecture is essential to sustain the activity of the calcium channel RyR1, which is located in the membrane of SR cisternae. However, little is known about the molecular mechanisms allowing the formation and maintenance of SR terminal cisternae. We have previously shown that ablation of triadin, a SR transmembrane protein interacting with RyR1, induces a modification of the shape of the triads in KO mice. Here we explore the intrinsic molecular properties of the triadin Trisk 95. *We show that when ectopically expressed, Trisk 95 is able to modulate reticulum membrane morphology. The membrane deformations that are induced by Trisk 95 are accompanied by modifications of the microtubule network organization. We provide evidences that the multimerization of Trisk 95 via disulfide bridges, and an indirect interaction with microtubules, are responsible for the ability of Trisk 95 to structure reticulum membrane. When domains responsible for these molecular properties are deleted from Trisk 95, its anchoring to the triads in muscle cells is strongly decreased. Overall, our data suggest that multimerization of Trisk 95 and binding to microtubules contribute to the organization of membranes of the SR in a triad.*

1067

DNA replication and nuclear membrane growth are coupled to nuclear migration in budding yeast.

D. Liakopoulos[1], M. Kirchenbauer[1]; [1]Biochemistry Center (BZH), University of Heidelberg, Heidelberg, Germany

During mitosis of budding yeast, astral microtubule-dependent forces facilitate migration and insertion of the nucleus into the bud neck, the future site of cytokinesis. Subsequently, chromosomes and the nuclear membrane are partitioned between daughters during anaphase spindle elongation. We show here that efficient insertion of chromosomes and the nuclear envelope into the bud neck requires one hand DNA replication and on the other hand nuclear membrane growth. Upon block in DNA replication chromosomes do not migrate into the bud neck. Mutations that cause untethering of chromosomes from the nuclear envelope (NE) facilitate chromosome insertion into the bud in cells with unreplicated chromosomes. In addition, as the nucleus enters the bud prior to anaphase, a NE subdomain becomes anchored to the bud cortex in an actin-dependent manner. Generation of this subdomain requires lipid synthesis, the secretory pathway and the exocyst complex. Exocyst mutations cause nuclear migration defects and display genetic interactions with mutations that deactivate astral microtubule-dependent nuclear migration. Thus, detachment of the chromosomes from the NE and exocyst-dependent anchoring of the NE at the cortex prior to anaphase facilitate correct positioning of the chromosomes and nucleus relative to the cleavage apparatus.

1068

Yip1A Cycling Between the ER and Golgi is Not Required for its ER Structuring Function.

K. M. Dykstra[1], N. Delrose[1], J. Suhan[1], T. H. Lee[1]; [1]Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

The endoplasmic reticulum (ER) in animal cells is a dynamic organelle whose structure is characterized by an interconnecting network of membrane sheets and branching tubules that extends from the nuclear envelope to the cell periphery. We have previously identified Yip1A as a key mediator of ER organization and dispersal. Yip1A depletion in HeLa cells led to dramatic restructuring of the network into multiple, micrometer-sized concentric whorls. Interestingly, Yip1A is not strictly localized to the ER, but rather is rapidly cycling between the ER and cis-Golgi and has been implicated in retrograde trafficking (Kano et al., 2009). In order to dissect Yip1A's ER structuring function away from other proposed roles for the protein in membrane trafficking, we created a Yip1A construct that was localized strictly to the ER. We determined that the cytoplasmic domain of Yip1A was sufficient for export of the protein out of the ER and that the first 83 amino acids were required, with their truncation leading to an ER restricted Yip1A construct. Through a gene replacement assay, we found this ER restricted Yip1A construct to be fully functional in maintaining ER network dispersal. This suggests that Yip1A cycling between the ER and Golgi is not required and that Yip1A is playing a direct role in structuring the ER. Current work includes alanine scanning the rest of the protein to identify critical residues in the transmembrane domain.

1069

ARL4A acts with GCC185 and CLASPs to modulate Golgi-derived microtubules and Golgi organization.

F-J. S. Lee[1], Y-C. Lin[1], T-C. Chiang[1], Y-T. Liu[1], Y-T. Tsai[1], L-T. Jang[1]; [1]National Taiwan University College of Medicine, Taipei, Taiwan

Golgi apparatus is essential for fundamental cellular functions. The structural integrity of the Golgi complex is known to be dependent upon microtubule-Golgi interaction and microtubule polymerization. The trans-Golgi network golgin GCC185 has been demonstrated to interact with the CLASP family of microtubule-binding proteins to recruit them to the Golgi, providing a microtubule-Golgi interaction and enhancing the elongation of Golgi-derived microtubules for Golgi maintenance. We show here that a less characterized ARL protein, ARL4A, acts with GCC185 to modulate Golgi-derived microtubules and Golgi organization. ARL4A directly interacts with GCC185 in a GTP-dependent manner. Sub-coiled-coil regions of GCC185's CC2 domain are required for the interaction between GCC185 and ARL4A. Depletion of ARL4A reproduces the GCC185-depleted phenotype, causing fragmentation of the Golgi compartment. GCC185 and ARL4A localize to the Golgi independent of each other. Deletion of the ARL4A-interacting region of GCC185 results in inability to maintain Golgi structure. Depletion of ARL4A impairs GCC185-CLASP interaction in vivo and abolishes the GCC185-mediated Golgi recruitment of CLASPs. Nocodazole washout experiments indicated that depletion of ARL4A, GCC185, or CLASPs impair the elongation of Golgi-derived microtubules and Golgi reassembly. In summary, we infer that ARL4A may alter integrity of Golgi structure by facilitating interaction of GCC185 with CLASPs, elongation of Golgi-derived microtubules, and Golgi reassembly.

Nucleocytoplasmic Transport

Function of mRNA binding by TREX2 components Sac3 and Thp1 in integrating transcription, processing and nuclear export.

A. Ellisdon[1], L. Dimitrova[2], E. Hurt[2], M. Stewart[1]; [1]MRC Laboratory of Molecular Biology, Cambridge, United Kingdom, [2]BZH, University of Heidelberg, Heidelberg, Germany

Nuclear export of messenger RNA requires formation of transport-competent mRNPs. TREX-2, a conserved TRanscription-EXport complex, coordinates transcriptional processes with the recruitment of export factors to nascent mRNA. Here, we report the crystal structure of a key TREX-2 segment, consisting of Sac3 residues 253-551 bound to Thp1 and Sem1. Both Sac3 and Thp1 have PCI folds based on a stack of α-helices, capped by a winged helix domain. Importantly, the juxtaposition of the Sac3 and Thp1 winged helix domains within TREX-2 generates a platform that mediates binding of nucleic acids. Structure-guided mutations in Sac3 and Thp1 underline the importance of the Thp1-Sac3 interaction and nucleic acid binding in coupling transcription with mRNP assembly/export. Overall, the structure of the Sac3-Thp1-Sem1 complex provides a structural basis for understanding how the TREX-2 complex facilitates the formation of export-competent mRNPs at the nuclear face of nuclear pores, and thereby provides a “fast track” for the nuclear export of a subset of transcripts such as those from the GAL system. The close juxtaposition of the winged helix domains of Sac3 and Thp1 is critical for binding mRNA and thereby bringing it in close apposition to the Mex67-Mtr2 export factor. This, in turn, facilitates a remodeling of the mRNP that displaces Yra1 while attaching Mex67-Mtr2 more strongly. Sem1 functions to stabilize Thp1 and probably functions in an analogous way in other complexes that contain PCI folds.

Etoposide-induced protein Ei24 is a novel negative regulator of nuclear import.

K. Lieu[1], E-H. Shim[2], J. Wang[2], G. Zambetti[2], D. Jans[1]; [1]Department of Biochemistry & Molecular Biology, Monash University, Clayton, Australia, [2]Department of Biochemistry, St. Jude Children's Research Hospital

Etoposide-induced mRNA 2.4kb (Ei24) was initially identified as a p53-induced pro-apoptotic gene, but a function for the encoded protein has yet to be described. Intriguingly, amino acid residues 44-94 of Ei24 share significant homology with the region of Importin (IMP)-α2 that binds IMPβ1, the IMP-β binding (IBB) domain, which we designated the IBB-like (IBBL) domain. Pulldowns from transfected HeLa cells indicate that GFP-Ei24 can bind specifically to endogenously expressed IMPα2 and IMPβ1, but not IMPα3. Additionally, Ei24 is able to reduce the nuclear accumulation of proteins dependent on IMPα2/β1 (e.g. p53) or IMPβ1 (e.g. telomeric-repeat binding factor 1) for nuclear import in cotransfected HeLa cells (overexpressing BclXL), as determined by quantitative confocal laser scanning microscopic analysis. In contrast, mutation of specific arginine residues to alanine within Ei24’s IBBL domain relieves Ei24’s inhibitory activity and does not affect the nuclear import of IMP-dependent cargoes. This is the first report that an endoplasmic reticulum (ER)-localised protein, Ei24, can negatively regulate nuclear transport globally by sequestering IMPβ1 and possibly IMPαs at the ER and thereby reduce the import of nuclear localizing proteins, with implications for critical cellular processes such as proliferation, differentiation and development. Since mutations in Ei24 are linked to

breast cancer, deregulation of Ei24 localization and/or activity clearly may be detrimental to normal cellular function and thus contribute significantly to oncogenesis.

Simulating nuclear pore transport: bridging the gap between qualitative theories and high precision experiments.

J. Mincer[1,2], S. Simon[1]; [1]Laboratory of Cellular Biophysics, Rockefeller University, New York, NY, [2]Department of Anesthesiology, Mount Sinai School of Medicine, New York, NY

Various theories attempt to explain selective transport through the nuclear pore complex. These theories lag in biophysical detail when compared with the current state of experiment that includes measurements of cargo transport at the single molecule level. Thus, progress in resolving between them is limited by the qualitative way in which these ideas have been formulated.
Our approach is to develop a computational simulation that is based on known structural elements rather than a particular transport theory. The results agree with a variety of experimental data including size cutoff for cargo transport with (30-nm diameter) and without (<10 nm) nuclear localization signals (NLS), macroscopic transport rates (hundreds per second), and single cargo transit times (milliseconds). The recently observed bimodal cargo distribution is predicted, as is the relative invariance of single cargo transit times out to large size (even as macroscopic transport rate decreases). Additional predictions concern the effects of the number of NLS tags, the RanGTP gradient, and phenylalanine-glycine nucleopore protein (FG-Nup) structure, flexibility, and cross-linking.
Significantly, results are consistent with and elucidate the molecular mechanisms of some existing theories (selective phase, virtual gate, and selective gate models). In effect, these results begin to bridge the gap between the current qualitative state of existing ideas of transport and the high precision experiments that elucidate transport at the single molecule level. Through our simulations, a model emerges that is a hybrid of a number of preexisting models as well as a Brownian ratchet model, in which a cargo-karyopherin complex remains bound to the same FG-Nups for its entire trajectory through the nuclear pore complex until RanGTP severs the cargo-Nup bonds to effect release into the nucleus.

1074

CRM1-independent Nuclear Export of the Thyroid Hormone Receptor is Mediated by Exportin 5.

K. Subramanian[1], H. Nelson[1], L. Allison[1]; [1]Biology, College of William and Mary, Williamsburg, VA

Thyroid hormone receptor α (TRα) and thyroid hormone receptor β (TRβ) are nuclear receptors that bind to thyroid hormone to activate or repress target genes involved in metabolism, growth, and development. Although primarily found in the nucleus, TRα and TRβ rapidly shuttle in and out of the nucleus through the nuclear pore complex. Previously, we showed that TR nuclear export is not completely blocked when cells are treated with leptomycin B to inhibit the export factor CRM1, suggesting that TR can also exit the nucleus by a CRM1-independent pathway. To determine which export factors are involved in the CRM1-independent pathway, RNA interference was used to knockdown gene expression of transportin 1, transportin 2, exportin 5, and exportin 6. The effect of knockdown on the nucleocytoplasmic distribution of GFP-tagged TRα and TRβ was assessed in live HeLa cells using fluorescence recovery after photobleaching (FRAP). Knockdown of exportin 5 altered TRs nuclear export dynamics; recovery was markedly slower in photobleached nuclei, indicating that nuclear export was inhibited. To determine whether increased nuclear export had an impact on TR-mediated gene expression, we co-

expressed TRα and TRβ, exportin 5, and a thyroid hormone response element (TRE)-mediated CAT reporter gene. CAT ELISA showed a decrease of TRE-mediated CAT reporter gene expression when increased amounts of exportin 5 were present. Further, we showed that when exportin 5 is over-expressed, the distribution of TR shifts to a more cytoplasmic localization. Taken together, our data suggest that TR nuclear export is mediated, in part, by exportin 5, and that disrupting the fine balance between nuclear import and export can lead to changes in TR-mediated gene expression.

1075

NLSs of Influenza nucleoprotein as novel targets for antiviral.

W. Wu[1], N. Pante[1]; [1]Zoology, University of British Columbia, Vancouver, B.C, Canada

Influenza A virus poses a serious threat to world public health, particularly the pandemic H1N1 and avian H5N1. Currently, the major anti-influenza strategies are vaccination and antiviral drugs. However, both of these approaches target structural components of the virus which undergo mutation and become resistant to these antiviral approaches. An alternative way to inhibiting influenza infection is to interfere with the viral entry into the nucleus, since this process is necessary for viral replication. So far, there are at least two stretches of amino acid sequences located on influenza nucleoprotein (NP) that are know to mediate the nuclear import of the viral ribonucleoproteins (vRNPs) containing the viral genome: NLS1 at the N-terminus of NP, and NLS2 spanning residues 198-216. Sequence alignment shows both NLSs on NP are highly conserved between different strains of influenza A, suggesting that NLSs are ideal candidate for novel antiviral approaches. To assess this, we are first defining the contribution of the NLSs of NP to nuclear import. The functional role of NLS1 has been very well characterized in previous studies. The specific role of the NLS2 is, however, ill-defined. In our study, we generated chimeric protein by fusing NLS1 or NLS2 to a heterologous protein and characterize the contribution of these NLSs to nuclear import. Our results showed that NLS2 renders a weak nuclear import behavior compared to NLS1. Interestingly, with only one basic amino acid difference (lysine to arginine) the NLS2 of seasonal flu (H1N1 and H5N1) contributes stronger to the nuclear import of the chimera protein than the NLS2 from pandemic H1N1 and avian H5N1. Using site-directed mutagenesis we further analyzed the contribution of the NLS2's basic amino acids to the nuclear import of the chimera protein. Our results suggest that NLS2 from pandemic H1N1 and avian H5N1 function as a classical bipartite NLS. However, NLS2 from seasonal flu (H1N1 and H5N1) behaves as a monopartite NLS instead of a bipartite NLS. By performing competition assays using NLS1 and NLS2 chimeras in infected cells, we found that the competing NLSs were able to successfully delayed infection of influenza A virus. This finding clearly indicates that a good strategy to employ in the development of new influenza antiviral drugs is to interfere with the function of NLSs of influenza NP.

1076

Remodeling of ribonucleoprotein complexes during export through the nuclear pore complex.

R. L. Adams[1], S. R. Wente[1]; [1]Cell and Developmental Biology, Vanderbilt University School of Medicine, Nashville, TN

Export of ribonucleoprotein (RNP) complexes from the nucleus requires multiple essential factors. Specific transport factors recognize the cargo and facilitate docking and translocation through the nuclear pore complex (NPC). These transport factors require interaction with a class of NPC proteins termed FG Nups for export. In addition, release of the transport factor from the RNP and changes in the RNP protein composition are key to conferring directional exit. For mRNA export, stimulation of the RNA-dependent ATPase Dbp5 directs transport directionality.

A key step in the Dbp5 cycle is the remodeling of the mRNP to release the general mRNA transport factor Mex67-Mtr2.

Ribosomal subunits are among the largest cargo transported through the NPC. Others have shown that the fully-assembled 60S subunit binds multiple different transport factors to allow efficient nuclear export. This includes a role for Mex67-Mtr2 and several others – Arx1, Ecm1, and the karyopherin Crm1. To determine whether Dbp5 is also responsible for removing Mex67-Mtr2 from 60S subunits, we generated and tested a series of double mutants with *dbp5* and alleles of genes encoding other reported ribosomal export factors. Strikingly, genetic interactions were observed between a *dbp5* mutant and mutants of ribosome export factors. Additionally, the *dbp5*^{ts} mutant accumulates 60S subunits in the nucleus. *In vitro* reconstitution experiments to assess remodeling are currently underway. These experiments suggest that Dbp5-mediated removal of Mex67-Mtr2 at terminal steps of NPC translocation is conserved between mRNA and 60S ribosomal export.

1077

Karyopherin-independent nuclear transport of large cytoskeletal proteins.

M. Kumeta[1], S. H. Yoshimura[1], K. Takeyasu[1]; [1]Kyoto University, Graduate School of Biostudies, Kyoto, Japan

The nucleocytoplasmic shuttling of molecules is an essential mechanism for eukaryotic cells to maintain proper cellular functions. The nucleoplasm is separated from the cytoplasm by the nuclear envelope, which harbors the nuclear pore complex (NPC) as a selective channel/barrier for macromolecules. In recent years, the presence and the functions of cytoskeletal proteins in the nucleus is becoming one of the active areas of research. In this study, we report the followings: (i) Some of the nuclear-localizing cytoskeletal proteins are much larger than the size limitation of the passive diffusion through the NPC and do not contain any classical nuclear localization signals (NLS). (ii) Analyses of the nuclear transport mechanisms using digitonin-permeabilized HeLa cells revealed that several large cytoskeletal proteins, including actinin-4, beta-I spectrin, and beta-catenin, can pass through the NPC in a karyopherin-independent manner. (iii) In contrast, a hydrophilic molecule, 70kDa dextran, was completely excluded from the nucleus. Considering their amphiphilic molecular structures, these cytoskeletal proteins may adapt their structure to the hydrophilic environment inside the NPC and spontaneously migrate into the nucleus without a help of karyopherins. (iv) The potential role of amphiphilic structural motif in nuclear targeting was revealed both *in vivo* and *in vitro*. When GFP-fused fragments containing several tandem arrays of spectrin-repeat, a structural motif found in actinin, spectrin, and dystrophin, were expressed in HeLa cells, the GFP signals were found in the nucleus. (v) The same GFP-fragments also exhibited the nuclear targeting properties by *in vitro* nuclear transport assay, suggesting the role of amphiphilic motif in nuclear targeting.

These findings demonstrate the dynamic nucleocytoplasmic shuttling of cytoskeletal giant proteins in a karyopherin-independent manner and suggest that size, shape, and hydrophobicity of the molecule are the possible determinants for the molecular transport through the NPC. We propose such spontaneous migration of large non-NLS proteins into the nucleus as an alternative mechanism of the nuclear transport which is mediated by amphiphilic structural motifs in the molecule.

1078

Investigating the mechanism and function of nuclear size regulation during *Xenopus laevis* development.

D. Levy[1], R. Heald[2]; [1]Molecular Biology, University of Wyoming, Laramie, WY, [2]Molecular & Cell Biology, University of California, Berkeley, Berkeley, CA

The size of the nucleus varies with cell type, developmental stage, and organism, yet the ratio of nuclear to cytoplasmic volume is tightly controlled in most systems. Altered nuclear size, nucleocytoplasmic ratio, or morphology is characteristic of many cancers, but the significance of nuclear size regulation for cell physiology is not understood. We are using the frog *Xenopus laevis* to study mechanisms of nuclear size control during development, and to determine the functional consequences of altering nuclear size in vivo. Nuclear size scales smaller during the rapid cleavages of early *X. laevis* embryos, both prior to the midblastula transition (MBT) and post-MBT. We showed previously that reductions in nuclear protein import regulate pre-MBT nuclear size, but how post-MBT nuclear size is determined is unknown. Interestingly, the MBT is marked by many changes including extension of cell cycle length, loss of cell division synchrony, and upregulation of zygotic transcription. To test whether changes occurring at the MBT alter nuclear size, we examined the role of nuclear export, which is upregulated at the MBT. Treating embryos or embryo extracts with a small molecule inhibitor of the major nuclear export factor Crm1 had no effect on nuclear size. However, large pre-MBT embryo nuclei shrank when incubated in post-MBT embryo extract, concomitant with loss of nuclear lamin B but no change in the number of nuclear pore complexes, suggesting that active remodeling of the nuclear lamina contributes to post-MBT nuclear size changes. We are currently testing whether changes in the composition or structure of nuclear and ER membranes regulate post-MBT nuclear size. Elegant work has shown that the timing of MBT correlates with the nucleocytoplasmic ratio. To test whether changing nuclear size alters the MBT, we injected one blastomere of a two-cell embryo with mRNA encoding importin α or Ntf2, factors we have shown to increase or decrease nuclear size, respectively. Embryo halves injected with importin α exhibited an apparently accelerated MBT as evidenced by premature slowing of cell divisions relative to the uninjected side, while Ntf2 injection delayed MBT. Nuclear size differences within the embryo persisted in tadpoles, whose tails consistently bent toward the side of the embryo with smaller nuclei. These results indicate that nuclear size influences cell division timing and patterning in the developing embryo. We are currently investigating how nuclear size correlates with the expression timing of different developmental markers and devising more assays to correlate nuclear size and cell function.

1079

Defining selective mRNA export mechanisms in response to stress in Saccharomyces cerevisiae.

B. J. Natalizio[1], S. R. Wente[1]; [1]Cell and Developmental Biology, Vanderbilt University, Nashville, TN

Eukaryotic cells respond to major cytotoxic environmental stress through dramatic alterations in gene expression. An essential process that regulates these changes in the gene expression pathway is the export of messenger RNA (mRNA) from the nucleus to the cytoplasm. As mRNA is synthesized, the transcript is packaged with proteins to form messenger ribonucleoprotein particles (mRNPs). The protein composition of these mRNPs is highly dynamic, characterized by the association and dissociation of specific proteins that mediate efficient mRNA translocation through nuclear pore complexes (NPCs) and proper gene expression under changing environmental stimuli. One fundamental cellular response pathway in the budding yeast *Saccharomyces cerevisiae* is the heat shock stress response. During the heat shock

response, transcription and export of specific heat shock-induced mRNAs are upregulated while non-heat shock-induced mRNAs are retained in the nucleus, liberating the translation machinery for synthesis of heat shock proteins. The precise molecular determinants that control the selective mRNA export of heat shock mRNPs remain largely uncharacterized.
Several key factors implicated in non-heat shock mRNA export are also essential for the export of heat shock mRNAs. One of these factors, mRNA export receptor Mex67, requires adaptor proteins to facilitate its efficient binding to mRNA; however, each of its previously identified adaptors (Yra1, Nab2, and Npl3) is dispensable for the export of heat shock mRNAs. To identify potential adaptors for Mex67 function in the heat shock mRNA export pathway, we isolated Mex67-associated mRNPs under heat shock and non-heat shock conditions. The composition of these purified complexes was examined by mass spectrometry and Pab1 was identified as a potential heat shock-specific Mex67 interaction partner. Using an *in vivo* [^{35}S]methionine-labeling assay, no defect in the production of heat shock proteins was observed in a panel of *pab1* deletion mutants encoding changes within the RNA binding domains. Postulating that Nab2 may compensate for the loss of Pab1 function, we generated *nab2 pab1* double mutants. Indeed, enhanced temperature sensitivity was observed, indicating a strong genetic interaction between Nab2 and Pab1. Our current work is focused on further characterizing the heat shock response by examining the roles of Nab2 and Pab1 in heat shock mRNA export as well as by isolating heat shock specific mRNPs. Together, these strategies aim to reveal the mechanism for Mex67-mediated export of heat shock mRNA.

1080

Nuclear trafficking of Dystrophin Dp71.

G. Velez Aguilera[1], R. Suarez[1], B. Cisneros[1]; [1]Genetica y Biologia Molecular, CINVESTAV IPN, Mexico

Dystrophin Dp71 is the major product of the Duchenne muscular dystrophy gene (DMD); however, its neuronal function is poorly understood. We have previously adopted the PC12 cell line as in vitro neuronal model for studying Dp71 function. These cells express two Dp71 splicing isoforms; both of them spliced out for exon 71 and with exon 78 either present (Dp71d) or spliced out (Dp71f). While the lack of exon 71 do not change the reading frame, the loss of exon 78 does, resulting in the replacement of the last 13 C-terminal hydrophilic amino acids of dystrophin with 31 new hydrophobic amino acids in the Dp71 protein. It seems that alternative splicing regulates the localization of Dp71; while Dp71f is distributed solely in the cytoplasm, Dp71d exhibits a predominant nuclear localization. In this study we revealed that the ZZ domain of Dp71d is sufficient to drive the nuclear import of Dp71d, suggesting that this motif might function as nuclear localization signal (NLS). Interestingly, we found that leptomycin B (LMB)-mediated nuclear export inhibition resulted in accumulation of both Dp71d and Dp71f, which indicates that Dp71f, previously regarded as exclusive cytoplasmic protein, undergoes indeed a transient nuclear import. Considering that Dp71f differs from Dp71d by the presence of 31 hydrophobic amino acids in the carboxy-terminus, we hypothesized that this motif contains a nuclear export signal that export Dp71f efficiently from the nucleus to the cytoplasm. Further studies are required to test this hypothesis.

1081

Structural insights into the function of Yrb2, a cofactor that facilitates CRM1-mediated nuclear export.

M. Koyama[1], N. Shirai[1], Y. Matsuura[1]; [1]Nagoya University, Nagoya, Japan

The karyopherin CRM1 mediates nuclear export of cargo macromolecules containing a leucine-rich nuclear export signal (NES). CRM1 forms a ternary complex with cargo and RanGTP in the

nucleus. This complex translocates across the nuclear pores and dissociates in the cytoplasm. The yeast protein Yrb2 is a nuclear protein containing nucleoporin-like FG repeats and a Ran-binding domain (RanBD) that is homologous to RanBP1. However, Yrb2 binds RanGTP only very weakly, unlike RanBP1 that binds RanGTP with high affinity and functions as a cytoplasmic disassembly factor for the CRM1-cargo-RanGTP complex. The null allele of Yrb2 is cold sensitive and deficient in NES-dependent nuclear export. Here we show that Yrb2 dramatically increases the rate of association of CRM1 and cargo in the presence of RanGTP. Both FG-repeats and RanBD of Yrb2 are required to increase the on-rate of cargo. Furthermore, we determined a 2.3 angstrom-resolution crystal structure of CRM1-Yrb2-RanGTP complex. The structure revealed FG-repeats binding sites on the outer surface of CRM1, and structure-based mutagenesis indicated that these sites are also the binding sites for FG-nucleoporins. The structure of CRM1-Yrb2-RanGTP complex is similar to the previously determined structure of CRM1-RanBP1-RanGTP complex in that the HEAT9 loop is bound to the inner surface of CRM1, keeping the NES-binding cleft closed. However, because the RanGTP-RanBD interactions are very weak, the dissociation of RanBD coupled with the opening up of the NES-binding cleft would be expected to occur easily. Once NES is bound to CRM1, re-binding of RanBD is inhibited, and this would in turn facilitate dissociation of FG-repeats of Yrb2. Based on the biochemical and structural data, we propose a two-step model in which Yrb2 functions catalytically as a coordinating scaffold to increase the efficiency of CRM1-mediated nuclear export: (i) The FG-repeats and RanBD of Yrb2 recruit CRM1 and RanGTP, forming a ternary CRM1-Yrb2-RanGTP complex. By occluding the FG-repeats binding sites, Yrb2 could prevent cargo-free CRM1 from docking at and moving through the nuclear pores, inhibiting futile export of cargo-free CRM1. (ii) The binding of NES to CRM1 is associated with the dissociation of Yrb2, forming a CRM1-cargo-RanGTP complex that has FG-repeats binding sites exposed and so can translocate across the nuclear pores. The dissociated Yrb2 would then participate in another round of the rapid assembly of export-competent complex in the nucleus.

1082

Characterization of the nuclear import pathway for the baculovirus AcMNPV.

S. Au[1], D. A. Theilmann[1,2], N. Pante[1]; [1]Zoology, University of British Columbia, Vancouver, BC, Canada, [2]Pacific Agri-Food Research Centre, Agriculture and Agri-Food Canada, Summerland, BC, Canada

Some animal viruses have been engineered to deliver genes into an individual's cells and tissues in the process of gene therapy to help treat diseases. For genes to be expressed, the viral vector containing the gene must successfully enter the nucleus of the recipient's cell. This process is often limited by cellular proteins and structures that block the accessibility of the nucleus. Baculovirus is a great example of an animal virus that is being developed for gene therapy, yet the mechanism this virus uses to enter the nucleus remains uncharacterized. Autographa californica multiple nucleopolyhedrovirus (AcMNPV), the archetype of the Baculoviridae family, is an arthropod-specific, enveloped, rod-shaped virus with circular double-stranded DNA genome that replicates in the nucleus of its host insect cells. Using electron microscopy we demonstrated that baculovirus nucleocapsids remain fully intact while entering the nucleus through nuclear pore complexes (NPCs). We have used the well-established digitonin permeabilized cell nuclear import assay to characterize in more detail the nuclear import of the baculovirus nucleocapsid. With this assay, we used fluorescently-tagged viral nucleocapsids and anti-nucleocapsid antibody, to determine the fate of the imported nuclocapsids visualized by fluorescence microscopy under different conditions (with and without energy, with and without cytosolic components, low temperature). Using this system, we observed that nuclear import of AcMNPV nucleocapsids in HeLa cells occur with or without energy and cytosolic components. Interestingly, nuclear import in its host insect cells took place

only in the presence of cytosolic components extracted from insect cells and an energy regenerating source. Our data suggests that the ability and efficiency of nuclear import of AcMNPV nucleocapsids differs depending on the cell type. Furthermore, we aim to deplete proteins on NPCs using siRNA to determine the role of these proteins in the nuclear import of AcMNPV nucleocapsids. Our study will elucidate cellular proteins vital to the nuclear import of baculovirus, thereby promoting different factors that can enhance the delivery of this virus into the nucleus. These results will aid in designing baculovirus as an efficient viral vector for gene delivery.

Nuclear Lamins

1083

Role of the ZMPSTE24 Protease in Lamin A Processing and Progeroid Disorders.

J. Barrowman[1], C. Hamblet[1], M. Kane[1], S. Michaelis[1]; [1]The Johns Hopkins School of Medicine, Baltimore, MD

The post-translational processing of the nuclear scaffold protein lamin A plays a critical role in human health and disease. Lamin A is first synthesized as a precursor protein that undergoes a set of sequential modifications, including farnesylation, proteolysis and carboxylmethylation of the C-terminal CAAX motif. The prenylated and methylated tail is then cleaved by the Zn^{2+} metalloprotease ZMPSTE24 to yield mature lamin A. While the purpose of removing the elaborately modified lamin A tail remains unclear, failure to do so underlies several human progeroid disorders, including the premature aging disease Hutchinson-Gilford Progeria Syndrome (HGPS), and may be relevant to normal aging as well. Eighteen distinct human ZMPSTE24 mutations have currently been identified that result in the progeroid disorders MAD-B, atypical progeria, and restrictive dermopathy (RD). Interestingly, diseases of the greatest severity correlate with higher amounts of uncleaved, persistently modified prelamin A. We have begun to characterize this critical enzymatic event by determining the features of both the ZMPSTE24 enzyme, and its substrate prelamin A, that are important for efficient cleavage of the lamin A tail. We have utilized activity assays to characterize human disease alleles of ZMPSTE24 that are predicted to retain partial activity, and we are developing an *in vitro* cleavage assay to better characterize the enzymatic mechanism. With regard to the lamin A substrate, we have determined that ZMPSTE24 recognition elements are completely contained within a small 41 amino acid C-terminal region. We have identified several contextual requirements within this region that include, in addition to the farnesylated cysteine, an amino acid preference in the region surrounding the cleavage site. Interestingly, increasing the distance between the farnesyl-cysteine and the cleavage site reduces the ability of ZMPSTE24 to cleave, suggesting a spatial requirement for enzyme binding and/or cleavage to occur. Our studies are uncovering important features of an enzyme whose activity is vital to human health and longevity.

1084

Mitotic Defects and Pervasive Aneuploidy Accompany Loss of RB1 Activity in Mouse *Lmna^{Dhe}* Dermal Fibroblasts.

C. Pratt[1], M. Curtain[1], L. Donahue[1], L. Shopland[2]; [1]The Jackson Laboratory, Bar Harbor, ME

Lamin A (*LMNA*) is a component of the nuclear lamina and is mutated in several human diseases, including Emery-Dreifuss muscular dystrophy and the premature aging syndrome Hutchinson-Gilford progeria syndrome. Cells from progeria patients exhibit cell cycle defects in

both interphase and mitosis. Mouse models with loss of LMNA function have reduced Retinoblastoma protein (RB1) activity, leading to aberrant cell cycle control in interphase, but how mitosis is affected by LMNA is not well understood. Cell cycle and structural phenotypes were examined in cells from mice with the *Lmna* allele, Disheveled hair and ears (*Lmna*^{Dhe}). Dermal fibroblasts from heterozygous *Lmna*^{Dhe} (*Lmna*$^{Dhe/+}$) mice exhibited many phenotypes of human laminopathy cells. These included severe perturbations to the nuclear shape and lamina, increased DNA damage, and slow growth rates due to mitotic delay. Interestingly, *Lmna*$^{Dhe/+}$ fibroblasts had reduced levels of hypophosphorylated RB1 and the non-SMC condensin II-subunit D3 (NCAP-D3), a mitosis specific centromere condensin subunit that depends on RB1 activity. Mitotic check point control by mitotic arrest deficient-like 1 (MAD2L1) also was perturbed in *Lmna*$^{Dhe/+}$ cells. *Lmna*$^{Dhe/+}$ fibroblasts were consistently aneuploid and had higher levels of micronuclei and anaphase bridges than normal fibroblasts, consistent with chromosome segregation defects. These data suggest that the effects of LMNA on RB1 include both interphase and mitotic cell cycle control, supporting a key role for RB1 in the phenotypes of laminopathy-related cells.

1085

Lamin-A/C is a nuclear rheostat that scales with tissue rigidity and modulates cell lineage.

J. Swift[1], T. Harada[1], J. Pinter[1], I. Ivanovska[1], A. Buxboim[1], D. E. Discher[1]; [1]Biophysical Engineering Laboratory, University of Pennsylvania, Philadelphia, PA

Lamin proteins of the nuclear envelope are expressed throughout the body, but lamin mutants such as those causing progeria syndrome often affect specific solid tissues. Here, the relative quantities of A/C and B-type lamins are measured as components of the nuclear proteome in a range of normal adult tissues using novel, label-free tandem mass spectrometry quantitation corroborated by immunoblotting. Cells derived from soft and stiff tissues are also micromanipulated and shown to have soft or stiff nuclei that reflect the levels of Lamin-A/C. Brain tissue, which is unaffected in progeria, has an elasticity about 10-fold softer than striated muscle and has proportionately lower levels of A-type lamins – about 40% of the level of B-type lamins that are uniformly expressed among tissues. Defects in muscle, cartilage and bone feature more prominently in progeria, and nuclei from these increasingly stiff tissues have increasing levels of A-type lamin. Manipulating Lamin-A/C expression in stem cells also directs cell lineage with knockdown favoring softer tissue cells. Stress-driven changes in nuclear protein structures are further revealed by differences in the covalent tagging of cysteines during application of mechanical shear stress. Thus we show that the nucleus is capable of physically transducing stress.

1086

Lamin mutations disturb actin organization and nuclear translocation of MRTF-A.

C. Ho[1], D. E. Jaalouk[2], J. Lammerding[1]; [1]Weill Institute of Cell and Molecular Biology, Cornell University, Ithaca, NY, [2]Brigham and Women's Hospital, Boston

Mutations in the LMNA gene encoding the ubiquitously expressed nuclear envelope protein lamins A and C cause Emery-Dreifuss muscular dystrophy (EDMD), dilated cardiomyopathy, and a broad spectrum of other diseases (laminopathies). The disease mechanism remains unclear, but the muscle-specific phenotypes in many of the laminopathies suggest a mechanical and/or tissue-specific transcriptional component to the disease mechanism. Myocardin-related transcription factor A (MRTF-A) was recently identified as an important player in cellular mechanosensing, responding to changes in actin polymerization by translocating to the nucleus, where it acts as co-activator for serum response factor (SRF).

OBJECTIVES: To test the hypothesis that lamin A mutations associated with muscular laminopathies can impair MRTF-A signalling and thereby contribute to muscle dysfunction in EDMD and dilated cardiomyopathy and to identify possible mechanisms.

METHODS: Using time lapse imaging, immunostaining, and other biochemical approaches, we examined MRTF-localization and signalling in mouse embryo fibroblasts (MEFs) from lamin A/C–null mice, animals carrying a lamin mutation causing dilated cardiomyopathy (Lmna N195K), and wild-type littermates. Immunostaining of skeletal and cardiac tissue sections were used to confirm MRTF-A localization in vivo.

RESULTS: Nuclear translocation of MRTF-A in response to serum stimulation was almost completely abrogated in lamin A/C–null and Lmna N195K mutant MEFs, and these cells had impaired activation of SRF-target genes. Consistent with the in vitro findings, nuclear localization of MRTF-A was significantly reduced in skeletal and cardiac muscle sections of lamin A/C–null and Lmna N195K mutant mice. The nuclear translocation defect was associated with altered actin polymerization dynamics in the lamin mutant cells. Since emerin, a nuclear envelope protein, was recently shown to promote actin polymerization and is mislocalized in lamin A/C mutant cells, we examined whether emerin could be involved in the observed MRTF-A translocation defect by altering nuclear or cytoskeletal actin dynamics. Importantly, emerin-null MEFs displayed similar defects in actin organization and MRTF-A translocation as the lamin mutant cells, and ectopic expression of emerin rescued the defects in emerin-null and lamin mutant MEFs.

CONCLUSIONS: We have identified a new mechanism by which lamins A and C, likely mediated by emerin, can modulate actin polymerization and thereby alter activity of MRTF-A and SRF-dependent genes, providing a possible explanation for the muscle-specific phenotypes in several laminopathies.

1087

The Roles of Nuclear Lamin B1 in Cell Proliferation, Longevity and Senescence.

T. Shimi[1], S. A. Adam[1], R. B. Hamanaka[2], V. Butin-Israeli[1], A. E. Goldman[1], C. Lucas[1], D. K. Shumaker[3], S. T. Kosak[1], R. D. Goldman[1]; [1]Cell and Molecular Biology, Northwestern University, Chicago, IL, [2]Division of Pulmonary and Critical Care Medicine, Northwestern University, Chicago, IL, [3]Urology, Northwestern University, Chicago, IL

The A- and B-type nuclear lamins (LA/C, LB1 and LB2) are the major components of the nuclear lamina, forming separate but interconnecting meshwork structures (Shimi et al., 2008). Numerous mutations in the human LA/C gene cause the rare premature aging disease Hutchinson–Gilford progeria syndrome (HGPS). Interestingly, fibroblasts from several HGPS patients had an early onset of replicative senescence in culture, and LB1 expression in these cells was significantly decreased during senescence (Taimen et al., 2009). We have investigated the physiological significance of this loss of LB1 expression in normal diploid WI-38 cells during normal senescence by immunofluorescence, quantitative immunoblotting and qRT-PCR. The expression of LA/C and LB2 remains unchanged during spontaneous senescence progression, but LB1 protein expression and LB1 mRNA decrease dramatically as cells approach and become senescent. The inactivation of the p53 and pRb pathways in LB1 silenced cells have revealed that premature senescence induced by oncogenic stress also decreases LB1 expression through a pRb-dependent mechanism. Furthermore, silencing LB1 expression using shRNA slowed cell proliferation and induced rapid premature senescence. We have studied the p53 and pRb pathways for this LB1 silencing effect by the inactivation of these

pathways and showed that the proliferation defects induced by LB1 silencing require the activation of p53 but not pRb. These results indicate that LB1 functions in proliferation are upstream of the p53 and pRb pathways. Interestingly, mitochondrial ROS production is reduced by LB1 silencing. This reduction is p53-dependent and can be rescued by growth under hypoxic conditions. Furthermore, our analyses of qRT-PCR arrays have indicated that several genes upstream of p53 and some p53 target genes are altered in expression. In contrast to the effects of LB1 silencing, the over-expression of LB1 increases both the rate of cell proliferation and longevity. This over-expression of LB1 causes cell cycle arrest at the G1/S boundary and hyperphosphorylation of pRb. These results demonstrate the importance of LB1 in regulating the proliferation and longevity of human diploid cells through a p53-ROS signaling pathway. Supported by the NCI and the Progeria Research Foundation.

Cardiac consequences of ERK1/2 phosphorylation in the Lmna-/- mouse model.

S. Chen[1], R. Frock[1], P. Lampe[2], B. Kennedy[1,3]; [1]Biochemistry, University of Washington, Seattle, WA, [2]Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA, [3]Buck Institute for Aging Research, Novato, CA

Mice lacking the *Lmna* gene (*Lmna*$^{-/-}$), a nuclear scaffold protein, display multiple tissue defects and die by 8 weeks of age from dilated cardiomyopathy with associated conduction defects. We sought to further characterize the cardiomyopathic phenotype and determine whether restoration of a cardiac-specific *Lmna* transgene (Tg) in a *Lmna*$^{-/-}$ mouse would specifically rescue its cardiac pathology. In order to achieve this, we crossed *Lmna*$^{+/-}$ mice (Sullivan et al., 1999) with mice overexpressing human wild-type lamin A driven by the heart-specific α-myosin heavy chain promoter (Wang et al., 2006). We measured the cardiac performance of the resulting *Lmna*$^{-/-}$; Tg mice by echocardiogram and electrocardiogram as well as performed histopathological and biochemical analyses on heart tissue.

We observed increased activating phosphorylation of ERK1/2 in hearts of *Lmna*$^{-/-}$ mice consistent with previous studies using the *Lmna*$^{H222P/H222P}$ knock-in mouse model for Emery-Dreifuss muscular dystrophy. We also observed an increased heart weight to body weight ratio in *Lmna*$^{-/-}$ mice consistent with findings that show ERK1/2 to be an important regulator of cardiac hypertrophy. *Lmna* transgene expression resulted in attenuated ERK1/2 phosphorylation relative to *Lmna*$^{-/-}$ and a corresponding partial rescue of the hypertrophy. *Lmna*$^{-/-}$; Tg hearts also display significantly increased contractility and preservation of myocardial performance compared to *Lmna*$^{-/-}$ hearts as measured by echocardiogram.

Connexin43 (Cx43), the protein primarily comprising gap junctions in the heart, is a known target for phosphorylation by ERK1/2 resulting in decreased permeability and function of the gap junction. We observed that Cx43 levels at the intercalated disc were significantly decreased in *Lmna*$^{-/-}$ hearts and partially improved in *Lmna*$^{-/-}$; Tg mice. Electrocardiography revealed arrhythmic events and increased frequency of PR interval prolongation in *Lmna*$^{-/-}$ mice, which was also partially rescued in *Lmna*$^{-/-}$; Tg mice. Ultimately, we achieved a 12% median extension in lifespan in *Lmna*$^{-/-}$; Tg mice compared to *Lmna*$^{-/-}$ mice.

We have shown that the absence of lamin A in the heart is lifespan-limiting and results in a cardiomyopathic phenotype likely due to downstream effects of ERK1/2 phosphorylation causing both hypertrophy and conduction defects. We plan to further investigate the conduction aspect of this phenotype by determining the phosphorylation state of three ERK1/2-specific serine residues of Cx43 (S255, S279, S282), and potentially others, in *Lmna*$^{-/-}$ hearts and

cardiomyocytes. In addition, we hope to determine whether the expression of a Cx43 knock-in mutant (S255A/S279A/S282A) will rescue the defects observed in the conduction system.

Compression-induced changes in chromatin movement and nucleoskeletal organization.

T. A. Alcoser[1], E. A. Booth-Gauthier[2], K. N. Dahl[2]; [1]Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, [2]Chemical Engineering, Carnegie Mellon University, Pittsburgh, PA

Cells experience a wide-range of physiological forces and biochemical cues that can regulate gene expression. These stimulants may change the placement of chromatin territories from peripheral, gene silencing, to central, active transcription regions. Defining the subnuclear architecture in a cell during external stimulation will lead to improved understanding of gene regulation. In order to measure general nuclear organizational change, we monitored the subnuclear space using particle tracking. HeLa and osteosarcoma (Saos-2) cells were transfected with gfp-tagged subnuclear fiducial particles and exposed to a compressive force assay. During compression, cells showed increased subnuclear movement in comparison to uncompressed cells and the magnitude of change suggests a shift from passive to active subnuclear order.

Alternatively, the disease Hutchinson Gilford progeria syndrome (HGPS) presents a model system in which a localization of lamins to the periphery of the nucleus causes a stiffening of the nuclear lamina and blebbing morphology. It is also believed that gene expression is inhibited by the expression of progerin and may cause a barrier during genome organizational response to mechanostransduction. HeLa and Saos-2 cells were co-transfected for expression of the progerin morphology and gfp-tagged subnuclear fiducial particles. In progerin-expressing cells the subnuclear movement shows no clear passive to active organizational response during compression. This lack of regime change may suggest that a stiffening of the lamina shell causes a discoordination during mechanotransduction and altered subnuclear order. Progerin-expressing cells also show unique crack propagation from points of lamina concentration. Altered nuclear structure in progerin causes differences in subnuclear order during compression and may correlate to unique changes in chromatin migration and gene expression.

1090

Molecular dynamics stimulations of nuclear lamin A and progerin tail domains confirmed by in vitro stability studies: implications for the nuclear lamina.

A. Kalinowski[1], Z. Qin[2], M. J. Buehler[2], K. N. Dahl[3]; [1]Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, [2]Civil and Environmental Engineering, Massachusetts Institute of Technology, [3]Biomedical and Chemical Engineering, Carnegie Mellon University

Studying the biophysical properties of proteins can provide insights into their *in vivo* behavior. Defects in lamin A, a nucleoskeletal intermediate filament protein, occur at many points in the protein and the relation of a particular mutation to the resulting clinical pathology is not understood. Secondary structure analysis of the tail domain indicates that it is a mainly intrinsically disordered protein. Replica exchange molecular dynamics simulations of the tail domain indicate that the tail domain exists as an ensemble of semi-stable structures. We confirm our simulated structures by comparing the thermodynamic properties of the ensemble structures to *in vitro* stability measurements. Interestingly, all the protein conformations show that the ZMPSTE 24 cleavage site of the precursor form of the protein orients itself in such a way as to facilitate cleavage during the maturation process. Furthermore, Δ50 lamin A tail domain, the mutant protein responsible for Hutchinson-Gilford progeria syndrome, was simulated in order to understand the effect of the characteristic 50 amino acid deletion on

protein conformation. Both experimentally and *in silico*, the Δ50 lamin A tail domain shows increased stability, appears more compact and displays less heterogeneity than the mature lamin A tail domain. Δ50 lamin A tail domain's compactness suggests a more general resistance to turnover and more stable filament structures, as previously observed, potentially leading to the toxic accumulation observed in disease. Altogether these results suggest that the altered structure and stability of the tail domain can explain changed protein-protein and protein-DNA interactions and may represent an etiology of the disease.

1091

B-type lamins regulates neither their bound genes nor embryonic stem cells but are essential for organogenesis.

Y. Kim[1], A. Sharov[2], K. Mcdole[1], M. Cheng[3], H. Hao[4], C-M. Fan[1], N. Gaiano[3], M. Ko[2], Y. Zheng[1]; [1]Carnegie Inst for Science, Baltimore, MD, [2]Developmental Genomics and Aging Section, NIA, NIH, Baltimore, MD, [3]Department of Neuroscience, Johns Hopkins Univ., [4]Microarray core facility, JHMI

B-type lamins are believed to regulate gene silencing of their tethered genes. They are also thought to be essential for several basic functions including cell survival, DNA replication, and cell proliferation. Using genome-wide chromatin-lamin B interaction and gene expression analyses, we show that chromatin-lamin-B interaction correlates with reduction of gene expression during embryonic stem cells (ESC) differentiation toward the trophectoderm (TE) lineage. To further investigate the significance of the chromatin-lamin-B interaction, we created lamin-B1 and -B2 double knock out (DKO) ESCs. These lamin-B DKO ESCs do not express any type of lamins including lamin-A/C, -B1, -B2 and -B3. Unexpectedly, their nuclear morphology, growth rates, ploidy, expression of pluripotent markers, and potential to differentiate to TE cells are indistinguishable from wild-type ESCs. Gene expression array analysis of these DKO ESCs and TE cells conclusively demonstrates that B-type lamins are not required for the silencing of their bound genes during ESC differentiation toward TE cells. Furthermore we report that the lamin-B DKO mice can develop to term. However they die soon after birth with a small body size and defects in multiple organs including the lung, diaphragm, phrenic nerves, and the brain. We further define the requirement for B-type lamins in regulating spindle orientation in neural progenitor cells (NPC), migration of neurons, and survival of both NPCs and neurons. While refuting several general requirements for B-type lamins, our findings redefine the essential role of these nuclear proteins in organogenesis.

Chromatin and Chromosome Organization

Characterization of Transcriptional Regulation in iPS Cells.

L. Varticovski[1], B. Thompson[1], L. Grontved[1], D. Stavreva[1], G. Hager[1]; [1]LRBGE, NCI, Bethesda, MD

Background: Induced pluripotent stem (iPS) cells generated from somatic cells by direct reprogramming have pluripotency potential similar to that observed for embryonic stem cells. It is essential to fully understand transcriptional regulation of the genome in pluripotency and differentiation. Transcription factors bind to specific DNA response elements to regulate target genes. Identification of any given transcription factor binding sites can be partially assessed by Chromatin Immunoprecipitation (ChIP) combined with deep sequencing (ChIP-seq). However, ChIP and ChIP-seq provide only a narrow view of one specific target. Our laboratory has

pioneered analysis of DNase I hypersensitive sites (DHS) combined with deep sequencing (DHS-seq) to interrogate the landscape of all sites in the genome accessible to transcriptional regulation (John et al, Nature Genetics, 2010). We recently characterized chromatin changes and identified critical transcriptional regulatory events involved during adipogenesis in cultured cells (Siersbæk et , EMBO J, 2011). *Objective:* Unbiased analysis of genome-wide accessible sites provides a global view of chromatin organization and uncovers novel regulatory elements that determine transcriptional regulation in pluripotency and differentiation. *Methods:* iPS cells derived from normal human donors were maintained on irradiated mouse embryonic fibroblast feeder layer (MEF) or on Matrigel, and differentiated into embryonic bodies or mesenchymal stem cells. *Results:* Pluripotent cells were characterized by DHS-seq, gene expression by qPCR and flow cytometry. Genome-wide chromatin accessibility was compared to ENCODE data for human ES cells. *Conclusions*: Our study is the first genome-wide analysis of transcription factor accessibility in human iPS cells. These data will provide a baseline for characterization of normal and disease-associated differentiation of human iPS cells.

Investigating linker histone H1 function and dynamics in Xenopus.

K. Miller[1], R. Heald[1]; [1]Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Linker histone H1 is a fundamental chromatin protein thought to compact nucleosomes into a 30 nm fiber, but its role in higher order chromosome architecture is poorly understood. In *Xenopus* egg extracts, H1 depletion causes a 2-fold lengthwise decondensation of mitotic chromosomes, while addition of exogenous H1 causes hypercompaction, indicating its important role in the establishing and maintaining proper mitotic chromosome structure in this system. Unlike core histones, H1′s association with chromatin is dynamic. We showed previously that rapid H1 turnover measured by fluorescence recovery after photobleaching (FRAP) requires cytoplasmic factors. Here we establish an assay to identify cellular factors that modify H1 dynamics during mitosis. Sperm chromatin in metaphase-arrested egg extract diluted 1:3 in buffer and supplemented with GFP-H1 is subjected to FRAP. In control reactions, fluorescence recovers with a half time of 2.3 seconds. Depletion of ATP from the system with Apyrase treatment abolishes dynamics. We are using this assay to evaluate the effects of known H1 chaperones, including importin beta and RanBP7, and nucleoplasmin. To identify other H1 interacting proteins and post-translational modifications that contribute to cell cycle-specific H1 dynamics, we are utilizing mass spectrometry to characterize the embryonic isoform H1M (B4). Our long term goal is to understand the mechanisms that regulate H1's dynamic behavior, particularly during mitosis, and how this translates into condensation of the mitotic chromosome.

1094

Rapid De Novo Centromere Formation Occurs Independently of Heterochromatin Protein 1 in C. elegans Embryos.

K. Yuen[1,2], K. Oegema[3], A. Desai[3]; [1]University of California, San Diego, San Diego, CA, [2]University of Hong Kong (Present Address), Hong Kong, China, [3]University of California, San Diego

Naked DNA injected into the *C. elegans* germline concatemerizes to form extrachromosomal arrays that are inherited through meiosis and mitosis with variable fidelity. The mechanisms underlying array formation and segregation are not known. Here, we show that extrachromosomal arrays form *de novo* centromeres at high frequency. This provides a unique

opportunity to study *de novo* centromere formation, which has proven challenging in most systems because of its extremely low frequency. *De novo* centromerized arrays recruit the centromeric histone variant CeCENP-A and its assembly factor KNL-2, build a kinetochore that includes microtubule binding and checkpoint signaling proteins, and autonomously segregate on the mitotic spindle. The DNA injected into the germline does not require any homology to *C. elegans* sequences to support array formation and segregation. Live imaging following injection of DNA into the syncytial germline revealed that arrays form after fertilization in the 1-cell embryo cytoplasm through a process that involves both homologous recombination and non-homologous end joining. Acquisition of segregation competency by the arrays lags behind their formation—individual arrays gradually transition from passive inheritance to active segregation during the early embryonic cell divisions. We used the rapid *de novo* centromerization of extrachromosomal arrays to investigate the role of heterochromatin in *de novo* centromere formation. Arrays become strongly enriched for the heterochromatin-associated H3K9me3 mark over time, indicating that centromerization is compatible with heterochromatin assembly. Using null mutants, we found that that the two Heterochromatin Protein 1 (HP1) family proteins HPL-1 and HPL-2 are dispensable for *de novo* centromerization. In addition, partial inhibition of the HP1 family proteins accelerated the acquisition of segregation competence, suggesting that HP1-dependent heterochromatin may antagonize *de novo* centromerization. These findings report the first direct visualization of new centromere formation in living cells, establish that naked DNA injected into the *C. elegans* germline rapidly builds *de novo* centromeres, and reveal that HP1-dependent heterochromatin assembly is not essential for *de novo* centromerization. Extrachromosomal arrays in *C. elegans* thus provide a robust model to investigate the initial assembly and self-organization of centromeric chromatin, which has the potential to advance artificial chromosome engineering in human cells.

1095

Systematic analysis of the dynamics of single chromosome territories in live eukaryotic cells.

W. Xiang[1], S. Huet[2], J. Ellenberg[1]; [1]Cell Biology and Biophysics Unit, EMBL Heidelberg, Heidelberg, Germany, [2]Institut de Génétique et Développement de Rennes (IGDR), Université de Rennes 1, Rennes Cedex, France

Our picture of general principles and specific mechanisms of how higher order chromatin organization in eukaryotic cells is established and maintained is still very incomplete. This gives a strong incentive for studying interphase chromosome structure and dynamics in vivo. In the past live cell studies have relied on the analysis of single fluorescently labeled loci, which has yielded a variety of interesting dynamic behaviors depending on the chromosomal context. However, we are currently lacking a global quantitative analysis of the dynamics of interphase chromatin.

Here, we established an approach that allows us to quantitatively analyze the dynamics of single chromosome territories in human cells in interphase. After replication labeling the DNA backbone by a pulse of fluorescent nucleotides, cells are cultured through successive cell divisions until only a single chromosome remains labeled in a speckled pattern. The dynamics of this territory is then recorded by high-resolution confocal time-lapse microscopy with up to 10 Hz sampling, followed by tracking of the labeled sub-territory positions and statistical analysis of the resulting trajectories. In a data set of 200 chromosomes and 977 foci trajectories, we characterized the diffusional behavior of interphase chromosomes at different time scales to obtain a global view of interphase chromatin dynamics and examine effects of subnuclear position and cell cycle progression from G1 via S to G2 phase. Our data reveals that interphase chromatin dynamics is highly constrained and is characterized by slow anomalous diffusion, with only very few loci showing rare more dynamic behavior. Interestingly, short-range diffusion

was significantly faster for euchromatic/early- compared to heterochromatic/late-replicating chromatin and euchromatic/early replicating chromatin dynamics changed with cell cycle progression. Our approach allows the quantitative comparison of the diffusional behavior of chromatin state between physiological and perturbed chromatin states.

1096

Differential gene expression of nuclear label-retaining cells in the normal mouse mammary gland.

J. P. Park[1], B. W. Booth[1]; [1]Institute for Biological Interfaces of Engineering, Clemson University, Clemson, SC

Introduction-Somatic stem cells are hypothesized to protect themselves from mutation and subsequent cancer risk through a process of selective segregation of template DNA strands during cell division. In the developing mouse mammary gland these cells can be identified through the incorporation and retention of nucleic acid label during stem cell synthesis associated with pubertal expansion of the gland. These labeled cells are termed label-retaining cells (LRCs) and are present after extended chase periods. The objective of these studies was to identify genes specific to LRCs in the developing mouse mammary gland.
Methods- Immunohistochemistry and PCR arrays were performed on tissue sections and cells respectively collected from murine mammary glands that had been labeled with 5-ethynl-2'-deoxyuridine (EdU) for 2 weeks during allometric ductal growth. The cells that incorporate the nuclear label and maintain the label following a 10-week chase period are termed label-retaining cells (LRCs). A second label, 5-bromodeoxyuridine (5BrdU), was administered 2 hrs before euthanasia to identify cells traversing the cell cycle. Just prior to euthanasia the mice received 5BrdU for 2 hours. Mammary glands were collected at 3 and 6 months of age, dissociated, stained for EdU and 5BrdU and sorted into 4 populations (double negative, EdU-positive, 5BrdU-positive, and double-positive). The RNA was isolated from the 4 populations and PCR-arrays were performed that target know stem cell genes and stem cell pathways.
Results-As determined previously a population of mouse mammary epithelial take up nuclear label and retain this label over an extended chase period with a certain number of these cells continuing to cycle. Our results indicate that genes associated with the Notch and Hedgehog signaling pathways are differentially regulated between LRCs and non-LRCs. Other genes found to be differentially expressed are involved in histone modification, DNA modification, and growth factor cleavage.

1097

Genome-wide Analysis of the Binding Sites of the JIL-1 H3S10 Kinase and its Contribution to Modulation of Gene Expression.

W. Cai[1], C. Wang[1], L. Shen[1], Y. Li[1], S. Liu[2], C. Yao[1], P. S. Schnable[2,3], J. Girton[1], J. Johansen[1], K. M. Johansen[1]; [1]Biochemistry, Biophysics & Molecular Biology, Iowa State University, Ames, IA, [2]Agronomy, Iowa State University, Ames, IA, [3]Data2Bio, LLC

The JIL-1 kinase localizes specifically to euchromatin interband regions of polytene chromosomes and is the kinase responsible for histone H3S10 phosphorylation at interphase in *Drosophila*. Mutational analyses have shown that *JIL-1* is essential for viability and genetic interaction assays with *JIL-1* hypomorphic and null allelic combinations demonstrated that JIL-1 can counterbalance the gene-silencing effect of the three major heterochromatin components Su(var)3-9, Su(var)3-7, and HP1a on position-effect variegation. In order to further determine the interplay between epigenetic chromatin modifications and gene expression, we conducted a genome-wide analysis of JIL-1 kinase binding sites by ChIP-seq and combined it with an analysis of whole genome transcription level changes by RNA-seq in the absence of JIL-1. In

order to have the ability to specifically map and correlate the location of JIL-1 binding sites with the locations of the epigenetic histone H3S10 phosphorylation mark, salivary gland cells from third instar larvae were analyzed. Salivary gland nuclei are all at interphase excluding contributions from mitotic histone H3S10 phosphorylation. We found that most of 1675 identified JIL-1 binding peaks locate around 200 bp upstream of transcription start sites. Furthermore, we compared the transcriptome profiles of salivary glands from wild type and *JIL-1* null mutants by next generation sequencing. Interestingly, in the absence of H3S10 phosphorylation by JIL-1 the expression of 68% of normally active genes (1057 out of 1556) was repressed, whereas the expression of most normally inactive genes (177 out of 181) was activated. Taken together, these observations suggest a model where histone H3S10 phosphorylation may play a dual role in modulating gene expression depending on the state and context of other epigenetic marks, but that H3S10 phosphorylation mainly facilitates gene expression of active genes by maintaining an open chromatin structure at promoter regions by counteracting heterochromatization. Supported by NIH grant GM62916.

1098

A Balance Between the Epigenetic Marks H3S10ph and H3K9me2 Modulates Gene Expression at the w^{m4} Allele in *Drosophila.*

C. Wang[1], W. Cai[1], Y. Li[1], J. Girton[1], J. Johansen[1], K. M. Johansen[1]; [1]Biochemistry, Biophysics & Molecular Biology, Iowa State University, Ames, IA

The JIL-1 kinase is a multidomain protein that localizes specifically to euchromatin interband regions of polytene chromosomes and is the kinase responsible for histone H3S10 phosphorylation at interphase. We have previously presented evidence that a function of the epigenetic histone H3S10ph mark is to antagonize heterochromatization by participating in a dynamic balance between factors promoting repression and activation of gene expression as measured by position-effect variegation (PEV) assays. Here we have tested this model by transgenically expressing various truncated versions of JIL-1, with or without kinase activity, and correlating their effect on PEV with the levels of the H3S10ph and H3K9me2 marks at two reporter genes as determined by ChIP assays. In the pericentric insertion line *118E-10* the level of the H3K9me2 mark at the *hsp70-white* reporter was inversely proportional to the H3S10ph level - with increased levels in the absence of H3S10 phosphorylation and decreased levels with increased levels of the H3S10ph mark. Interestingly, however, *JIL-1* can act either as an enhancer or indirectly as a suppressor of w^{m4} PEV, depending on the precise levels of JIL-1 and H3S10 phosphorylation and the concomitant effects on H3K9me2 distribution. The w^{m4} X chromosome contains an inversion that juxtaposes the euchromatic *white* gene and pericentric heterochromatic sequences. Consequently, Lerach et al. (Genetics, 173:2403, 2006) proposed a model where the suppression of PEV of w^{m4} in strong *JIL-1* hypomorphic backgrounds is due to a reduction in the level of heterochromatic factors at the pericentromeric heterochromatin near the inversion breakpoint site that reduces their potential for heterochromatic spreading and silencing. As predicted by this model the results show that compared to wild-type levels suppression of PEV of w^{m4} is directly correlated with a decrease in the H3K9me2 mark at the *white* gene. Supported by NIH grant GM62916.

1099

The budding yeast Cse4 nucleosome is precisely positioned within the 80-bp Centromere DNA Element II.

K. Krassovsky[1,2], J. Henikoff[1], S. Henikoff[1,3]; [1]FHCRC, Seattle, WA, [2]University of Washington, Seattle, WA, [3]Howard Hughes Medical institute

The centromere is the genetic locus that organizes the proteinaceous kinetochore and is responsible for attachment of the chromosome to the spindle at mitosis and meiosis. In most eukaryotes, the centromere consists of highly repetitive DNA sequences that are occupied by nucleosomes containing the CenH3 histone variant, whereas in budding yeast, an ~120-bp Centromere DNA Element (CDE) that is sufficient for centromere function is occupied by a single CenH3 (Cse4) nucleosome. However, the precise location, structure and composition of this nucleosome has been contested. To address this issue, we mapped yeast centromeric chromatin at single base-pair resolution using micrococcal nuclease (MNase) mapping, chromatin immunoprecipitation and paired-end sequencing. Intact particles containing both Cse4 and H2A are precisely protected from MNase over the entire CDE of all 16 yeast centromeres in both solubilized chromatin and the insoluble kinetochore. Small DNA binding proteins protect CDEI and CDEIII and delimit the centromeric nucleosome particle to the ~80-bp CDEII, enough for only a single DNA wrap. Functional centromeres are immediately flanked by subnucleosome-sized particles, and beyond by well-positioned conventional nucleosomes. Surprisingly, Cse4 overproduction caused genome-wide incorporation of Cse4-containing nucleosomes that wrap as much DNA as octameric particles produced in vitro. Preferential enrichment of these misincorporated nucleosomes at sites of high histone turnover suggests that stabilization of the Cse4 particle with a single DNA wrap at the CDE is necessary for kinetochore maintenance. Our findings reconcile seemingly conflicting observations in previous studies of centromeric nucleosomes.

Nuclear architecture in Caenorhabditis elegans embryos.

T. Cermanova[1,2], C. Lanctôt[3], I. Raška[3]; [1]Institute of Cellular Biology a Pathology, First Faculty of Medicine, Charles University in Prague, Prague, Czech Republic, [2]Institute of Physiology, Academy of Sciences of the Czech Republic, Prague, Czech Republic, [3]Institute of Cellular Biology a Pathology, Czech Republic

Most of the studies in the field of nuclear architecture have been performed either on blood cells or cells in culture. As a result, data on in vivo nuclear architecture is generally lacking. We have therefore initiated a study of nuclear architecture in a widely used model organism, the Caenorhabditis elegans nematode. This small roundworm presents several advantages for such a study, the most significant of which being that it develops according to an invariant cell lineage. The developmental constancy of C.elegans allows 1) to compare nuclear architecture in cells that are rigorously equivalent in terms of history, developmental potential and gene expression profile; and 2) to identify changes in the nucleus associated with lineage commitment and cellular differentiation. Our initial experiments have been aimed at providing a detailed description of nuclear organization and structure in early embryonic cells of C. elegans. Since growth does not occur during the development of this organism, nuclear size diminishes as embryogenesis proceeds. Our investigation focuses on the consequence of this size reduction on the organization of the interchromatin compartment. Preliminary resuls are reported here.

Homologous chromosome interaction after induction of double-strand DNA breakage in G0/G1-phase cells.

M. Gandhi[1], V. Evdokimova[1], Y. E. Nikiforov[2]; [1]University of Pittsburgh, Pittsburgh, PA, [2]Univ Pittsburgh Sch Med, Pittsburgh, PA

Background: The main mechanisms of DNA double strand break repair in vertebrates are believed to be nonhomologous end-joining (NHEJ) in G0/G1-phase cells and homologous recombination in S/G2 cells, where a sister chromatid provides a template for repair. **Methods**: We explored a hypothesis that homologous recombination is more common than previously expected and can occur during the G0/G1 phase, where a homologous chromosome may be used as a template for repair. We used multicolor 3D-FISH with arm-specific paints and cenrtromeric probes and confocal microscopy to analyze the interaction between pairs of homologous chromosomes in both untreated and irradiated (5 Gy) primary cultured human epithelial thyroid cells and fibroblasts. PCNA and cyclin A immunostains were used to define the cell cycle stage. **Results**: The immuno-FISH analysis of six chromosomes (chr. 2, 3, 10, 11, 16, and 17) revealed that 15-26% (mean, 19%) of homologous chromosome pairs in G0/G1-phase cells had spatial contact between reciprocal arms in untreated epithelial cells and fibroblasts. Following exposure to ionizing radiation, the frequency of arm-specific contact between homologous chromosomes doubled to 28-45% (mean, 38%). For comparison, the contact between opposite arms of homologous chromosome (p:q) was close to 1% (range, 0.6-1.6%) for all chromosomes in untreated cells and it remained at the same level after cell irradiation, likely representing a level of random contact. **Conclusions**: The results of this study indicate that in G0/G1-phase human cells homologous chromosomes can make contact which is increased after induction of double strand DNA breaks by radiation. It is conceivable that this process offers homology for homologous recombination to occur during G0/G1 phase of the cell cycle.

Identifying the First Telomerase RNA in a Filamentous Fungus.

P. V. Kuprys[1], T. M. Hauer[1], S. M. Davis[2], D. V. Gonzalez[2], K. E. Kirk[2]; [1]Biology, Lake Forest College, Lake Forest, IL

The ends of eukaryotic chromosomes are protected by nucleoprotein structures termed telomeres, which are synthesized by the essential enzyme, telomerase. We are studying the telomeric components of the *Aspergilli*, as these filamentous fungi have exceptionally short telomeres. A key component of telomerase, the telomerase RNA, has not been identified in any filamentous fungus. The telomerase RNAs from even closely related organisms are highly divergent and thus are difficult to identify through bioinformatics. Since *Aspergillus oryzae* has a particularly long telomeric repeat of 5' TTAGGGTCAACA 3', and we knew the telomerase RNA must contain this sequence as a template to synthesize the telomeres, we were able to identify roughly 20 candidate sequences in the *A. oryzae* genome. Experiments utilizing RT-PCR and PCR have shown that one candidate located on chromosome III is transcribed whereas all other candidates in the genome were not transcribed. The 5' end of this RNA sequence has been identified using RLM-RACE to be at most 301 bp from the start of the template, but the 3' end remains undetermined. Successive experiments using 3' RACE have proved inconclusive indicating that the 3' end of the telomerase RNA could lack a poly(A) tail. Using RT-PCR, we determined that the 3' end is between 1567 and 1775 bp from the template. These results

suggest that the total telomerase RNA length in *A. oryzae* is between 1868 and 2076 bp. The length is plausible as it is similar to the telomerase RNA lengths of yeasts. This suggests that we may have discovered the first telomerase RNA in a filamentous fungus.

Potential Recombinogenic Genes Interact With Each Other At Nanometer Distances In Human Interphase Nuclei.

M. Gandhi[1], Y. Nikiforov[1]; [1]University of Pittsburgh, Pittsburgh, PA

Background: It has been well established that loci which participate in oncogenic rearrangements are non-randomly positioned and close to each other in human cell nuclei. However the actual distance between these loci has never been determined. The phenomenon of Fluorescence Resonance Energy Transfer (FRET) is observed when a donor flourophore is close enough to transfer some of it energy to an acceptor flourophore. The objective of this study was to perform FRET on directly labeled DNA molecules in order to determine the spatial distance between potentially recombinogenic loci. **Methods**: Touch preparations of cells from freshly excised normal human thyroid tissue and TPC1 cell lines were subjected to 3-D fixation to preserve the nuclear architecture and assayed using FISH and confocal microscopy. FRET-SE (sensitized emission) analysis was carried out in 2 donors with 500 nuclei analyzed for each case using Alexa 488-594 donor-acceptor combination. **Results**: To validate the use of FRET-SE in combination with DNA-FISH, TPC1 cell line that harbors the *RET/PTC1* rearrangement with fusion of *RET* and *H4* was used as a positive control. FRET between *RET* and *H4* probes was observed in 96.1% of the analyzed nuclei with mean FRET efficiency value (Eapp) of 14.40% (Donor-Acceptor (DA) distance = 8.15 nm). For the experimental set, touch preparations of normal thyroid cells were subjected to DNA-FISH with probes for *RET* and *H4*, *RET* and *NCOA4,* and *BRAF* and *AKAP9*, which are partners of recurrent chromosomal rearrangements found with different incidence in thyroid cancer. The frequency of probe pairs that showed FRET were as follows: *RET-H4* – 5.31 ± 1.09%, *RET-NCOA4* – 3.57 ± 0.28%, *BRAF-AKAP9* – 1.77 ± 0.01%. Based on the mean Eapp values for each of the probe pairs the DA distances for these probe pairs ranged from 8.61nm to 9.77nm. The FRET frequencies for the probe pairs did not correlate with genomic separation between the loci (r = 0.5355) but correlated with the incidence of respective rearrangements in thyroid tumors (r = 0.9877). **Conclusion**: Using FRET analysis of DNA-FISH preparations, we found that potential recombinogenic genes can be positioned in human interphase nuclei within nanometer distances of each other and the frequency of such a close positioning correlates with the prevalence of respective chromosomal rearrangements in human tumors.

Investigation of the *Drosophila* MAGE gene.

X. Li[1], S. C. Hughes[1,2], R. Wevrick[1]; [1]Department of Medical Genetics, University of Alberta, Edmonton, AB, Canada, [2]Department of Cell Biology, University of Alberta

MAGE (Melanoma antigen) is an expanded gene family in placental mammals. MAGE proteins play important roles in cell cycle regulation and neuronal differentiation. Two MAGE genes, Necdin and MAGEL2, are inactivated in the neurodevelopmental disorder Prader-Willi syndrome, along with other genes. Non-mammalian organisms, including the fruit fly *Drosophila melanogaster*, have a single MAGE gene in their genome. The *Drosophila* MAGE gene (DMAGE) may play a role in cell cycle regulation and cell survival in postembryonic neurogenesis. MAGE proteins are part of a chromosome maintenance complex (SMC5/6) in yeast and human cells. We hypothesize that the *Drosophila* MAGE protein is also part of the *Drosophila* SMC5/6 protein complex that plays a role in maintaining genome stability and

regulating cell cycle. Co-immunoprecipitation and *in vitro* pull-down experiments demonstrate that the DMAGE protein interacts with the NSE4 and the NSE1 subunits of the SMC5/6 complex. Over-expression of DMAGE in flies and a *Drosophila* cell line indicate that DMAGE may arrest cell proliferation. We also generated a null DMAGE *Drosophila* mutant which we tested for sensitivity to selected genotoxic agents. In conclusion, it appears that DMAGE cooperates with the SMC5/6 complex to maintain genome stability and it may also play a role in regulating the cell cycle. We would like to acknowledge the funding from the Cancer Research Society (Canada).

Single molecule dynamics of chromatin fibers.

C. Limouse[1], C. Fuller[2], A. Straight[2], H. Mabuchi[1]; [1]Applied Physics, Stanford University, [2]Biochemistry, Stanford University, Stanford, CA

The first level of genome organization within the eukaryotic nucleus is the wrapping of DNA around histones to form chromatin. Higher order organization and compaction of the chromatin fiber is required to package the genome into the nucleus in interphase and to condense chromosomes for mitotic segregation. Although condensed within the cell, chromatin must remain accessible to the enzymatic machinery that replicates, transcribes, repairs and segregates the genome. Despite extensive work on chromatin and chromosome organization we have an incomplete understanding of the basic physical properties of the chromatin fiber, how those properties influence the dynamics and organization of chromosomes, and how they may be modulated epigenetically. In order to measure the dynamics of chromatin fibers we are applying a new method that enables us track the diffusion of single fluorescently labeled molecules of chromatin in solution. Our tracking method utilizes spatial modulation of a focused laser beam used to excite Cy3b attached covalently to a chromatin fiber, analog demodulation to extract an error signal, and real-time feedback to piezoelectric positioning stages to compensate for Brownian motion. We have been able to monitor the changes in compaction of single chromatin fibers in response to changes in the ionic environment by measuring changes in the diffusion coefficient. Using chromatin fibers with single molecule fluorescent labels we have monitored the association and dissociation kinetics of individual chromatin fibers in solution via quantitative fluorescence measurements, and have begun to study association morphology by studying the dependence of the diffusion coefficient of an aggregate on the number of fibers contained. We are working to characterize the interaction of chromatin molecules in response to changes in ionic strength or chromatin binding proteins, and have begun to explore the use of tracking Fluorescence Correlation Spectroscopy (tFCS) as an improved approach to characterizing mechanical properties of individual aggregates. We are exploring the use of tFCS to characterize conformational fluctuations of individual chromatin fibers and fiber-aggregates on timescales ranging from microseconds to seconds. Unlike traditional methods such as analytical ultracentrifugation that measure the ensemble properties of chromatin in solution, we are able to measure heterogeneous distributions with single-fiber resolution and to characterize the response of individual chromatin fibers to environmental changes. These methods enable us to measure changes in the properties of chromatin in response to DNA sequence, chromatin composition and modification, macromolecular crowding and specific chromatin binding proteins.

Scaling Chromosome Condensation to Cell Size.

A-M. Ladouceur[1], P. Maddox[1]; [1]IRIC, Université de Montréal, Montréal, Québec, Canada

During development or differentiation, cells often change in size. Mechanisms describing how organelles scale their size to the continuously changing size of cells are poorly understood. This problem is well exemplified during embryonic development of organisms like *Caenorhabditis elegans* or *Xenopus laevis*. As a consequence of multiple rounds of cell divisions without changing the size, cells decrease in length by two orders of magnitude (from 1,2 mm to 12 ìm) in *X. laevis*. Using *X. laevis* or *C. elegans* embryos as model organisms, it has been shown that mitotic structures including mitotic spindle length, centrosome size and nucleus size all scale with cell size. Despite these dramatic changes, the genome size is constant in all diploid cells in an organism. In order to facilitate cell division in smaller cells, mitotic chromosomes must increase the degree of condensation throughout development. In *C. elegans* adult worms, the mitotic chromosomes are more condensed in smaller cell then in larger cells. We are using the invariant developmental program of *C. elegans* embryos to investigate how cells adapt the level of chromosome condensation as cell decreases in size. Preliminary results indicate that metaphase plate length scales with cell size. This change in chromosomes condensation could be an outcome of a cellular size control or a programmed developmental change. To test the first hypothesis, we aim to assess the implication of known DNA condensation and cell size scaling factors on scaling of the metaphase plate length to cell size. Key regulators of mitotic chromosome assembly include DNA topoisomerase II, the condensin complexes, histone H1 or post-translational modification of histones such has H3 S10 phosphorylation. A differential recruitment of those factors on mitotic chromosomes could adjust the level of condensation according to cell size. Quantitative immunofluorescence of those factors will be use to evaluate their recruitment on mitotic chromosomes. Previous works have shown that cell size, spindle length and centrosomes size are internally controlled and interdependent. We will test if the size of those structures can affect the length of the metaphase plate by use of RNAi depletion of known proteins required to set the size of those structures. To test the second hypothesis, we are currently optimizing a large-scale screen to identify new genes that would affect the metaphase plate length during development. We aim to deplete known embryonic lethal gene and use time-lapse microscopy to observe mitosis during the development of *C. elegans* embryos. The overall goal of this study is to identify new mechanisms regulating size of organelles.

The Unusual Features of Active Genes on Drosophila melanogaster Chromosome Four: Reinterpreting the Roles of Chromatin Modifications.

S. C. Elgin[1], N. C. Riddle[1], T. Gu[1], Y. L. Jung[2], modENCODE Drosophila Chromatin Consortium[3]; [1]Washington University in St. Louis, St Louis, MO, [2]Harvard Medical School, [3]Lawrence Berkeley National Laboratory, Berkeley, CA

The small fourth (dot) chromosome of *Drosophila melanogaster* exhibits overall characteristics of a heterochromatic domain, including high levels of H3K9me2/3 and HP1a, but contains ~80 genes in its 1.2 Mb distal portion. Mapping of histone modifications and chromosomal proteins in S2 and BG3 cells, as well as several life stages, shows that these genes have unique characteristics, distinctive from active genes in either euchromatin or pericentric heterochromatin. H3K9me2/3 and HP1a are depleted at the TSSs (transcription start sites) of active fourth chromosome genes, which, as expected, are occupied by H3K4me2/3 and RNA pol II. However, POF, HP1a, and H3K9me3 are found at high levels across the gene body. There is no evidence of euchromatin “islands” supporting expression. Reporter sites permissive

for expression appear to be those regulated (in at least some cell types) by the Polycomb system. While fourth chromosome genes exhibit the same range of expression levels as do euchromatic genes, there are few if any associated with a paused polymerase. The continued presence of HP1a and H3K9me3 at active genes results in a shift in association patterns, with H3K9me2 now being unique in its stronger correlation with inactive genes. Depletion of POF results in loss of HP1a from fourth gene bodies, but HP1a continues to be present in the pericentric heterochromatin and at repeat clusters on the fourth, indicating a dual targeting mechanism for HP1a association with the fourth chromosome. These findings challenge our prior interpretations of the role of chromatin structure in gene regulation and focus attention on the modifications at the TSS. Supported by NIH grants U01HG0004258 to GH Karpen and R01 GM068388 to SCRE.

The role of Sir4 in de novo assembly of heterochromatin in budding yeast.

M. Parsons[1], A. D. Rudner[1]; [1]University of Ottawa, Ottawa, ON, Canada

Changes in the locations and boundaries of heterochromatin are critical during development of multicellular organisms, and *de novo* establishment of heterochromatin in budding yeast, *Saccharomyces cerevisiae*, is the best understood example of how these dynamic changes occur in the context of cell cycle progression. Heterochromatin in budding yeast is composed of polymers of the SIR (Silent Information Regulator) complex bound to nucleosomal DNA. Assembly of heterochromatin requires all three proteins of the Sir complex: the histone deacetylase, Sir2 and the histone binding proteins Sir3 and Sir4.

De novo assembly of heterochromatin in budding yeast requires at least one to five cellular divisions. Previous studies have shown that this assembly is not regulated by active DNA replication but by another event that occurs in the S-phase of the cell cycle. Recent work has suggested that the cell cycle inhibition of chromatin modifying enzymes may be the mechanism for how cells limit when they can assemble new sites of heterochromatin.

Halving the levels of Sir4 in cells causes a dramatic loss of silencing at telomeres, and these data have led us to test a simple hypothesis: the abundance of Sir4 protein regulates the assembly of new regions of heterochromatin, and its regulated destruction may prevent this assembly during the G1 phase of the cell cycle.

We are examining *de novo* assembly of heterochromatin using an assay for establishment of a site of heterochromatin in individual cells. Introduction of additional copies of *SIR4* on low copy plasmids leads to a marked increase in the number of cells that are able to establish heterochromatin after only one division. Addition of *SIR4* at high copy number leads to ablation of this effect, while overexpression of Sir4 prevents establishment of heterochromatin. Additionally, halving the amount of *SIR4* decreases the ability of cells to establish new sites of heterochromatin. We are currently testing if the stability of Sir4 changes in G1 and whether changes in Sir4 levels are epistatic to mutations in histone modifying enzymes.

Deciphering the CENP-A nucleosomal structure.

A. Padeganeh[1], A-M. Ladouceur[1], J. Boisvert[1], J. Dorn[1], P. Maddox[1,2]; [1]IRIC, University of Montreal, Montreal, QC, Canada, [2]Pathology and Cell Biology, University of Montreal, Montreal, QC, Canada

Chromosome segregation during mitosis is mediated by the formation of a linkage between centrometic DNA and microtubules that generates force to faithfully distribute them into daughter cells. Defects in centromeres result in aneuploidy, which is considered as a hallmark of cancer and a number of devastating human pathologies such as embryonic implantation

failure. Centromeric regions are defined by nucleosomes containing the histone H3 variant, CENP-A. CENP-A is proposed to act as an epigenetic mark specifying and maintaining centromere identity in each cell division, thus maintaining ploidy. In dividing cells, incorporation of new CENP-A into nucleosomes is not coupled to DNA replication. During S-phase, the CENP-A population is distributed equally between the newly synthesized centromeres of the daughter chromomsomes. After cell division, centromeres are repopulated with CENP-A during G1 in preparation for the subsequent S-phase. During the past few years, there has been much debate over the molecular composition of the CENP-A nucleosomes in respect to the canonical octameric nucleosomes. Our goal is to visualize components of single CENP-A nucleosomes and thereby define structural elements constituting the centromeric nucleosomes. To do this, we developed a total internal reflection fluorescence microscopy (TIRFM) assay coupled to a nucleosome-immunoprecipitation technique to visualize single CENP-A nucleosomes. Nuclei were extracted from HeLa cells stably expressing a CENP-A-YFP fusion, sonicated and perfused into our custom-designed flow chambers. The resultant single-molecule images were analysed by an automated detection software developed by our group and confirmed by manual analysis. Our preliminary observations, confirmed by the two methods, suggest that there is a mixed population of one- and two-CENP-A containing nucleosomes in HeLa cells. By visualizing other key components of centromeric nucleosomes and generating cell cycle staged extracts, our approach will thus help shed light on fundamental aspects of centromere biology.

1110

CENP-A Nucleosome Structure Transits Between Tetramers and Octamers Throughout the Cell Cycle.

M. Bui[1], E. Dimitriadis[1], Y. Dalal[1]; [1]National Institutes of Health, Bethesda, MD

Controversy over the structure of the centromeric CENP-A nucleosome has ignited debate that spans organisms from plants, yeast, flies, and humans. The range of reported structures include octamers, hexamers, and both hetero- and homo-typic tetramers. To reconcile these differences, several have proposed that the centromeric nucleosome transitions between octamers, tetramers, and intermediates (Probst et al, 2009; Dalal and Bui, 2010). We sought to test this hypothesis by synchronizing human cells at Early G1, G1/S, S, and G2/M phases. Utilizing biophysical Atomic Force Microscopy (AFM) and biochemical purifications of CENP-A nucleosomes, we were able to track structural and kinetochore protein dynamics across the cell cycle. Further studies are currently underway to elucidate the mechanistic properties involved in structural transitions, and whether this mechanism is conserved in other organisms.

1111

The Chl1 helicase, Fen1 flap endonuclease and the establishment factor Ctf7/Eco1 interact together to perform a role in cohesion establishment.

S. Rudra[1], R. V. Skibbens[1]; [1]Lehigh University, Bethlehem, PA

The accurate segregation of chromosomes to each daughter cell requires sister chromatid cohesion to maintain the identity of sister chromatids from the time of DNA replication to anaphase onset. The establishment of cohesion involves the acetylation of a cohesion subunit (Smc3) by the establishment factor Ctf7/Eco1 (Unal et al. 2008; Ben-Shahar et al. 2008). Ctf7/Eco1 interacts with a number of replication proteins (RFC complexes, PCNA) and DNA helicases (Chl1) (Kenna and SKibbens, 2003, Moldovan et al. 2003, Skibbens, 2004, Maradeo and Skibbens, 2010); all of which play individual roles in sister chromatid cohesion. The actual mechanism of cohesion establishment is still largely unknown. Here, we provide new evidence from Saccharomyces cerevisiae that Chl1 promotes cohesion establishment through a post-replicative model. Our results show that Chl1 interacts with chromatin under normal conditions,

contrary to previous studies which suggest that Chl1 chromatin recruitment is dependent on DNA damage (Ogiwara et al. 2007). We also show that Chl1 chromatin recruitment is cell cycle regulated. Next, we document novel genetic interactions between CHL1 and FEN1 and also between CTF7/ECO1 and FEN1. Subsequent co-immunoprecipitation studies further reveal that Chl1 physically interacts with Fen1. Preliminary results also show that Fen1 physically interacts with Ctf7/Eco1. These observations provide strong evidence in support of a post replicative model of cohesion establishment, wherein lagging strand processing events are coupled to the process of cohesion establishment. We speculate that the post replicative events help establish cohesion by either enhancing the acetyl-transferase activity of Ctf7/Eco1 or making the cohesin subunits more accessible to Ctf7/Eco1 dependent acetylation. Taken together, our study reveals important information that for the first time directly links the process of cohesion establishment to post replicative events.

Mitosis and Meiosis II

1112

Consequences of a prolonged mitosis.

L. Krenning[1], R. H. Medema[1]; [1]Netherlands Cancer Institute, Amsterdam, Netherlands

During mitosis, the replicated genome is segregated into the two daughter cells. Microtubules emanating from opposing spindle poles attach to the DNA through kinetochores, allowing sister chromatids to be pulled to opposite sides of the cell. Attachment occurs at random such that many incorrect microtubule-kinetochore attachments can occur during the early stages of mitosis that can potentially lead to incorrect segregation of sister chromatids. The spindle assembly checkpoint senses these incorrect attachments and provides time for the correction of these attachments by preventing mitotic progression until all attachments are corrected. Nonetheless, some incorrect attachments may not be sensed by the SAC, causing sister chromatids to segregate incorrectly. Recently, evidence was presented for the existence of an additional checkpoint that could restrict the proliferative capacity of cells that were generated from a “problematic” mitosis as the duration of mitosis itself determines the proliferative capacity of the daughter cells (Uetake and Sluder, 2010). This could provide a means by which cells that have encountered problems during mitosis and therefore might have spent more time in mitosis than normal, can be excluded from the cell cycle.

The aim of our research is to elucidate the mechanisms involved in the timing of mitosis that dictate the proliferative capacity of daughter cells. In order to biochemically assess the mechanisms involved in the G1 arrest we developed an experimental setup that allows us to investigate the events during mitosis and the subsequent G1 phase that are involved in arresting the cells. We have observed an increase in mitotic p53 protein level, when cells are trapped in mitosis for a prolonged period of time. Moreover, daughter cells originating from a prolonged mitosis show increased p53 protein levels whereas daughter cells originating from a normal mitosis do not. The increase of mitotic p53 levels seems to be translation dependent.

Analysis of sororin phosphorylation and dephosphorylation.

M. R. Dreier[1], W. R. Taylor[1]; [1]Biological Sciences, The University of Toledo, Toledo, OH

Cell cycle control mechanisms are altered in cancer cells, often leading to chromosomal instability; however, these mechanisms are not fully characterized. Cohesin, a protein complex consisting of Smc1, Smc3, Scc1, and Scc3, protects sister chromatids from separating at inappropriate times. In addition, certain accessory proteins to cohesin, such as sororin, are required for cohesion maintenance. Cdk1-mediated phosphorylation of sororin regulates sister chromatid cohesion. These results were obtained by mutating nine Cdk1 consensus sites to alanine to create sororin-9A. Through co-immunoprecipitations, chromosome drops, and localization studies, we were able to show that sororin-9A stays bound to chromatin throughout mitosis, while sororin-WT is removed at prometaphase. Next, we generated glutamic acid mutations to create sororin-9E. We co-transfected HeLa M cells with shRNA sororin and sororin-9E and quantified the mitotic index. As expected, knocking down sororin increased the mitotic index, likely as a result of activation of the spindle assembly checkpoint. Surprisingly, sororin-9E was able to rescue the mitotic block caused by shRNA sororin. Interestingly, Nishiyama et al. (2010) demonstrated that sororin binds to PDS5, an accessory protein to cohesin, through an FGF motif. We therefore mutated the FGF motif in sororin-9A to AGA, co-transfected HeLa M cells with shRNA sororin and the sororin-9A AGA mutant and quantified the mitotic index. We expected cells to be blocked in mitosis because sororin is theoretically no longer able to bind to PDS5, thereby activating the spindle assembly checkpoint; however, the sororin-9A AGA mutant behaved like wild-type sororin. These results suggest that sororin has an additional binding partner to PDS5. Even though we have identified the kinase responsible for phosphorylating sororin, the phosphatase that dephosphorylates sororin remains elusive. Sororin is known to be dephosphorylated by four hours after nocodazole release (Rankin et al., 2005). Okadaic acid, an inhibitor of PP2A, delayed the dephosphorylation of Sororin-WT upon nocodazole release; suggesting that PP2A or another okadaic acid-sensitive phosphatase targets sororin for dephosphorylation upon mitotic exit. Future experiments will be to determine the other protein or proteins that bind to sororin and confirm that the phosphatase is PP2A. From these experiments we hope to fully characterize the roles of phosphorylation and dephosphorylation in sororin regulation.

1114

Structural Basis of Interaction between Human Survivin and N-terminus Histone H3 Phosphorylated on Threonine 3.

E. Niedzialkowska[1,2], W. Minor[2], J. Higgins[3], T. Stukenberg[1]; [1]Department of Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA, [2]Department of Molecular Physiology and Biological Physics, University of Virginia, Charlottesville, VA, [3]Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital, Harvard Medical School, Boston, MA

A four-protein complex known as chromosome passenger complex (CPC) is a central regulator of mitosis. The proper regulation of chromosome segregation requires the positioning of the CPC to the inner centromere, which is a region on mitotic chromosomes between kinetochores. We have recently shown that this inner centromere localization is mediated by the survivin subunit of the CPC complex, which binds to the N-terminal tail of histone H3 that has been phosphorylated on Thr3 by the Haspin kinase.
Here we used X-ray crystallography to characterize molecular-level interactions between human survivin and the N-terminus histone H3 phosphorylated on Thr3. Our crystal structure of wild-type survivin complexed with the N-terminus of histone H3 phosphorylated on Thr3 revealed that the histone tail binds to the surface of the BIR domain and the phosphorous group of H3-

Thr3 is bound by His80 and Lys62 from this domain. Survivin Glu65 binds the side chain of Arg2 of the tail and Asp71 recognizes the N-terminal Ala1 in a hydrophobic pocket formed by Leu64, Glu76 and Trp67. Survivin point mutants at either His80Ala, Glu65Ala and Lys62Ala bind the phosphorylated histone tail poorly as measured by isothermal titration calorimetry, which confirms the importance of these amino acids to histone tail binding. When a 12mer histone tail peptide was co-crystalized, only the N-terminal four residues were ordered.
The determined structure of wild-type survivin with bound histone H3 demonstrates how the phosphorylation mark on Thr3 can be recognized by survivin and is an another example of how BIR domains recognize the N-terminal residues of proteins.

1115

Localization determinants in the carboxy-terminal region of human Topoisomerase IIα.

A. B. Lane[1], D. J. Clarke[1]; [1]Department of Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN

It is not known how the essential enzyme DNA topoisomerase IIα becomes localized to condensed chromosomes in mitosis. Here we define primary sequence features in the enzyme's carboxy terminal region (CTR) that are critical for this function. Consistent with previous reports we find that two regions of the CTR have nuclear localization signal (NLS) activity required for nuclear import of TopoIIα. Unexpectedly, we find that NLS elements are required for the localization of TopoIIα to mitotic chromosomes. Along with the hKid chromokinesin, this is a second example of NLS-dependent chromosome targeting, indicating that this may be a general mechanism in mitotic cells. We show that neither nuclear localization during interphase nor passage through nuclear pores is required for the targeting of TopoIIα to mitotic chromosomes. Therefore, nuclear import *per se* is not strictly coupled to the mechanism of mitotic chromosome targeting. Furthermore, the NLS elements are not sufficient for chromosome targeting: we identify a third essential domain in the CTR of the enzyme (here named the TDT domain: TopoIIα DNA Tether) that binds directly to DNA and without which TopoIIα chromosome localization is compromised. Unlike the NLS elements, the TDT in isolation is sufficient for chromosome localization. Finally, we have examined the significance of these features using a novel knockdown/rescue assay in HeLa cells. The data presented characterize an unexpected relationship between nuclear localization sequences and chromosome binding which is entirely dependent on the C-terminus of TopoIIα, and provides mechanistic insight into how the enzyme is localized to mitotic chromosome where it performs its essential activity in sister chromatid resolution.

1116

Investigating the Role of Spindle-Associated F-actin in Mitotic Spindle Structure and Function.

A. Kita[1], W. Bement[1,2]; [1]Program in Cellular and Molecular Biology, University of Wisconsin, Madison, Madison, WI, [2]Zoology Department, University of Wisconsin, Madison

Mitotic spindles are microtubule-based structures responsible for partitioning genetic information into each new daughter cell. The role of microtubules and microtubule-associated proteins in this process has been well characterized, however whether or not F-actin is required—or is even present--within the spindle has long been controversial. In this work we examine spindle-associated F-actin in the intact Xenopus laevis epithelium. Immunofluorence of labeled phalloidin revealed F-actin at spindle poles, F-actin cables extending from poles towards the cortex, and F-actin cables spanning between poles within the spindle. Similar localization patterns are detected with gamma-actin antibodies. Live imaging experiments corroborated these results and highlighted the dynamic nature of these actin cables as they move within and

around the spindle throughout mitosis. In addition, treatment with the Arp2/3 complex inhibitor CK-666 resulted in a loss of cortical F-actin, while spindle-associated F-actin and mitotic spindle structure remained intact. Collectively, these results show that a) mitotic spindles in intact vertebrate epithelia contain a substantial amount of F-actin cables; b) these cables form coincident with spindle assembly, and; c) spindle F-actin, rather than cortical F-actin, may be essential for proper mitotic spindle structure and function.

1117

Microtubules search for lost kinetochores by pivoting around the spindle pole.

D. Ramunno-Johnson[1], I. Kalinina[1], A. Nandi[2], A. Krull[1], B. Lindner[2], N. Pavin[1,3], I. Tolic-Nørrelykke[2]; [1]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, [2]Max Planck Institute for the Physics of Complex Systems, [3]University of Zagreb

During cell division, proper segregation of genetic material between the two daughter cells requires that the spindle microtubules attach to the chromosomes via kinetochores, protein complexes on the chromosome. In fission yeast, kinetochore capture by microtubules can be observed when kinetochores are lost in the nucleoplasm, which can be induced by spindle disassembly during metaphase. It is, however, unknown how microtubules find lost kinetochores. We observed that lost kinetochores are captured by microtubules pivoting around the spindle pole body, instead of extending towards the kinetochores. By introducing a theoretical model, we show that the observed random movement of microtubules is sufficient to explain the process of kinetochore capture. We thus reveal a mechanism where microtubules explore space by pivoting, as they search for intracellular targets.

1118

Checkpoint-independent stabilization of kinetochore-microtubule attachments by Mad2 in human cells.

L. Kabeche[1], D. Compton[1]; [1]Biochemistry, Dartmouth Medical School, Hanover, NH

Faithful chromosome segregation is required for cell and organism viability, and is lost in solid tumors with aneuploid karyotypes that display chromosomal instability (CIN). Mitotic fidelity in normal cells in ensured through two mechanisms: the spindle assembly checkpoint (SAC) and the cellular mechanism that corrects errors in kinetochore microtubule attachments (k-MT). The SAC prevents anaphase onset until all chromosomes attach to spindle microtubules, and provides time for the correction of k-MT attachment errors that arise in prometaphase. Mad2 is essential for SAC function and is frequently overexpressed in tumor cells where it increases the frequency of lagging chromosomes in anaphase. We have previously shown that cancers cells with CIN have hyperstable k-MT attachments and fail to efficiently correct k-MT attachment errors elevating the frequency of lagging chromosomes in anaphase. This suggests a role for Mad2 in regulating the stability of k-MT attachments. To address this we manipulated the cellular levels of Mad2 and used fluorescence dissipation after photoactivation to measure k-MT stability in human normal diploid RPE-1 cells. We show that k-MT attachments are destabilized by Mad2 depletion and hyperstabilized by Mad2 overexpression in both prometaphase and metaphase cells. The consequence of hyperstabilized k-MT attachments induced by Mad2 overexpression is the persistence of k-MT attachment errors manifest by lagging chromosomes in anaphase, an effect that can be rescued by increasing the k-MT turnover rate by expression of the kinesin-13 MCAK. These effects on k-MT attachment stability are independent of the mitotic checkpoint because k-MT attachment stability is unaltered upon Mad1 depletion and Mad2 overexpression hyperstabilizes k-MT attachments in Mad1-deficient cells. Mad2 mediates these effects by altering the centromeric quantity and activity of Aurora B, a kinase known to regulate k-MT attachment stability. Thus, Mad2 acts independently of the checkpoint to stabilize

k-MT attachments generating a positive feedback loop for checkpoint satisfaction by driving microtubule occupancy at kinetochores.

1119

The Kif18A chromosome alignment mechanism differentially affects mitotic progression among human cells.

A. S. Gayek[1], R. Ohi[1]; [1]Department of Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

During cell division, the kinesin-8 Kif18A regulates kinetochore-microtubule plus-end dynamics to drive metaphase chromosome alignment. Studies thus far suggest that Kif18A is essential in human cells: HeLa cells depleted of Kif18A exhibit a robust, spindle assembly checkpoint (SAC)-dependent arrest. Strikingly, we found that non-transformed euploid RPE-1 cells do not arrest in mitosis when siRNA-depleted of Kif18A despite exhibiting a defect in chromosome positioning prior to anaphase onset. To determine the extent to which this interline variation occurs, we used RNAi to deplete Kif18A from a panel of twelve transformed and nontransformed human cell lines, and gauged mitotic arrest by an increase in mitotic index. Cell lines showed a range of responses, from strong arrest to no arrest despite a sharp decrease in Kif18A levels as gauged by immunofluorescence. Arrest correlated with SAC signaling: HeLa cells showed an increase in kinetochore-localized Mad1 puncta when depleted of Kif18A, whereas RPE-1 cells did not. Consistent with this observation, the intrakinetochore distance (delta) in Kif18A-depleted HeLa cells was systematically reduced compared to Kif18A-depleted RPE-1 cells. Kif18A is required for normal metaphase chromosome alignment in cells which do not depend on it for mitotic exit: Kif18A-depleted RPE-1 cells initiate anaphase without first achieving tight metaphase chromosome alignment. Surprisingly, despite a defect in chromosome mis-alignment, we did not observe a strong increase in kinetochore oscillation amplitude (DAP, deviation from the average position) in Kif18A-depleted RPE-1 cells. In conclusion, we have found that some tissue culture cell lines satisfy the SAC and exit mitosis despite depletion of Kif18A and a lack of proper metaphase chromosome alignment. The cellular characteristics that underlie a dependence on Kif18A are currently under study.

1120

P21- activated kinase 4 (PAK4) is required for metaphase spindle positioning and anchoring.

G. Bompard[1], G. Rabeharivelo[1], J. Cau[2], A. Abrieu[1], C. Delsert[1,3], N. Morin[1]; [1]CRBM, CNRS UMR5237, Montpellier, France, [2]MRI, CNRS, [3]LGP, IFREMER

The oncogenic kinase PAK4 was recently involved in the regulation of G1 and G2/M phases of the cell cycle. We also identify that PAK4 regulates Ran GTPase activity during mitosis. Here, we show that, PAK4 depleted cells enter mitosis and maintain a prolonged metaphase like state. In these cells, chromosome congression to the metaphase plate occurs with normal kinetics but is followed by an extended period during which membrane blebbing and spindle rotation are observed. We find that bipolar PAK4 depleted metaphase like spindles have a defective astral MTs network that likely prevent efficient spindle anchoring and proper spindle tension. As a result, the mitotic spindles are not centered in the cell but in close contact with the cell cortex, centrosome fragmentation occurs, a subset of chromosomes detach from the metaphase plate and move toward the spindle poles inducing a scattered chromosome phenotype with active spindle checkpoint (SAC).

PAK4 regulates the acto-myosin cytoskeleton dynamics and we report that PAK4 depletion results in the induction of cortical membrane blebbing during prometaphase arrest. However, we show that membrane blebs that are strongly enriched in phospho-cofilin are not responsible for

the poor anchoring of the spindle. Since PAK4 depletion interferes with proper localization of components of the dynein dynactin complexes, we propose that PAK4 deletion mediated mitotic defects could reflect a loss of the activity of the motor protein.

1121

Function of protein 4.1R in mitotic spindle orientation.

N. Ma[1], P. Wadsworth[2], E. J. Benz Jr.[1], S-C. Huang[1]; [1]Medical Oncology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA, [2]Biology Department, University of Massachusetts Amherst

Protein 4.1R, originally characterized as a crucial membrane skeletal protein in mature red cells, plays an important role in cell division during mitosis. Biochemical studies have revealed that 4.1R binds to microtubules, stabilizes the spectrin-actin network and anchors it to the plasma membrane, and directly interacts with the large nuclear mitotic apparatus NuMA protein, suggesting that 4.1R plays diverse roles within the cytoskeleton. However, the importance of the interaction between 4.1R and cytoskeletal proteins is still unclear. Here, we show that 4.1R contributes to kinetochore-microtubule attachments, spindle organization and orientation. During mitosis, 4.1R is accumulates in the cell cortex at the end of retraction fibers, and is localized throughout the spindles and spindle midzone. Depletion of 4.1R by RNA interference induced mitotic delay and defects in retraction fiber formation, chromosome alignment, spindle assembly and spindle orientation. Spindle misorientation is linked to unstable astral microtubules and suppressed by the restoration of 4.1R in 4.1R-depleted cells. 4.1R depletion mislocalized the p150Glued subunit of dynactin and NuMA. Our data support a model in which 4.1R recruits NuMA at cell cortex, which provides link between cell cortex and the force generator dynein, to regulate spindle orientation during mitosis.

1122

The spindle assembly checkpoint fails to monitor the lack of tension on few kinetochores in meiosis I mouse oocytes.

A. Kolano[1], S. Brunet[1], A. Silk[2], D. Cleveland[3], M. Verlhac[1]; [1]CIRB, Collège de France, Paris, France, [2]Oregon Health and Science University, [3]Ludwig Institute for Cancer Research and Department of Cellular and Molecular Medicine

Chromosome segregation in female meiosis I is unusual in that the acentrosomal meiotic spindle poles are not anchored via astral microtubules to the cortex. By Cre recombinase-mediated removal in oocytes of the portion of the gene encoding the microtubule binding site of NuMA, implicated previously in anchoring microtubules at poles in concert with cytoplasmic dynein, we determine that without functional NuMA microtubules lose connection to meiosis I spindle poles, resulting in highly disorganized early spindle assembly. Subsequently, very long spindles form with hyperfocused poles. The kinetochores of homologs make stable attachments to microtubules in these spindles, but with reduced tension and accompanied by alignment defects. Despite this, the spindle assembly checkpoint is not activated and advance to anaphase I and first polar body extrusion take place without delay. Females without functional NuMA in oocytes are hypofertile, producing aneuploid eggs with altered chromosome number for one or more chromosomes. These findings establish that in mammalian meiosis I the spindle assembly checkpoint is weaker than in mitosis, with one or a few misattached kinetochores unable to sustain meiotic arrest and offering an explanation for why meiosis I in mammals is so error prone.

1123

Dalek: A mammalian outer nuclear envelope protein required for early meiotic progression in mice.

D. Kim[1], H. Horn[2], C. Stewart[2], B. Burke[2], K. Roux[1]; [1]Children's Health Research Center, Sanford Research/USD, Sioux Falls, SD, [2]Institute of Medical Biology, Singapore

The nuclear envelope has a specialized role in early meiotic prophase I. Chromosomes attach to the surface of the nuclear envelope (NE) through interactions with inner nuclear membrane SUN-domain proteins. These SUN-domain proteins interact lumenally with outer nuclear membrane KASH domain proteins that associate with cytoskeletal constituents, including the dynein motor complex. The primary purpose of this specialized structure appears to involve the translocation of meiotic chromosomes during the process of homolog pairing, synapsis and/or recombination. Meiotic KASH and SUN constituents have been functionally characterized in a variety of model organisms; however, in mammals only the SUN-domain protein Sun1 has been identified. Here we describe the identification and characterization of Dalek, a mammalian KASH domain protein expressed in early meiotic germ cells where it is detected at the NE-chromosome attachment site, coincident with telomeres and Sun1. We can demonstrate that Dalek interacts with the cytoplasmic dynein motor complex, which is colocalized with Dalek at the NE-chromosome attachment sites during early meiosis. Loss of Dalek in homozygous gene-deleted mice leads to sterility, diminished gonad size, and meiotic germ cell arrest. These studies support our overall hypothesis that Dalek is the mammalian KASH-domain protein required for active movement of chromosomes during early meiotic prophase I.

1124

Maternally-recruited Aurora C kinase is more stable than Aurora B to support mouse oocyte maturation and early development.

O. Davydenko[1], K. Schindler[1], B. Fram[1], R. Schultz[1], M. Lampson[1]; [1]Department of Biology, University of Pennsylvania, Philadelphia, PA

Oocytes express meiosis-specific forms of many proteins required for maturation, including proteins that function in cell division such as WEE1B, REC8, and Aurora kinase C (AURKC). AURKC is a germ cell specific member of the conserved Aurora kinase family, and is most similar to the ubiquitously expressed AURKB. Because of their similarity, the significance of AURKC is unclear. AURKB is degraded in mitotic cell divisions and contains destruction motifs that AURKC lacks, suggesting that differential stability underlies the requirement for AURKC. Here we show that endogenous AURKB protein decreases during maturation while AURKC increases. Using fluorescently-tagged reporter proteins, we find that AURKB is gradually degraded while AURKC is more stable. The increase in AURKC reflects a maturation-associated recruitment of *Aurkc* mRNA. *Aurkb* is not transcribed until the blastocyst stage, which suggests that AURKC compensates for loss of AURKB during maturation and early development. Consistent with this model, we find that female *Aurkc*$^{-/-}$ mice are subfertile. Oocytes from these mice take longer to undergo anaphase I and have a higher incidence of abnormal chromosome configurations. Moreover, when isolated from knockout mice, fewer *in vitro*-cultured embryos develop to the blastocyst stage. In contrast to its centromere localization in wild-type oocytes, AURKB mimics AURKC localization on chromatin in mutant oocytes, suggesting that AURKB and AURKC have similar functions. Taken together, our results provide an explanation for the existence of AURKC in oocytes based on both message recruitment and protein stability.

1125

MPF and MAPK are required for inhibiting premature destruction of the APC D-box substrates in mouse oocytes.

I. NABTI[1], J. Carroll[2]; [1]University College London, London, United Kingdom, [2]University College London, United Kingdom

In meiosis and mitosis, APC^{cdc20} ubiquitinates securin and cyclin B1 to induce anaphase onset and exit from M-phase. More recently, it has been shown that APC^{cdh1} is required for maintaining prophase I arrest by suppressing the levels of cyclin B1. Moreover, during prometaphase I, APC^{cdh1} degrades Cdc20 thereby delaying the onset of APC^{cdc20} activity and the onset of anaphase. However, in contrast to mitosis, the meiotic mechanisms of APCregulation are as yet unexplored, especially during the prolonged prometaphase I.

Here we show that inhibition of MPF and MAPK, but not either one alone, using roscovitine and UO126, respectively, induces premature decrease in the levels of the APC D-box substrates during prometaphase of meiosis I. This effect could be rescued using the proteasome inhibitor MG132, indicating that the decrease is due to a premature targeted destruction. These results suggest that the activity of MPF and MAPK is required for the stability and accumulation of the APC D-box substrates during prometaphase I. Ongoing work is set to explore the mechanisms behind such premature instability upon the inhibition of MPF and MAPK activities.

1126

Efficient siRNA-mediated gene silencing in mouse oocytes by long-term follicle culture.

A. Metchat[1], M. Freudzon[2], J. Ellenberg[1]; [1]Cell Biology and Biophysics, EMBL, Heidelberg, Germany, [2]Yale university

Accurate chromosome segregation during oocyte meiosis is fundamental for fertility and normal development of the early embryo. In most animals, and importantly mammals and humans, the first meiotic division is extremely asymmetric to retain the maternally deposited storage proteins and RNA required by the early embryo in the oocyte. The mechanisms of asymmetric mammalian meiosis and chromosome segregation are molecularly not understood and require robust molecular loss-of-function approaches. Mouse oocytes are the experimentally accessible model system closest to human physiology. Although female germ line specific conditional knockout strategies exist and have been employed successfully in the past to identify regulators of meiosis, this approach is very time consuming and thus effectively limits loss-of-function analysis to a few genes.

Therefore, we established a new and simple approach to study gene function in mouse oocytes, by knocking down genes during oocyte growth in long-term follicle culture. siRNA microinjection into early preantral follicle-enclosed oocytes isolated from 12-day old mice followed by eight day in vitro culture leads to efficient knock down of the targeted genes in fully grown maturation competent oocytes. Importantly, this includes genes with abundant and stable maternally deposited protein products that can no longer be silenced in fully grown oocytes. We demonstrate the validity of our method with three genes involved in meiotic cell division: Polo like kinase 1 (Plk1), Cenp-c and Formin2 (Fmn-2). Using our rapid silencing method, we observed defects in asymmetric spindle migration (Fmn2) or chromosome segregation (Plk1 and Cenp-c) that are in agreement with previous reports from knock-out mice. Our robust method allows us to rapidly inactivate even highly expressed and stable gene products and thereby provides us with a tool to study gene function in mammalian oocyte maturation in an efficient and reliable manner. This method will be invaluable to unravel the molecular mechanism of the first asymmetric meiotic division in mouse oocytes.

1127

Mitotic cell rounding is essential for proper spindle assembly.

M. Le Berre[1], D. Bonazzi[1], V. Magidson[2], A. Khodjakov[2], M. Piel[1]; [1]Institut Curie, Paris, France, [2]Wadsworth Center

In the vast majority of described cases, animal somatic cells round up as they get in mitosis. When cells are in a dense tissue, like an epithelium or a tumor, they are able to deform their neighbors to achieve a nearly perfect spherical shape. Several studies have investigated the molecular and structural changes related to mitotic rounding, but the function of this drastic change in shape is still unknown. Many cultured animal cells display a similar mitotic rounding behavior, interphase cells being often only a few microns high (typically 5 to 7 µm), while spherical mitotic cells can reach up to 20 µm above the culture substrate. We developed a device to precisely control the distance between two surfaces, one bearing cultured cells and the other being made of a material of controlled stiffness. Cells were able to deform ceilings of up to a few kPa while rounding up, which is a typical tissue stiffness. But for harder ceiling (above 10 kPa), they were prevented from rounding and displayed spindle orientation and spindle assembly defects. Using hard ceilings, we precisely varied the spacing. When the ceiling was at 10 µm, spindle orientation was lost but division was normal. Leaving even less place for cell rounding lead to formation of abnormal spindles: normal bipolar mitotic spindles would first form but spindle poles would eventually break before all chromosome had congressed, leading to mutlipolar spindles, mitotic catastrophe and eventually death of cells attempting to divide. We then tried to understand why mitotic spindle assembly is affected by space limitation. Studying in more details chromosome congression in mitotic cell prevented from rounding, we observed that chromosome capture and bi-orientation was strongly affected, leading to chromosomes detaching from the metaphase plate, eventually forming ectopic poles. A model for efficient kinetochore bi-orientation was recently proposed by A. Khodjakov and A. Mogilner, stating that initial chromosome organization in a 'rable star' conformation was essential. Lack of space would thus prevent such a spatial organization of prometaphase chromosomes, leading to mono-oriented kinetochores, or even synthelic attachments. When the delay in kinetochore capture was too long, unattached kinetochores would nucleate their own microtubule fibers, eventually leading to formation of ectopic spindle poles. These results lead us to propose the following working model: mitotic cell rounding would allow cells to push their neighbors and thus to protect the space in which the mitotic spindle is assembled, in order to accurately segregate their chromosomes. In addition, our assay might allow us to discover the precise mechanism by which cells are able to round up when confined by a soft material. We could show that affecting cell rounding mechanism would induce death of cells attempting to divide under a soft material, while either control cells under similar constrain, or cells treated but not confined would divide normally. Cancer cells might be even more sensitive than normal cells to defects in rounding as they often have more chromosomes and are growing in a stiffer environment, suggesting that targeting mitotic cell rounding could be a potent anti –tumor approach.

1128

Reorganization of spatial-temporal dynamics of Eg5 in the mitotic spindle requires TPX2 and dynein.

A. Gable[1], M. Qiu[2], J. Titus[1], S. Balchand[1], C. Fagerstrom[1], J. L. Ross[1], N. P. Ferenz[1], N. Ma[3], G. Yang[2], P. Wadsworth[1]; [1]Department of Biology, University of Massachusetts, Amherst, MA, [2]Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, [3]Dana Farber Cancer Institute, Amherst, MA

The homotetrameric plus-end directed kinesin-5, Eg5, cross-links and slides antiparallel microtubules and is required for centrosome separation during spindle formation. Eg5 localizes to spindle microtubules and is enriched at spindle poles. How the spatial and temporal distribution of Eg5 is regulated throughout mitosis is not established. To address this, we used fluorescence recovery after photobleaching (FRAP) and total internal reflection fluorescence (TIRF) microscopy. GFP^{LAP} tagged Eg5 was expressed from a mouse bacterial artificial chromosome (BAC) under the control of the endogenous promoter. Using the S-peptide in the LAP tag we show that GFP^{LAP} -Eg5 and endogenous Eg5 interact in cells, and that GFP^{LAP}-Eg5 co-localizes with endogenous Eg5 throughout mitosis. FRAP experiments show that GFP^{LAP}-Eg5 is highly dynamic with a recovery half-time < 10 sec in the half-spindle of prometaphase, metaphase and anaphase cells. To gain additional insight into the behavior of Eg5, we used TIRF microscopy. Fluorescent punctae of GFP^{LAP}-Eg5 were highly dynamic and maximum intensity projections of time series of images showed that the punctae aligned along linear tracks. Automated particle tracking showed that most punctae had dwell times less than 0.2 sec. Plots of mean displacement for punctae on astral microtubules showed minus-end directed motion during metaphase; in anaphase cells motion was directed toward microtubule plus-ends. On interzonal microtubules, punctae showed diffusive or transiently directed behavior, and the mean displacement was less than that observed on astral microtubules. Following inhibition of dynein with CC1, minus-end directed motion of Eg5 on astral microtubules was reduced; depletion of TPX2, which interacts with Eg5, resulted in plus-end directed motion on astral microtubules in metaphase cells. However, Eg5 motion on interzonal microtubules was not changed by these treatments. Our results show that Eg5 is highly dynamic on spindle microtubules; that poleward transport requires dynein and TPX2.

1129

How Physical Confinement Regulates Spindle Assembly and Size.

M. C. Good[1], M. Vahey[2], R. Heald[1]; [1]Cell and Developmental Biology, UC Berkeley, Berkeley, CA, [2]Bioengineering, UC Berkeley

A fundamental question in biology is how large intracellular structures, such as the mitotic spindle, can assemble and function across the broad range of cell sizes in the embryo . This problem has been difficult to address since no single tissue culture system exists that can generate large quantities of cells spanning the range of eukaryotic cell sizes (from 10 to 1000 microns in length). Our objective was to create cell-like compartments in vitro to probe whether physical confinement can directly control steady-state spindle length. We used a combination of *Xenopus* egg extract systems, which can cycle and self-assemble spindles in vitro, and a number of techniques for encapsulation (extract droplets, giant unilamellar vesicles filled with cytoplasm, and PDMS chambers), to create artificial cells of varying size, each with the ability to generate a functional spindle. Preliminary results demonstrate that the *Xenopus* spindles can sense and respond to the size of the environment they assemble in. These findings suggest that at least partial spindle scaling can occur independently from developmental regulation.

1130

Kif18A Accumulation at the Microtubule Plus-End Modulates Destabilization Activity.

L. N. Weaver[1,2], M. Gardner[2,3], S. L. Shaw[1], C. E. Walczak[1]; [1]Indiana University, Bloomington, IN, [2]MBL Physiology Course, Woods Hole, MA, [3]University of Minnesota

The mitotic spindle maintains a constant length and size despite the constant switching of the spindle microtubules (MTs) between states of polymerization and depolymerization. Members of the Kinesin-8 family are important for chromosome positioning and for regulation of spindle length. The human Kinesin-8, Kif18A, is a plus-end directed motor that could act either as a plus-end MT depolymerase or as a plus-end capping protein. To determine the mechanism that Kif18A uses to regulate spindle length, we expressed a series of GFP-tagged Kif18A domain constructs in HeLa cells. We found that Kif18A has an ATP-independent MT binding site at the C-terminal end of the tail domain that is important for proper localization of the protein. Overexpression of a construct lacking this region abolishes plus end accumulation of Kif18A and its ability to regulate spindle length. To explore how a depolymerase or a capping protein could promote MT destabilization, we used a Monte Carlo simulation to ask how changing the motor's motility or binding properties would affect MT length distributions. Our modeling predicts that both fast motility and retention at the MT plus end are important for MT destabilization activity. In addition, our simulations suggest that a depolymerase and a capping protein can use very different underlying mechanisms to generate nearly identical effects on MT length distribution. We are currently testing our model-based hypothesis for how the additional MT binding site in the Kif18A tail affects its ability to destabilize a dynamic population of MTs *in vitro*. Together our data highlight the complex control of MT dynamics necessary for controlling proper spindle morphology.

1131

Nucleation and Transport Organize Microtubules in the Meiotic Spindle.

J. Brugués[1], V. Nuzzo[1], E. Mazur[1], D. Needleman[1]; [1]Harvard University, Cambridge, MA

Spindles are arrays of microtubules that segregate chromosomes during cell division. It has been difficult to distinguish between different models of spindle assembly due to a lack of information on the organization of microtubules in these structures. Here we present a novel method, based on localized laser ablation and high resolution imaging, capable of measuring the detailed architecture of spindles and find that microtubules are shortest near poles and become progressively longer towards the center of the spindle. These data, in combination with biochemical perturbations and mathematical modeling, is sufficient to reject previously proposed models of spindle assembly. Our results support a new model of spindle assembly in which microtubule polymerization dynamics are not spatially regulated, microtubule transport locally sorts microtubules — determining their proper organization in the spindle without moving them appreciable distances —, and the length of the spindle is largely controlled by the profile of microtubule nucleation.

1132

Tropomyosin 4, actin binding protein, contributes to the proper spindle orientation during mitosis and meiosis.

N. Tokai-Nishizumi[1], M. Ohsugi[1], T. Yamamoto[1]; [1]Division of Oncology, Institute of Medical Science, University of Tokyo, Minato-ku, Japan

The network of actin filaments participates in the dynamic regulation of mitotic cellular functions, including centrosome migration, spindle orientation and cytokinesis. The actin cytoskeleton is reorganized during mitosis to form rounded cells with increased cortical rigidity, suggesting that

the formation and function of actin filaments are regulated through mitotic progression. Polo-like kinase 1 (Plk1) is a key regulator of cell cycle progression, especially relevant to the events at mitosis. We identified an actin-filament associated protein tropomyosin 4 (Tm4) as a possible substrate of mitotic kinase Plk1. Tropomyosins are α-helial dimers that bind and stabilize actin microfilaments by regulating their accessibility to other actin-associated proteins. To address the function of Tm4 during mitosis, we performed immunofluorescence microscopic analysis using anti-Tm4. The results showed that Tm4 localized to the centrosome, cell cortex and cytoplasm through prophase to metaphase. Then, we analyzed the effect of siRNA-mediated Tm4-depletion by live-cell imaging and immunofluorescence analysis. We found that Tm4 siRNA treatment destabilized cortical actin organization. This resulted in irregular centrosome movement and misorientation of the spindle, which ended up with a delay of anaphase onset. We further showed that Tm4-depletion by siRNA causes the defect of myosin II cortical recruitment, which contributes to centrosome movement. Expression of wild-type Tm4, but not unphospholylated Tm4 mutant, restored the proper spindle orientation, confirming the requirement of phosphorylated Tm4 for proper spindle orientation. Our results suggest that Plk1-mediated Tm4 phosphorylation stabilizes cortical actin networks during mitosis and thus is required for accurate spindle orientation. Further experiments with mouse oocytes revealed that Tm4 depletion inhibited meiotic maturation. Taken together, we conclude that Tm4 plays important roles in spindle orientation and chromosome migration in both mitosis and meiosis.

1133

Plk1 regulates the kinesin-13 Kif2b to promote accurate chromosome segregation.

E. Hood[1,2], A. Kettenbach[2,3], S. Gerber[2,3], D. Compton[1,2]; [1]Biochemistry, Dartmouth Medical School, Hanover, NH, [2]Norris Cotton Cancer Center, Lebanon, NH, [3]Genetics, Dartmouth Medical School, Lebanon, NH

The polo-like kinase Plk1 is overexpressed in many human cancers and is associated with tumorigenesis. Plk1 is a key regulator of mitosis through its phosphorylation of substrates with roles in numerous processes including spindle assembly, centrosome maturation, checkpoint signaling, and cytokinesis. Recent evidence has revealed that Plk1 also plays a role in chromosome segregation through regulation of kinetochore components such as dynein and CLIP-170. Here we identify a novel kinetochore substrate of Plk1, the human kinesin-13 Kif2b, which promotes faithful chromosome segregation through correction of improper kinetochore-microtubule (k-MT) attachments. Using selective Plk1 inhibitors and in vitro phosphorylation assays coupled with mass spectrometry, we show that Plk1 directly phosphorylates Kif2b at two residues, and that these phosphorylation events differentially regulate its cellular function. Phosphorylation of Serine 204 is required for the kinetochore localization of Kif2b, and phosphorylation of Threonine 125 is required for Kif2b activity. A non-phosphorylatable Serine 204 mutant fails to localize to kinetochores and cannot correct k-MT attachment errors, while a non-phosphorylatable Threonine 125 mutant localizes normally but also fails to correct k-MT attachment errors. These data demonstrate a novel mechanism for Plk1 in ensuring accurate chromosome segregation through regulation of k-MT dynamics and correction of k-MT attachment errors.

1134

Unpaired chromosomes in Caenorhabditis elegans female meiosis are associated with abnormal segregation.

D. B. Cortes[1], F. J. McNally[1]; [1]MCB, University of California Davis, Davis, CA

Attachment between homologous chromosomes during meiosis I is essential for accurate segregation of chromosomes. Surprisingly, humans with three X chromosomes (triploX) have

normal fertility and give birth predominantly to children with a normal chromosome complement (Reference). If the unpaired X segregated randomly at meiosis I, triploX mothers would produce 50% eggs with one X and 50% eggs with two X chromosomes. The low frequency of XXX and XXY offspring observed suggests that human female meiosis possesses a mechanism that prevents the inheritance of the unpaired X chromosome. In the *C. elegans him-8* mutant, which possesses two unpaired univalent X chromosomes at meiosis I, a similar situation occurs. If the two univalent X chromosomes segregated randomly at meiosis I, him-8 mutants should produce 25% XO male, 50% XX hermaphrodite and 25% XXX progeny. Instead Hodgkin et al. (REFERENCE) reported 38% XO male, 56% XX hermaphrodite and 8% XXX progeny, suggesting that female meiosis in *C. elegans* also possesses a mechanism of selective removal of unpaired X chromosomes. We are currently testing the hypothesis that univalent X chromosomes are selectively extruded into the first polar body. Using live imaging and fixed immunofluorescence, we found that 96% of *him-8* metaphase I spindles have 7 chromosomes at meiosis I whereas X% of wild-type metaphase I spindles had 6 chromosomes. This result demonstrates that both univalent X chromosomes in him-8 worms are still present at metaphase I. 100% of wild-type metaphase II spindles had 6 chromosomes whereas 41% of him-8 metaphase II spindles had 5 chromosomes, 55% had 6 chromosomes and 4% had 7 chromosomes. These numbers suggest that univalent chromosomes are lost between metaphase I and metaphase II. 86% of him-8 anaphase I spindles had 1 or 2 lagging chromosomes whereas only 2% of wild-type anaphase I spindles had lagging chromosomes. Quantification the fates of lagging chromosomes reveals that 60% of these are expelled into the polar body and 33% them are retained in the embryo. Our results are consistent with a model in which univalent X chromosomes biorient at metaphase I but lag at anaphase I because cohesin between sister chromatids is not cleaved. The delayed, poleward movement of these bioriented univalents is biased toward the polar body end of the spindle.

1135

Activation of Homologous Recombination (HR) and Non-Homologous End Joining (NHEJ) Repair on Double-Strand Breaks of Mitotic Telomeres.

B. Alcaraz Silva[1], M. Berns[1]; [1]Developmental and Cell Biology, Beckman Laser Institute; University of California Irvine, Irvine, CA

Telomeres are essential for protecting chromosome ends from degradation and chromosome fusion. Uncapping of telomeres during interphase elicits a DNA damage response mechanism that results in chromosomal end fusion, chromosome instability and eventually tumorigenesis. However, information about how telomeres detect and repair the damage during mitosis is not well known. In the present study we investigate the repair of HR and NHEJ in laser microirradiation-induced DSBs of telomeres that are induced during the mitotic phase. To determine the nature of DSB repair in mitosis, we irradiated individual telomeres of asynchronous cells with a laser dose that allows cell survival. Microirradiation was used in combination with GFP live-cell imaging and dual-labeling to study DSB repair by monitoring the co-localization of yH2AX with factors involved in either HR or HNEJ. We found that DNA repair proteins (Ku, BRCA1, FANCD2, WRN) and checkpoint sensors (p-Chk1, p-p53) are recruited to microirradiated telomeres. In addition, the phosphorylation status of the Chk1 protein kinase, a well-characterized checkpoint target protein was observed. Consistent with the presence of recognition factors and amplification kinase ATM, phosphorylated Chk1 was present in microirradiated telomeres, and was able to activate chk1-dependent cell cycle arrest. Despite this, telomeres fail to accumulate the checkpoint mediator 53BP1 protein. In addition, we have determined that the kinetics of NBS1 localization at DSBs on telomeres appears to be faster compared to non-telomere areas. In contrast, Ctip, which mediates the first step of resection during HR, is recruited later than the NHEJ and HR repair proteins. These results may provide

information about the accessibility of damaging agents and repair processes in telomere DNA, thus contributing to a better understanding of aging and cancer.

1136

Survivin-Independent Chromosome Biorientation and Segregation.

C. S. Campbell[1], A. Desai[2]; [1]Ludwig Institute for Cancer Research, La Jolla, CA, [2]Ludwig Institute for Cancer Research

The Chromosomal Passenger Complex (CPC) participates in multiple events during cell division. The four subunits of this complex are the kinase Aurora B, its activating scaffold INCENP, and the targeting factors Survivin and Borealin. The C-terminus of INCENP binds and activates Aurora B kinase. The N-terminus of INCENP trimerizes with Survivin and Borealin to form the CPC. One of the CPC's major functions is during chromosome segregation, where it corrects improper attachments between the centromere regions of chromosomes and spindle microtubules. Recent work has shown that CPC inner-centromere targeting involves recognition by the Survivin subunit of two distinct histone modifications: one modification is directly recognized by a domain of Survivin and the other modification is recognized by Shugoshin, which in turn binds to Survivin. Thus, the current paradigm for CPC function in chromosome segregation is based on Survivin-dependent recognition of specific chromatin features near centromeres. We have generated mutants in the budding yeast INCENP (Sli15) subunit of the CPC that no longer bind to Survivin (Bir1) or Borealin (Nbl1). Surprisingly, cells where the only source of INCENP is this mutant protein exhibit no chromosome segregation defects or growth defects, even under conditions that enhance the consequences of mild chromosome segregation errors. Even more unexpectedly, these INCENP mutants completely alleviated the severe growth defects and cell lethality observed in genetic deletions of either Survivin or Borealin. These INCENP mutants also completely suppressed the severe growth and chromosome segregation defects observed in mutants of proteins that function upstream of Survivin recruitment to chromatin. However, a strong synthetic negative growth defect is observed when INCENP mutants are combined with mutants of the inner-kinetochore COMA complex. These data, which reveal normal chromosome biorientation and segregation in the absence of Survivin, challenge the current paradigm that CPC function in chromosome segregation is based on Survivin-dependent recognition of specific chromatin features at centromeres and indicate that there are additional pathways mediating CPC targeting and function during chromosome segregation.

1137

Interkinetic nuclear migration in the vertebrate neural tube.

P. Spear[1], C. Erickson[1]; [1]UC Davis, Davis, CA

Neural progenitor cells in the pseudostratified neuroepithelium in vertebrates undergo interkinetic nuclear migration, which results in mitotic cells localized to the apical surface whereas interphase nuclei are distributed throughout the rest of the epithelium. Using time-lapse confocal microscopy on chicken neural tube and mouse cerebral cortex slices, we show that the speed of nuclear migration toward the apical surface increases at the start of G2 phase, and this is a microtubule-dependent process. Late in G2 phase, centrosomes leave the apical surface after cilia are lost. Nuclear envelope breakdown initiates away from the apical surface at the time that centrosomes reach the nucleus. The mitotic cell then rounds up to the apical surface, which is an actin-dependent process. Centrosome detachment from the apical surface is correlated with ciliary breakdown. When ciliary breakdown is inhibited, nuclear envelope breakdown occurs closer to the apical surface.

1138

Aneuploidy causes chromosome mis-segregation and karyotype-dependent phenotypic differences in cancer cells.

J. Nicholson[1], A. Mattingly[1], D. Cimini[1]; [1]Biological Sciences, Virginia Tech, Blacksburg, VA

Cancers display distinct aneuploid karyotypes and typically mis-segregate chromosomes at high rates. While chromosome mis-segregation results in the generation of aneuploidy by definition, the effect aneuploidy has on chromosome segregation is unclear. To test the effects of aneuploidy on chromosome segregation we utilized the pseudo-diploid colorectal cancer cell line DLD1 (2n=46) and variants of this line containing defined artificial trisomies for chromosomes 7 and 13, termed DLD1+7 and DLD1+13 respectively. We found that the two aneuploid lines exhibited higher rates of chromosome mis-segregation compared to the pseudo-diploid cell line. These results were confirmed by metaphase spread analysis, which showed that the proportion of cells with abnormal chromosome number is larger in the aneuploid cell lines compared to the pseudo-diploid one. Time-lapse analysis of mitosis showed that DLD1+7 cells progressed through mitosis (nuclear envelope breakdown – anaphase onset) more slowly whereas DLD1+13 cells progressed with similar timing compared to DLD1 cells. Interestingly, however, DLD1+13 cells frequently exhibited cytokinesis failure or delay. Accordingly, we observed high rates of polyploidization in DLD1+13 cells as detected by metaphase spread analysis. Microarray analysis of genes overexpressed on chromosome 13 reveal spastic paraplegia 20 (SPG20) overexpressed 9.27 fold (Upender et al., *Can. Res.*, 2004). The protein Spartin encoded by SPG20 has been previously implicated in the progression of cytokinesis (Renvoise et al., *MBoC*, 2010), suggesting that overexpression of this protein may explain the phenotypes observed in DLD1+13 cells. Experiments aimed at testing this hypothesis are currently ongoing. Overall, our study shows that aneuploidy is sufficient to induce chromosome mis-segregation in cancer cells. Moreover, our data indicate that different aneuploidies are associated with distinct chromosome segregation defects and distinct cellular phenotypes.

1139

Discovery of Novel Anti-Mitotic Compounds Targeting Hec1.

L. Laine[1], J. H. Mäki-Jouppila[1,2], A. Kukkonen-Macchi[1], T. Nyholm[3], P. Tiikkainen[1], L. Kallio[1], M. J. Kallio[1,2]; [1]VTT Medical Biotechnology, Turku, Finland, [2]University of Turku, Turku, Finland, [3]Åbo Akademi University, Turku, Finland

Hec1 (also called Ndc80) contributes to proper microtubule-kinetochore interactions and spindle assembly checkpoint (SAC) signalling, two functions that are required for normal mitotic progression. Perturbation of Hec1 results in SAC signalling defects, chromosome misalignment, and structural spindle abnormalities. High expression levels of Hec1 are linked to poor prognosis in many cancers making Hec1 a potential mitotic target for cancer intervention by small compounds. We have conducted a combination of virtual and cell-based high-throughput screens to identify small molecules that target the microtubule-binding domain of Hec1. Three million commercially available compounds were screened virtually using FRED and SurFlex softwares. The top 150 compounds were tested in cell-based assays for their ability to induce mitotic arrest. This led to the discovery of several hit compounds that cause chromosome misalignment and mitotic arrest. All hit compounds affect the formation of correct kinetochore-microtubule attachments and, importantly, some of them do not interfere with tubulin polymerization in vitro. The two most promising compounds selected for further studies show binding to Hec1 in preliminary protein-ligand interaction assays. These compounds also inhibit the growth of various cancer cell lines and reduce the size of prostate cancer cell spheroids in 3D cultures. We have recently identified effective structural analogs of the original hit compounds. Interestingly, one hit and its analog exhibit cancer cell selectivity as they potently

kill the tumorigenic MCF7 breast cancer cells but do not affect the growth of the non-tumorigenic MCF10A breast epithelial cells. Currently we are running pilot animal experiments with the lead compounds.

1140

A 3-M syndrome associated complex in regulating mitosis and cytokinesis and maintaining genome integrity.

J. Yan[1], Z. Li[1], K. Cappell[2], A. Whitehurst[2], Y. Xiong[1]; [1]Lineberger Cancer Center, UNC at Chapel Hill, Chapel Hill, NC, [2]UNC at Chapel Hill

Cullins are a family of evolutionarily conserved proteins that bind to the small RING finger protein, ROC1, to constitute potentially a large number of distinct E3 ubiquitin ligases. Disruption of cullin 7 (Cul7) in mice causes intrauterine growth retardation and perinatal death, and germline mutations in human CUL7 are associated with 3-M syndrome and short stature in Yakuts characterized by pre- and postnatal growth retardation. We found that CUL7 is localized on the mitotic apparatus, and CUL7 depletion causes chromatids alignment delay, prometaphase arrest, mid-body premature disassembly, tetraploidy, and wide spread mitotic cell death. We showed that the function of CUL7 is essential for normal microtubule dynamics and CUL7 depletion sensitizes cells to microtubule stress. These mitotic, cytokinesis and microtubule defects caused by CUL7 depletion can be rescued by wild type, but not CUL7 mutants derived from 3-M patients and were recaptured in CUL7 mutated 3-M skin fibroblasts. We further demonstrate that the product of the other two 3-M associated genes, OBSL1 and CCDC8, bind CUL7 and, when depleted, destabilizes CUL7 or compromises CUL7 localization to the mitotic apparatus, leading to similar defects in microtubule dynamics, mitosis and cytokinesis. We propose a 3-M associated complex in maintaining the microtubule and genome integrity that is essential for the normal development.

1141

Analysis of cell division defects during the progression of the atherosclerosis.

R. V. Silverman-Gavrila[1], L. B. Silverman-Gavrila[2], M. Bendeck[1,3]; [1]LMP, University of Toronto, Toronto, ON, Canada, [2]Physiology, Univeristy of Toronto, Toronto, ON, Canada, [3]Univeristy of Toronto

Smooth muscle cells (SMCs) proliferation in atherogenesis leads to neointimal thickening. We set to analyze the division rate, the frequency of division defects, and key regulators of division fidelity during progression of in neointimal layer as well as the medial layer beneath it and comparison with adjacent medial layers and uninjured media.
Using a balloon injury rat carotid artery model we studied the division rate as well as karyokinesis and cytokinesis defects in rat carotid neointimal layer at 4 days after balloon injury, the time when the first SMCs start to migrate and form the neointimal layer. The division rate and division defects were higher in the neointimal layer compared to uninjured controls and medial layers where migration of SMCs was not initiated. The division rate in the neointimal layer and in the medial layer beneath it were comparable, but the defect frequency was higher in the neointimal layer. The division rate in neointimal layer increase to 7 days, then it decreased slightly, while apoptosis increased from 4 days to 14 days, suggesting that at 7 days there is a maximal neointimal thickening due to proliferation. PKCα and RHAMM inhibition in a wounded injury cultured neointimal SMCs model caused an increase in multipolar division spindles, centrosome fragmentation and detachment from spindles, binucleate cells, and micronuclei, suggesting that they are required for karyokinesis and cytokinesis fidelity.

RHAMM centrosomal targeting sequence is necessary for normal cellular localization of RHAMM and for spindle pole organization in division and for rear polarization of MTOC of interphase migratory neointimal SMCs.
Neointimal SMCs from injured rat carotid arteries and underlying medial SMCs exhibit elevated rates of proliferation, and the neointimal cell exhibit spindle and cell division defects. PKCαand RHAMM regulate the fidelity of centrosome based division events in neointimal SMCs, and represent valuable targets for possible control of progression of atherogeneis. The centrosomal targeting sequence of RHAMM is necessary for its localization and for spindle pole organization and rear polarization of MTOC.

Novel Imaging Reagents

1142

PAmKate is a novel far-red probe of the PARFP family for multicolor super-resolution FPALM cell imaging.

F. Subach[1], V. Verkhusha[1], M. Gunewardene[2], S. Hess[2]; [1]Anatomy and Structural Biology and Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, [2]Physics and Astronomy, Institute for Molecular Biophysics

We have developed a far-red shifted photoactivatable red fluorescent protein (PARFP), named PAmKate. Before photoactivation PAmKate absorbs at 440 nm and does not fluoresce. After photoactivation with UV-violet light it becomes fluorescent. As compared to PAmCherry1, PAmKate has ~20 red-shifted excitation and ~30 nm red-shifted fluorescence. PAmKate was applied to a super-resolution 3-color ratiometric fluorescence photoactivation localization microscopy (FPALM) simultaneously with Dendra2 and PAmCherry1 PARFPs, which were spectrally resolved based on photon counts in two imaging channels. The 3-color FPALM imaging of fibroblasts revealed the specific interactions between the membrane proteins and membrane-associated actin. Based on experimental data for our dark-to-red PARFPs, including PAmTagRFP, PAmCherry1, and PAmKate, we propose three types of the photoactivation mechanisms. PARFPs of the first type (PAmCherry1-like type) stop its chromophore maturation at a dark B form (Subach et al., 2010a). Illumination of the B form with UV-violet light results in its oxidation and formation of a red fluorescent R form (B->R). PARFPs of the second type (PATagRFP-like type) stop its chromophore maturation at a dark V form (Subach et al., 2010b). During subsequent illumination with UV-violet light it is oxidized via the B form to the fluorescent R form (V->B->R). PARFPs of the third type (PAmKate-like type) mature with the formation of a dark protonated far-red H-FR form. Illumination of the H-FR form with UV-violet light results in its deprotonation with the formation of a far-red fluorescent FR form (H-FR->FR). Exploring different photoactivation mechanisms will allow design of future advanced photoactivatable probes for super-resolution cell imaging such as orange-shifted PARFPs and PARFPs with large Stokes shifts. Multicolor FPALM, such as demonstrated using PAmKate, will allow addressing mechanistic questions regarding biological functions including mapping of several molecules within a molecular machine, stoichiometric arrangement of several molecules within a subcellular structure, and motion of several molecules within a subcellular environment.

1143

Photoswitchable orange fluorescent protein forms novel far-red chromophore after irradiation with visible light.

O. Subach[1], G. Patterson[2], V. Verkhusha[1]; [1]Department of Anatomy and Structural Biology, and Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY,

[2]*Biophotonics Section, National Institute of Biomedical Imaging and Bioengineering, National Institutes of Health, Bethesda, MD*

Photoswitchable fluorescent proteins (PSFPs) with red-shifted illumination are in high demand. In this work based on mOrange we have developed a monomeric PSmOrange protein that is initially orange (ex/em at 548/565 nm) and becomes far-red (ex/em at 636/662 nm) after irradiation with blue-green light. Compared to orange proteins, PSmOrange has greater brightness, better photostability, higher photoswitching contrast, and faster maturation.
PSmOrange has several advantages over green-to-red PSFPs. First, red-shifted characteristics of PSmOrange enable its utilization for multicolor imaging with a cyan-to-green PSCFP2. Second, a good spectral resolution between forms of PSmOrange and red fluorescence of mCherry allows use of these two proteins in the same cell for multicolor imaging. Third, photon statistics of the photoconverted PSmOrange molecules showed that PSmOrange can be used in photoactivation localization microscopy (PALM) experiments and provides a signal considerably far-red shifted compared to other PSFPs. Fourth, when excited using 633 nm or 638 nm lasers or 640/30 nm excitation filter, the photoconverted PSmOrange has higher brightness than conventional far-red fluorescent proteins. Fifth, PSmOrange can be photoconverted with blue light in tissues of a living mouse directly through the skin.
Mass spectrometry of PSmOrange showed that fluorescence of photoconverted PSmOrange results from a novel chromophore containing N-acylimine with a carbon-oxygen double bond coplanar with other double bonds of the chromophore. Thus, our work has resulted in development of the new probe that extends cell and tissue imaging capabilities and has provided insight into photoconversion mechanism of the orange to the far-red state.

1144

A bacteriophytochrome-based near infra-red fluorescent protein for in vivo imaging.

G. S. Filonov[1], K. D. Piatkevich[1], L-M. Ting[2], K. Kim[2], V. V. Verkhusha[1]; [1]Department of Anatomy and Structural Biology and Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, [2]Department of Medicine and Department of Microbiology and Immunology, Albert Einstein College of Medicine, Bronx, NY

Non-invasive imaging of dynamic processes in animal tissues using fluorescent proteins (FPs) is a powerful emerging technique due to its simplicity and versatility. However, such application of FPs in mammals has long been challenging since hemoglobin and melanin absorb light in the same spectral region where the majority of FPs are excited and fluoresce. Molecular evolution of the RpBphP2 bacteriophytochrome allowed us to develop a near infra-red fluorescent protein named iRFP, with the excitation/emission maxima at 690 nm/713 nm, inside of so called "near-infrared optical window" where mammalian tissues are relatively transparent. The high brightness and stability in cells, high photostability, and low cytotoxicity suggest iRFP as a probe of choice for the long-term whole-body imaging of small animals. We demonstrated visualization of mouse internal organs by targeting iRFP encoding adenoviruses into liver. Bright iRFP signal was observed for 10 days after virus injection, indicating the protein is stable in vivo. Another important application of iRFP that was shown was fluorescence-based monitoring of the growth of a mouse tumor xenograft. iRFP signal from the developing tumor was observed starting one week after cancer cell injection. To become fluorescent, iRFP requires the endogenous chromophore biliverdin, a product of heme metabolism in all mammalian tissues. Since iRFP has high affinity for biliverdin, the relatively low endogenous concentration of the latter is enough to make iRFP fluorescent, which eliminates the need for the exogenous biliverdin injection. Thus, iRFP is as easy to use as conventional GFP-like proteins. Spectral properties suggest iRFP as a probe for FACS sorting using common 633-640 nm red lasers. Compared to previously developed phytochrome-based probes, iRFP demonstrated superior in vitro and in

vivo properties. Comparing iRFP with far-red GFP-like FPs showed that iRFP provided substantially higher a signal-to-background ratio in a mouse model. Currently, iRFP is the brightest bacteriophytochrome-based and the most far-red shifted FP. Future iRFP applications include imaging of internal organs, monitoring of tumor growth, spreading of infection in body, and tissue development and regeneration.

1145

The GAF only domain TePixJ from Cyanobacteriochrome of Thermosynechococcus elongatus BP-1 transfected into mammalian cells for enhanced microscopy.

R. F. Meza-Acevedo[1], T. Ou[1], D. Thompson[2], A. Popovic[1], D. B. Salantes[1], B. Vaccaro[1], E. Charbonneau[1], J. Darnton[1], L. Roberts[1], A. Breen[1], J. Lagarias[2], N. Rockwell[2], S. Spiller[1]; [1]Mills College, Oakland, CA, [2]UC Davis

Phytochromes are widely occurring photoreceptors that mainly respond to red/far-red light in the visible spectrum. Thermophilic cyanobacteria such as *Thermosynechococcus elongatus BP-1* has a phytochrome homologue that demonstrates it's ability to fluoresce red after a mutation in its GAF domain sequence. In this study we characterized isolated GAF domain of TePixJ (Tll0569) from class II cyanobacteriochromes. The project explores use of the GAF only domain of this protein with and without a mutation, which modifies cyanobacteriochromes into a short, bright red fluorescent biliprotein. The truncated GAF domain of TePixJ is 174 amino acids long which is much shorter than previously characterized Infrared Fluorescent Proteins (IFPs). We are engineering a plasmid that can be transfected into mammalian cells using DsRed-Monomer-Actin and AcGFP1-Tubulin vectors as models. Once our protein is expressed in mammalian cells after transfection, it will help with the visualization of the actin or tubulin cytoskeleton under enhanced microscopes. Transfected lymphocyte cells expressing the red-tagged cytoskeleton will be imaged during infection with GFP-labeled HIV in collaboration with partners at the Center for Biophotonics Science and Technology (CBST-UC Davis).

1146

Optimization of amino acid length of the GAF domain of Tlr0924 cyanobacteriochrome from Thermosynechococcus elongatus BP-1 for bright-red fluorescence.

K. Beck[1], S. Dwojak[1], A. Breen[1], S. Lane-Njuguna[1], L. Roberts[1], V. Parson[1], E-I. Charbonneau[1], N. C. Rockwell[2], J. C. Lagarias[2], S. C. Spiller[1]; [1]Biology, Mills College, Oakland, CA, [2]University of California, Davis

Cyanobacteriochromes are photoreceptor proteins found in cyanobacteria and structurally related to plant phytochromes. Cyanobacteriochromes covalently bind a linear tetrapyrrole to the GAF domain and are blue/green photoreversible. Analysis of the Tlr0924 cyanobacteriochrome from the thermophilic cyanobacterium Thermosynechococcus elongatus has shown that the protein exhibits photoconversion between blue and green-absorbing states across a wide range of temperatures. Furthermore, the mutant C499D protein no longer retains the ability to interconvert between the blue and green light-absorbing states and instead fluoresces red. This red fluorescent property has the potential to be useful as a tag for microscopic visualization in living cells. We have fully characterized the spectral properties of the full length mutant protein and have designed four truncations of the GAF domain. Our goal is to determine the smallest possible amino acid sequence that retains or enhances the spectral properties of the full-length mutant. We have altered the amino acid sequence at both ends to determine the most appropriate boundaries for the GAF domain. Both ends of the GAF domain are part of alpha helices which are presumed to contribute to the structural stability of the molecule. The binding pocket into which the tetrapyrrole is nestled is made up of beta-pleated sheets which are contiguous with these alpha helices. Our work seeks to elucidate the role of

the length of the alpha helices in preserving structure and function of the small bright red fluorescent tags derived from Tlr0924.

1147

Elongation of the Tll0899 GAF domain from the Thermosynechoccus elongatus cyanobacterium for enhanced red-fluorescent proteins.

A. C. Magallan[1], S. Dwojak[1], A. Breen[1], J. C. Lagarias[2], N. C. Rockwell[2], S. C. Spiller[1]; [1]Biology, Mills College, Oakland, CA, [2]Molecular and Celullar Biology, UC Davis, Davis, CA

Cyanobacteriochromes derive from a family of bilin photoreceptors commonly found in plant phytochromes. These photoreceptive proteins are blue/green photoreversible and function by covalently binding to a linear tetrapyrrole with the GAF domain. Our study involves the cyanobacteriochrome Tll0899 from Thermosynechococcus elongatus, a thermophilic cyanobacterium. We have shown that a mutation in the Tll0899 (152 amino acids) results in a red fluorescent protein that no longer interconverts between blue/green photoreversibility. This mutated red fluorescent protein has an absorbance peak that is not as bright as we desire. If the brightness is enhanced, we plan to utilize this property as a tag to visually observe microscopic cellular events. Tll0899 is unique among this class with a motif of DXDW; all other class II cyanobacteriochromes contain the motif DXDF. The ends of the GAF domain are part of the alpha helices of the protein. These helices are alleged to be the structural support of the molecule. We suggest that the previous truncations of the GAF domain of Tll0899 were too short and hypothesize that the elongation at the ends of the GAF domain will be a stronger structure allowing the protein to fluoresce more brightly. Currently we have four new sequences, each of which vary in number of extended amino acid lengths to the GAF domain. Our goal is to determine if one of these extended GAF domains can enhance the red fluorescence of the mutated protein.

1148

Monomeric Orange Fluorescent Protein with a Large Stokes Shift for Advanced FCS and FRET Microscopy.

D. Shcherbakova[1], M. Hink[2], T. Gadella[2], V. Verkhusha[1]; [1]Albert Einstein College of Medicine, Bronx, NY, [2]University of Amsterdam, Amsterdam, Netherlands

Multicolor imaging using fluorescent proteins (FPs) is a powerful approach to study processes in live cells. Of special interest are the methods that utilize a single excitation wavelength such as the multicolor single-laser fluorescence cross-correlation spectroscopy (FCCS) and simultaneous imaging of several biosensors, which are based on the fluorescence resonance energy transfer (FRET). These techniques require probes with new spectral properties to complement the existing FP toolbox. We have developed a monomeric orange FP with a large Stokes shift (LSS), named LSSmOrange. With excitation/emission maxima at 437/572 nm, respectively, it fills up a gap in the palette of LSS FPs between the green T-Sapphire, yellow mAmetrine and red LSSmKate1, LSSmKate2, and mKeima. LSSmOrange has the brightness comparable to that of T-Sapphire and mAmetrine, pKa value of 5.7, and half-time of its chromophore maturation of 2.3 h at 37°C. Photostability of purified LSSmOrange is similar to that of T-Sapphire, mAmetrine, and mKeima. Due to a lack of other excitation peaks except 437 nm, LSSmOrange can be used as an additional orange color for imaging with conventional orange and red FPs. We demonstrated the applicability of LSSmOrange for multicolor applications using a single-wavelength excitation of several FPs with distinct emission spectra. LSSmOrange is well spectrally resolved with red LSSmKate1, green T-Sapphire and blue TagBFP in a flow cytometry with a single excitation laser. We also applied LSSmOrange to a four-color single-laser FCCS approach using four different FPs. We demonstrated that the four-

color FCCS can be utilized to study co-migrating and single-migrating particles of different stoichiometry. In combination with far-red mKate2 protein as an acceptor, LSSmOrange makes an efficient FRET pair. It can be used together with common CFP-YFP pair in a dual-FRET imaging using a single excitation wavelength. We applied this strategy to simultaneously monitor two biosensors in a live cell.

1149

Optical recording of action potentials in mammalian neurons with a voltage indicating protein.

D. Hochbaum[1], J. Kralj[2], A. Douglass[3], A. Cohen[2]; [1]Applied Physics, Harvard University, Cambridge, MA, [2]Chemistry and Chemical Biology, Harvard University, Cambridge, MA, [3]Molecular Cell Biology, Harvard University

Reliable optical detection of single action potentials in mammalian neurons has been one of the longest-standing open challenges in neuroscience. Here we achieve this goal in cultured neurons using a new voltage indicating protein (VIP1) which has approximately 10-fold improvements in sensitivity and speed over other genetically encoded voltage indicators. The endogenous fluorescence of our microbial rhodopsin-based VIP1 showed 2-fold variation in brightness over physiological voltage range, with a sub-millisecond response time. Single action potentials yielded bursts of fluorescence with optical signal-to-noise ratio > 10. The mutant VIP2 showed 50% greater sensitivity than VIP1 and lacked endogenous proton pumping, but had a slower response (41 ms). VIP2 was still capable of resolving individual action potentials. Microbial rhodopsin-based voltage indicators promise to enable optical interrogation of complex neural circuits, and electrophysiology in systems for which electrode-based techniques are challenging.

1150

Expanding the scope of bioluminescence imaging: synthetic luciferins and mutant luciferases.

S. Miller[1], K. Harwood[2], R. Reddy[2], D. Mofford[2]; [1]Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA

Firefly luciferase-catalyzed light emission from D-luciferin is widely used as a reporter of gene expression and enzymatic activity both in vitro and in vivo. Despite the power of bioluminescence for non-invasive tumor imaging and anti-cancer drug discovery, light emission from luciferase is fundamentally limited by the photochemistry of the luciferin substrate and its ability to access the luciferase (modulated by affinity, cell permeability, and cellular efflux). We have recently described synthetic aminoluciferin derivatives such as CycLuc1 and CycLuc2 which exhibit light emission at longer wavelengths than D-luciferin (> 600 nm) and have increased affinity for luciferase. However, these desirable properties come with the caveat that aminoluciferin substrates exhibit marked burst kinetics with wild-type firefly luciferase due to product inhibition. To help overcome this limitation, we have screened for and identified mutant luciferases that can efficiently emit light with aminoluciferins, both in vitro and in live mammalian cells. We have also synthesized new aminoluciferins that are substrates for these mutant luciferases and yield bioluminescent light emission at even longer wavelengths that are more suitable for whole animal imaging (> 630 nm). Together, these synthetic luciferin substrates and mutant luciferases have the potential to expand the scope of bioluminescent detection, allowing bioluminescence at wavelengths where tissue is more transparent to light, and the construction of orthogonal luciferase-luciferin pairs for multiplexed bioluminescent imaging.

1151

Directed Evolution of a Probe Ligase and Application to Imaging of Intra- and Inter-cellular Protein-Protein Interactions.

K. A. White[1], C. Uttamapinant[1], A. Y. Ting[1]; [1]Chemistry, Massachusetts Institute of Technology, Cambridge, MA

Chemical fluorophores such as Cy dyes and AlexaFluors have superior photophysical properties to fluorescent proteins and are much smaller. To use such fluorophores for protein imaging in living cells, we have developed a site-specific protein labeling method based on engineered enzymes that catalyze fluorophore ligation onto peptide recognition sequences within living cells. Here, we will describe two efforts to re-engineer the *E. coli* enzyme, lipoic acid ligase (LplA), to catalyze ligation of fluorescent probes onto recombinant proteins, instead of its natural substrate lipoic acid. First we will describe the structure-guided mutagenesis of LplA to accept a blue coumarin fluorophore. The resulting “coumarin ligase” can be used to image a wide variety of cellular proteins with high signal/noise ratio and minimal steric perturbation. Second, we will describe the use of yeast display evolution and fluorescence activated cell sorting to evolve LplA into a probe ligase with high activity in the secretory pathway. Selections from a 10^7 library of LplA variants produced a mutant with dramatically improved activity compared to the hand-engineered ligase, and could be used to image cell surface protein-protein interactions within the same cell, as well as between contacting cells. These probe ligases should be useful tools for cell biologists interested in studying protein function in living cells with minimal steric perturbation.

1152

Wash-Free Fluorescence Imaging in Living Cells using SNAP-tag Fluorogenic Probes.

I. R. Correa Jr. [1], X. Sun[1], A. Zhang[1], B. Baker[1], L. Sun[1], C. Provost[1], J. Buswell[1], C. J. Noren[1], M. Q. Xu[1]; [1]New England Biolabs, Ipswich, MA

The ability to study the dynamic functions of proteins in living cells has been greatly aided by the development and application of tagging tools. An emerging technique for live cell imaging and proteomics applications is the site-specific labeling of cellular proteins with chemical probes. In this approach, small organic molecules are coupled to the protein being studied via a fusion tag, either by self-labeling or enzymatic ligation. Among the most prominent fusion tags is the SNAP-tag, an engineered variant of the human repair protein O6-alkylguanine-DNA alkyltransferase (hAGT) that covalently reacts with O6-benzylguanine (BG) derivatives bearing a chemical or optical probe. During the reaction with a substrate, a stable thioether bond is formed between the reactive cysteine of the tag and the label. SNAP-tag reactions proceed with a well-defined mechanism, predictable stoichiometry and rapid kinetics, irrespective of the fusion protein attached to the tag. However, as for the vast majority of chemical labeling approaches, a thorough wash step is required to reduce fluorescence background signals due to the presence of unreacted probes. Besides being a tedious and time-consuming process, this requirement may potentially limit some applications, such as direct quantification of protein concentration in cell lysates or real-time monitoring of molecular events like receptor-ligand binding, endocytosis, trafficking, and expression of newly synthesized proteins. Thus a strong need remains for efficient molecular imaging methods that enable researchers to assess real-time detection and high-contrast imaging. Herein, we report the design and application of intramolecularly quenched fluorogenic probes that become highly fluorescent upon reaction with SNAP-tag. We demonstrated the feasibility of wash-free labeling protocol for plasma membrane localization and internalization of the epidermal growth factor receptor (EGFR) in living HEK293 cells. We successfully obtained wash-free images of intracellular SNAP tagged histone H2B or β-tubulin in U2OS cells using cytoplasmic delivery techniques, such as glass beads or transfection

reagents, to deliver cell-impermeant fluorogenic probes. In summary, the labeling system described here opens new avenues for for real-time monitoring of highly dynamic processes in living cells, and for high throughput screening of proteins in complex biosystems and drug discovery.

1153

A chemical strategy for the delivery of sulfonated fluorophores into live cells.

S. Pauff[1], S. C. Miller[1]; [1]Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA

Live cell fluorescence imaging permits real-time observation of cellular activity. However, most cell-permeable organic fluorophores are very hydrophobic, localizing to cellular membranes and organelles rather than the cytoplasm. One method to increase the water-solubility of a molecule is through the use of sulfonate groups. Unfortunately, this highly polar negatively-charged group generally prevents passage of the molecule through the lipid membrane.

Our lab has developed a method to block the negative charge of sulfonated dyes by disguising them as chemically-stable, esterase-labile sulfonate esters. We have shown that these protecting groups are cleaved by pig liver esterase (PLE) in vitro. Moreover, this strategy can be used to deliver dansyl sulfonate dyes into the cytoplasm of live cells. We next sought to determine whether this approach could be applied to the delivery of near-IR fluorophores, which are more synthetically challenging but superior for live cell imaging.

Living tissue is most transparent to near-IR light (650-900 nm), the ideal wavelength range for the imaging of living systems. However, near-IR fluorophores necessarily present a larger planar hydrophobic surface area than visible-wavelength dyes, increasing their propensity to aggregate. Furthermore, most unsulfonated near-IR dyes are cationic and readily accumulate in mitochondrial membranes. By applying our delivery method to these molecules, we hope to be able to image cells in real-time without the damage incurred by shorter wavelength radiation.

Here we report the synthesis of highly photostable near-IR oxazine fluorophores that incorporate esterase-labile sulfonate esters. We have found that the sulfonate protecting groups in these near-IR dyes, like those of dansyl sulfonates, are selectively unmasked by pig liver esterase. These dyes have potential applications for imaging of anion efflux by drug resistance pumps and for the labeling of cellular proteins with near-IR fluorophores.

1154

Mixed-surface, Lipid-tethered Quantum Dots for Targeting Cells and Tissues.

Y. Zang[1], A. Riddle[1], A. Cochrane[1], E. Whitley[1], I. Schneider[1], A. Clapp[1]; [1]Iowa State University, Ames, IA

Quantum dots (QDs), with their variable luminescent properties, are rapidly transcending traditional labeling techniques in biological imaging and hold vast potential for biosensing applications. An obstacle in any biosensor development is targeted specificity. Here we report a facile procedure for creating QDs targeted to the cell membrane with the goal of cell-surface protease biosensing. This procedure generates water-soluble QDs with variable coverage of lipid functional groups. The resulting hydrophobicity is quantitatively controlled by the molar ratio of lipids per QD. Appropriate tuning of the hydrophobicity ensures solubility in common aqueous cell culture media and while providing affinity to the lipid bilayer of cell membranes. The reaction and exchange process was directly evaluated by measuring UV-vis absorption spectra associated with dithiocarbamate formation. Cell membrane binding and endocytosis rates were

assessed using flow cytometry and total internal reflection fluorescence imaging with live cells. Tissue affinity was measured using histochemical staining and fluorescence imaging of frozen tissue sections. Increases in cell and tissue binding were found to be regulated by both QD hydrophobicity and surface charge, underlying the importance of QD surface properties in the optimization of both luminescence and targeting capability.

1155

Two-color in vivo Single mRNA Counting in Yeast for Measuring Intrinsic Noise.

S. Hocine[1], D. Zenklusen[2], J. A. Chao[1], R. H. Singer[1]; [1]Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, [2]Département de biochimie, Université de Montréal, Montreal, QC, Canada

The development of a method for live cell imaging of mRNA has yielded important information concerning transcription, mRNA export and localization. However, it has been generally limited to tagging of a single gene and has failed to generate resolution of single mRNAs in yeast. The ability to image mRNA in two colors with equal specificity and sensitivity drastically increases the experimental range of the system, making it possible to observe two mRNAs simultaneously, or to tag different regions of the same transcript. Here, we describe a method using a new RNA-tag, derived from the PP7 bacteriophage, for visualizing single *MDN1* transcripts. Single molecule counting using this PP7-system in combination with the MS2-system is used to quantify expression of endogenous MDN1 alleles. Time-dependent expression analysis in diploid yeast revealed that both alleles were expressed independently of one another, with uncorrelated steady-state fluctuations that provide the first measurement of intrinsic noise in mRNA expression over time. Supported by grant GM 57071 to RHS.

Cell Biology Assays Using Improved DNA Detection Reagents.

F. K. Harlan[1], Y. Jiang[1], R. Galvao[2], T. Deligeorgiev[3], J. J. Naleway[1]; [1]Research, Marker Gene Technologies, Inc., Eugene, OR, [2]Institute of Molecular Biology, The University of Oregon, Eugene, OR, [3]Department of Chemistry, The University of Sofia, Sofia, Bulgaria

Symmetrical homodimers of cyanine dyes are known to have exceptional sensitivity for detection of nucleic acids with very high fluorescence enhancement upon binding to DNA. In addition, they exhibit increased quantum yields and stability upon binding due to their high affinity for the nucleic acids. We have recently synthesized a series of homodimeric dyes including 6-chloro-YOYO-1 and 6-chloro-TOTO-1 that are analogs of the commercial dyes YOYO-1 and TOTO-1. They differ from the commercial products in that they have chloro-substituents at the six-position of the benzoxazole or benzothiazole rings respectively. Each dye has also been prepared with different anionic counterions imparting improved water solubility. In addition, their excitation and emission spectra upon DNA binding (EX 450 and 520 nm; EM 510 - 540 nm, quantum, yield 0.5) overlaps well with common fluorescence detection systems.
These new analogs have been found to have an approximately two-fold increased sensitivity in gel electrophoresis detection of dsDNA prestained with these new dyes over their parent analogs. The new dyes have also found application in a number of cell biology assays. Staining of fixed chromatin of human breast cancer cells (MDA-MB-231) exhibited bright green signal, providing an alternate fluorescence detection of chromatin/DNA over DAPI. The new dyes have also found use for post-staining amplification products in Loop Mediated Isothermal Amplification (LAMP) assays. In this assay, we utilized 4 primer sequences which recognize 6 distinct regions of bacteriophage or lacZ DNA and a strand disrupting polymerase for amplication under isothermic conditions. In addition, upon application at 1 uM concentration, the new dyes have been found to be suitable for staining flash frozen, ethanol fixed brain tissue

sections. Since these new dyes are cell-membrane impermeant, they have been found to be suitable for distinguishing dead cells when used at a 0.5 uM concnetration and therefore act as a vital reagent in a Live:Dead format assay. In addition, they are less hazardous than other DNA stains and can thus be utilized in live cell analysis formats. In conclusion, our new 6-chloro-YOYO-1 and 6-chloro-TOTO-1 dyes have increased sensitivity in detection and can be a suitable reagent for a number of important biological assays. This work is funded in part by grant number NSF-IIP0923953 from the National Science Foundation-USA.

Toward Unbiased Direct DNA and RNA Labeling Systems.

Y. Jiang[1], C. A. Harrington[2], M. A. Naleway[1], S. M. Strain[3], S. L. Savage[2], R. E. Slottke[2], K. A. Vartanian[2], J. J. Naleway[1]; [1]Research, Marker Gene Technologies, Inc., Eugene, OR, [2]Gene Microarray Shared Resource, Oregon Health and Sciences University, Portland, OR, [3]CAMCOR, University of Oregon, Eugene, OR

Problems with current genomic microarray analysis techniques include hybridization perturbation caused by base labeling and enzyme-introduced sequence bias for labeling. To solve these problems, we have developed a series of new ultrasensitive labeling reagents for directly labeling DNA or RNA samples isolated from live cells or tissues or prepared by PCR. From their unique diazo reactive group as well as 31P-NMR studies, these labeling reagents have been found to directly modify terminal and backbone phosphate groups of DNA or RNA samples. We developed these new reagents for use in fluorescent (TAMRA, Cy3, Coumarin) as well as hapten (biotin) labeling protocols. The new labeling reagents have been shown to cause less hybridization perturbation.

The effects of the direct labeling method on hybridization efficiency as well as in comparison with existing techniques were examined. Biotin labeling of miRNA isolated from NIH3T3 murine fibroblasts was hybridized to Affymetrix GeneChip miRNA (v1) arrays and compared to poly(A) polymerase enzyme-based labeling which is the adopted labeling method used in most miRNA microarray protocols. We observed a 0.68 Pearson Correlation Coefficient between these two labeling methods, with the new direct labeling reagent detecting 24.4% more sequences. A 13.3% bias in labeling was found for sequences ending with a 3'-uracil for the enzymatic labeling method versus a 1.7% bias for our chemical labeling method. Certain hairpin sequences also exhibited biased labeling. Reports from multiple labs regarding enzyme-based bias in labeling are consistent with these observations. To confirm the differential labeling is due to the enzymatic sequence bias, we also compared biotin labeled miRNA with a chloroethylamino reactive biotin direct-labeling reagent which directly modifies the bases of nucleotides. We observed a 0.97 Pearson Correlation Coefficient with 17.8% higher mean intensity using our new direct labeling over the chloroethylamino direct labeling biotin system. In addition, all four miRNA probes miR-{467a,328,206,214}, which lack G,A,C and U respectively, were labeled and exhibited minimal sequence dependence compared with a 10% hybridization bias for the reactive chloroethylamino biotin labeling of miR-328 and 214 over miR-467a and 206.

We also isolated miRNA from both etoposide-treated and non-treated NIH3T3 cells, and labeled them using our direct biotin labeling reagent and analyzed the miRNA patterns using the miRNA Affymetrix (v1) arrays. The differential expression miRNA patterns obtained upon etoposide treatment were consistent with the literature as well as confirmed by northern blot and qPCR. Uses of these methods to determine the pattern of gene expression upon therapeutic treatment as well as for pharmacokinetic analysis of DNA or RNA based drug therapies have been developed. This work is supported by NSF grant IIP-0923953.

Voltage-Gated Channels and Neurotransmission

Molecular dissection of epilepsy-related neuronal secreted protein, LGI1.

Y. Fukata[1], N. Yokoi[1], T. Ohkawa[1], M. Fukata[1]; [1]National Institute for Physiological Sciences, Okazaki, Japan

LGI1 is a neuronal secreted protein, and its mutations cause an inherited form of human epilepsy, autosomal dominant partial epilepsy with auditory features (ADPEAF). Also, autoantibodies against LGI1 is involved in limbic encephalitis with seizures and memory impairment. We have recently reported that 1) LGI1 functions as a ligand for epilepsy-related transmembrane proteins, ADAM22 and ADAM23, and enhances AMPA receptor (AMPAR)-mediated synaptic transmission and that 2) loss of LGI1 in mice reduces AMPAR-mediated synaptic transmission and causes lethal epilepsy. However, the molecular function of LGI1 still remains unclear. Here, we focused on human epilepsy-related LGI1 mutations, as characterization of these mutations helps understand LGI1 patho-physiological functions. We isolated LGI1 mutants identified in ADPEAF pedigrees. Most of LGI1 mutants were not secreted as previously reported (secretion negative mutation, Sec-). Notably, we found that some of reported point mutations did not affect LGI1 secretion process (secretion positive mutation, Sec+). When expressed in the LGI1-knockout mice, both LGI1 mutants could not rescue the epileptic phenotype, under the conditions wild-type LGI1 could rescue it. We found that LGI1(Sec-) did not bind to ADAMs in the brain, and instead that it robustly interacts with proteins involved in biosynthetic secretion pathway. Consistently, this mutant protein was mislocalized in the hippocampus. In contrast, LGI1(Sec+) showed reduced binding to ADAM receptors, and its protein stability was robustly hampered. Thus, secretion and binding to ADAM22/23 are essential for anti-epileptic function of LGI1.

Antibodies and Autoimmunity: a role in neurodegeneration.

J. Douglas[1,2], M. Levin[1,3], L. Gardner[1,4], C. Groover[2]; [1]Neurology, University of Tennessee Health Science Center, Memphis, TN, [2]Research Inc., VAMC Memphis, Memphis, Tn, [3]Neurology, VAMC Memphis, Memphis, TN, [4]Research Inc., VAMC Memphis, Memphis, TN

Objective: To demonstrate a link between autoimmunity to heterogenous ribonucleoprotein A1 (hnRNPA1) and neurodegeneration.
Methods: We utilized microarray analysis, protein and mRNA immunoprecipitation, proximity ligation assay (PLA) and immunohistochemistry.
Results: Multiple sclerosis (MS) is an autoimmune disease that is increasingly recognized as a neurodegenerative disorder. To further investigate this concept, we explored the impact of autoantibodies on neuronal cells. hnRNPA1 autoantibodies are present in biological fluids of MS patients. Whether these molecules penetrate neuronal cells is unknown. One potential mechanism of antibody entry into neurons is endocytosis. To test if endosomes contributed to antibody penetration, we labeled early endosomes with GFP using baculovirus expressing mammalian promoter (BacMam, Invitrogen) and Rab5a targeting sequence. Antibodies to hnRNPA1 and human IgGs were labeled with Atto 550 ester dye for colocalization analysis. The results of these experiments indicate that fluorescently tagged antibodies penetrate neuronal cells by endocytosis. In addition to neuronal penetration, antibodies to hnRNPA1 appeared to alter neuronal phenotype. Next, we hypothesized that antibodies to hnRNPA1 present in the neuronal cytoplasm might interfere with normal protein function and alter RNA levels. Following transfection of anti-hnRNPA1 antibodies into neurons, microarray analysis showed alterations in

spastin (SPG4) RNA levels. Mutations in SPG4 result in hereditary spastic paraplegia; a genetic disease clinically indistinguishable from progressive forms of MS. Further, spastin contains an MIT (microtubule interacting and trafficking protein) site and has been shown to play a role in microtubule stability, synaptic growth and transmission in neurons. Due to this potential link between an autoimmune reaction and a neurodegenerative disease, we evaluated protein-protein interactions between hnRNPA1 and SPG4. Through protein and mRNA immunoprecipitation and proximity ligation assays (PLA) we show that molecular interactions occur between hnRNPA1 and SPG4.
Conclusion: These data suggest a strong connection between autoimmunity and neurodegeneration in MS patients. Autoantibodies penetrate neuronal cells by endocytosis and have a negative effect on the cellular viability. In addition, we have also shown that an interaction exists between hnRNPA1 and SPG4 at the protein and mRNA levels. Further studies are currently taking place to map the site of protein and mRNA interaction between hnRNPA1 and SPG4.

1160
Ca^{2+} Binding by Synaptotagmin's C2A Domain Essential for Synchronous Synaptic Transmission.
A. R. Striegel[1], L. M. Biela[1], C. S. Evans[2], Z. Wang[2], J. B. Delehoy[1], R. B. Sutton[3], E. R. Chapman[2], N. E. Reist[1]; [1]Dept. of Biomedical Sciences, Colorado State University, Fort Collins, CO, [2]Dept. of Physiology, University of Wisconsin, Madison, [3]Dept. of Cell Physiology and Molecular Biophysics, Texas Tech University Health Sciences Center

Synaptotagmin is the major calcium sensor for fast synaptic transmission which requires synchronous fusion of multiple synaptic vesicles. Synaptotagmin contains two calcium binding domains: C2A and C2B. Ca^{2+} binding to C2A has been thought to be extraneous for triggering synchronous fusion because mutations that remove the negatively-charged residues required for Ca^{2+} binding support efficient synchronous fusion. Yet C2A Ca^{2+}-dependent effector interactions *are required* for efficient synchronous fusion. How can the effector interactions be more significant for function than Ca^{2+} binding itself? Based on a structural analysis, we generated a novel mutation of a single Ca^{2+}-binding residue in C2A that blocked Ca^{2+} binding, but *maintained* the negative charge of the pocket. Electrophysiological analyses demonstrated that this C2A mutation resulted in ~80% decrease in synchronous transmitter release and a decrease in the apparent Ca^{2+} affinity of release. Our findings now reveal that previous aspartate to asparagine mutations in C2A inadvertently mimicked Ca^{2+} binding. We show the function of Ca^{2+} binding to C2A is to neutralize the negative charge of the pocket, thereby unleashing the fusigenic activity of synaptotagmin. Our results now demonstrate that Ca^{2+} binding by C2A is a critical component of the electrostatic switch that triggers synchronous vesicle fusion during synaptic transmission.

Role of the Na+/K+ ATPase in auditory mechanosensation in Drosophila melanogaster.
M. Roy[1], R. G. Kavlie[2], E. Sivan-Loukianova[1], D. F. Eberl[1]; [1]Biology, University of Iowa, Iowa City, IA, [2]University College London

Plasma membrane localized Na+/K+ ATPase is important for maintaining ionic homoeostasis in most biological systems. The alpha subunit is the main catalytic pump, which depends on a beta subunit for its transport to the plasma membrane and also for regulating its activity. In adults,

both alpha subunit (ATPα) and Nrv3 (one of the 3 known beta subunit proteins) are expressed in brain, eye and neurons of fly auditory organ (Johnstons Organ or JO) located in the second antennal segment. In addition, ATPα has high expression in the ablumenal plasma membrane of scolopale cells, a support cell type in the auditory organ. The goal of our study is to investigate the functional role of Na+/K+ ATPase in hearing and we hypothesize that it plays a critical role in establishing and maintaining the ionic content of the scolopale space, an extracellular receptor lymph space surrounding the sensory dendrites and enclosed by the scolopale cell of the JO sensory organs. We knocked down expression of ATPα and each of the 3 beta subunits in the JO with UAS/Gal4 mediated RNA-interference (RNAi). Knocking down the ATPα in neurons and scolopale cells using specific drivers resulted in complete loss of hearing as was tested by our auditory electrophysiology assay. Immunohistochemistry shows that these animals lack ATPα expression in the scolopale cells and Electron Microscopy (EM) shows abnormal accumulation of electron dense material in the scolopale space. Knocking down nrv3 in neurons results in hearing loss but knockdown in the scolopale cell does not. RNAi mediated knockdown of nrv2 but not nrv1 (genes encoding the other two beta subunits) in the scolopale cell resulted in almost complete loss of hearing, suggesting its scolopale cell specific role in audition. In conclusion, the Na+/K+ ATPase is likely to be an important molecular player in auditory mechanotransduction by virtue of its role in maintaining the ionic homeostasis in a specific support cell type of the hearing organ.

All -Trans-Retinoid Acid Induces the Differentiation of Encapsulated Mouse Embryonic Stem Cells into GABAergic Neurons.

C. A. Addae[1], E. Martinez-Ceballos[1]; [1]Environmental Toxicology, Southern University and A&M College, Baton Rouge, LA

Embryonic stem (ES) cells are pluripotent cells that can differentiate into all three main germ layers: endoderm, mesoderm, and ectoderm. ES cells can be differentiated into several specific cell types depending on the growth factors used to induce their differentiation. A number of methods have been developed to differentiate ES cells into neuronal phenotypes such as sensory neurons, motor neurons, and interneurons. However, differentiation of ES cells into GABAergic interneurons has progressively been a challenge. The main output of inhibitory GABAergic interneurons is the gamma-aminobutyric-acid (GABA). A reduction in GABA signaling can cause neuronal disorders such as epilepsy, autism, seizure, and insomnia. In this study, we generated GABAergic neurons by encapsulating mouse ES cells in alginate-based hydrogels followed by treatment with 5μM all-trans-retinoid acid (RA). Encapsulated ES cells were cultured for eight days and RA was applied at days 4 and 6. On day 8, cells were removed from the hydrogels followed by plating on poly-D-lysin and laminin-coated dishes. The final maturation step was accomplished by culture in supplemented Neurobasal medium for an additional period of 6 days. Our encapsulation-based protocol resulted in a 2-fold increase in neuronal differentiation as compare to a standard non-encapsulation encapsulation protocol. Furthermore, our results indicate that encapsulation of mouse ES cells in alginate-based hydrogels generate GABA-positive neurons (~87-93%) after RA treatment and without the addition of expensive growth factors. The results obtained from these studies may result in more efficient and scalable differentiation strategies for the generation in culture of GABAergic interneurons that are suitable for future therapeutic applications. Thus, the relevance of this technology extends beyond the enrichment of research to the fields of cell replacement therapy and functional CNS treatment modalities.

1163

Calpain and calcineurin in low-frequency depression at phasic synapses of neuromuscular junction.

L. B. Silverman-Gavrila[1], M. Praver[2], M. P. Charlton[1]; [1]Physiology, University of Toronto, Toronto, ON, Canada, [2]Medicine, Columbia University, New York, NY

Low-frequency depression (LFD) at crayfish leg extensor phasic synapse of neuromuscular junction (NMJ) is regulated by presynaptic calcineurin. Since calcium buffering by slow chelator EGTA-AM does not block LFD, but the fast chelator BAPTA-AM inhibits LFD, depression is not caused by residual free calcium, but rather the Ca2+ sensor for LFD may be close to a Ca2+ source at active zone. LFD may require activation of presynaptic calcineurin by calpain. Both proteins are present at nerve terminals as shown by immunostaining and Western blot analysis. Calpain inhibition with calpain inhibitors (calpain inhibitor I, MDL-28170, and PD 150606, but not by control PD 145305) inhibits LFD both in intact and in dissected preparations probably acting presynaptically as suggested by miniEPSP analysis. Calpain activity was detected in crayfish preparations using a fluorimetric assay and was modulated by calcium and calpain inhibitors. LFD inhibition by calpain inhibition causes rearrangement of tubulin cytoskeleton at phasic terminals. Another form of synaptic depression, high frequency depression (HFD) does not involve protein phosphorylation- or calpain-dependent mechanisms. In conclusion LFD involves a specific pathway in which local Ca2+ signaling activates calpain and calcineurin at active zones and causes changes of tubulin cytoskeleton during LFD.

Up-regulation of TREK-2 Potassium Channels in Astrocytes Requires de novo Protein Synthesis: Relevance to Neuroprotection.

A. F. Rivera-Pagan[1], L. Kucheryavykh[1], Y. Kucheryavykh[1], L. A. Cubano[2], S. N. Skatchkov[1], M. J. Eaton[1]; [1]Biochemistry, Universidad Central del Caribe, Bayamon, Puerto Rico, [2]Anatomy, Universidad Central del Caribe, Bayamon, Puerto Rico

Background: Excitotoxicity due to glutamate receptor over-activation is one of the key mediators of neuronal death after an ischemic insult. A major function of astrocytes is to maintain low extracellular levels of glutamate. Glutamate transport by astrocytes requires a hyperpolarized membrane potential conferred by the presence of potassium channels in the astrocytic membrane. In normal conditions, Kir 4.1 potassium channels are predominantly responsible for maintaining the hyperpolarized membrane potential of astrocytes, but these channels are inhibited during ischemia when ATP is depleted, therefore, an alternative pathway is necessary to maintain glutamate homeostasis during ischemia. We have previously shown that ischemia functionally up-regulates TREK-2 potassium channels in astrocytes.

Objective: The purpose of the present study was to determine the mechanism leading to TREK-2 up-regulation and to assess the contribution of TREK-2 potassium channels to glutamate clearance during ischemia.

Methods: Rat cortical astrocytes were subjected to simulated ischemia (anoxia and reduced glucose) and compared to astrocytes grown in under normoxic conditions with normal glucose. Electrophysiological measurements were used to determine functionality of the TREK-2 channels, whereas real time RT-PCR and Western Blot were performed to determine mRNA and protein levels, respectively. Glutamate clearance was assessed using a colorimetric assay.

Results: Ischemia increased TREK-2 protein levels by 65% and this effect was reversed by the protein synthesis inhibitors emetine (60nM) or cyclohexmide (1μg/ml). In contrast, TREK-2 mRNA levels were not increased in response to ischemia. Whole cell voltage-clamp studies revealed that astrocytes exposed to ischemic conditions had increased temperature sensitive outward currents as compared with control suggesting greater numbers of TREK-2 functional

channels in the astrocytic membrane. Finally, we found that the contribution of TREK-2 channels to overall astrocytic glutamate clearance was greatly increased after ischemia.
Conclusions: Taken together, these data suggest that TREK-2 channels in astrocytes are up-regulated during ischemia through a mechanism requiring de novo protein synthesis. This up-regulation may help to maintain lower extracellular glutamate concentrations and contribute to neuronal rescue.

A Novel Fluorescent Protein and Biotin Tagged Nav1.6 Channel Allows Analysis of Voltage-gated Sodium Channel Dynamics in Hippocampal Neurons.

E. Akin[1], A. Weigel[2], D. Krapf[3], M. Tamkun[4]; [1]Cell and Molecular Biology, Colorado State University, Fort Collins, CO, [2]Biomedical Engineering, Colorado State University, [3]Colorado State University, [4]Biomedical Sciences, Colorado State University

Voltage-gated sodium channels (Nav) are essential for most neuronal excitability and are concentrated at the axon initial segment (AIS) where they are thought to be responsible for action potential initiation. While much is understood about channel structure and function, there is limited information on how cells process sodium channel proteins in real time. How sodium channels are trafficked and localized to the AIS remains unknown. In addition, it is unclear what percentage of AIS channels are actually sodium conducting. Since the large sodium channel cDNAs are difficult to manipulate, the most elegant trafficking work to date has utilized chimeric proteins containing the sodium channel ankyrin-binding motif fused to other membrane proteins. While these approaches address aspects of sodium channel localization, they cannot address sodium channel function and there is always the question of whether these chimeras faithfully reproduce wild-type sodium channel behavior. Appropriately tagged full-length and functional sodium channels are required if sodium channel cell biology is to advance. In the present study, Nav1.6 was tagged with GFP or Dendra2 fluorescent proteins and an extracellular biotin acceptor domain (BAD) in order to allow for visualization and single particle tracking of functional sodium channels on the surface of living cells. This Nav1.6 construct demonstrated wild-type Nav1.6 activity when expressed in hippocampal neurons. Confocal microscopy indicated the tagged channel trafficked efficiently to the cell surface and had a dense accumulation at the AIS. Alexafluor 594-conjugated streptavidin binding indicated the surface density of channels at the AIS was approximately 60 times greater than on the soma. This density compares with that for the endogenous Nav1.6 channel. Fluorescence recovery after photobleaching (FRAP) and single particle tracking showed that channels at the AIS had recovery time constants of greater than 2 hours and were confined to 60nm +/- 20nm compartments. In summary, our study demonstrates the creation of a functional sodium channel construct with fluorescent protein and extracellular biotin reporters that has both wild-type trafficking and biophysical properties. This construct will be utilized to examine channel turnover, trafficking, diffusion and location-dependent function in neuronal cells.

Anterograde and Retrograde Axonal Transport

1166

Axonal transport of neurofilaments in the mouse optic nerve: a single population of neurofilaments moving intermittently at a broad range of average rates.

Y. Li[1], P. Jung[1], A. Brown[3]; [1]Physics and Astronomy, Ohio University, Athens, OH, [3]Neuroscience, Ohio State University, Columbus, OH

The axonal transport of neurofilaments in mouse optic nerve has been controversial for more than two decades. The central issue is whether or not neurofilaments are deposited into a persistently stationary cytoskeletal network during their transport along this nerve. We have used computational modeling to address this controversy, taking advantage of the wealth of published radio-isotopic pulse-labeling and morphometric data available for neurofilaments in the mouse visual system. We show that the published data can be explained fully by a “stop and go” model of neurofilament transport, in which axons contain a single population of neurofilaments that move in a rapid, intermittent and bidirectional manner. Importantly, we find that a single set of parameters in our model is sufficient to fully explain three different aspects of the data: the shape and location of the transport waves at multiple time points, the decay kinetics from a nerve window, and the observed gradient in neurofilament content along these axons. In addition, we find that the transport kinetics are not consistent with deposition of neurofilaments into a persistently stationary phase, and that a simple deposition model cannot account for the observed gradient in neurofilament content. Finally, we show that the original published evidence upon which the deposition model was based is most likely an experimental artifact due to contamination of the neurofilament transport kinetics with cytosolic proteins that move at faster rates. While neurofilaments alternate between moving and pausing states on a time scale of minutes or hours, our data indicate that on a time scale of days or weeks they behave as a single population. All the neurofilaments in these axons move, and they do so with a single broad and continuous distribution of average rates that is dictated by the intermittent and stochastic nature of their transport behavior.

1167

Local acceleration of neurofilament transport at nodes of Ranvier.

C. L. Neuendorf[1], J-P. Julien[2], P. Jung[1], A. Brown[1]; [1]Ohio State University, Columbus, OH, [2]Laval University, Canada

Neurofilaments are abundant structural components of the axonal cytoskeleton and are actively transported along axons in a rapid, intermittent and bidirectional manner. In myelinated axons, the axonal thoroughfare is dramatically constricted at regular intervals by nodes of Ranvier, where the number of neurofilaments can decrease locally by tenfold or more. This local constriction creates a potential bottleneck for axonal neurofilament traffic. To avert neurofilament traffic jams and accumulations, we hypothesize that neurofilament transport must be more efficient in nodes than in the flanking internodes, much as water flows more rapidly at a narrowing of the banks of a river. To test this hypothesis, we developed a novel Thy1-PAGFP-NFM transgenic mouse, which expresses a photoactivatable neurofilament protein (photoactivatable green fluorescent protein linked to neurofilament protein M) in neurons. Tibial nerves were removed from adult mice and perfused with oxygenated saline at 37°C during imaging. Axon health was monitored by observation of organelle movement using bright field illumination, and neurofilament transport was monitored by epifluorescence microscopy using the fluorescence photoactivation pulse-escape technique. We activated the neurofilament fluorescence in contiguous nodal and internodal segments along single myelinated axons and

then imaged the activated regions at intervals for thirty minutes to analyze the kinetics of neurofilament departure. On average, the axonal neurofilament content and cross-sectional area in the nodes was 14±7% and 8±3% of the flanking internodes, respectively (n=11). In all cases, the fluorescent neurofilaments departed the nodes faster than the internodes, with 65±15% remaining in internodal regions and 37± 12% in the nodal regions after thirty minutes, and this difference was statistically significant ($p<0.0001$, n=14; paired t-test). No fluorescence decay was observed in the presence of metabolic inhibitor, confirming that the loss of fluorescence was due to active transport. These data demonstrate that the velocity of neurofilament transport is regulated at nodes of Ranvier to ensure a stable neurofilament distribution and axonal morphology. We speculate that the neurofilament accumulations and swollen axons seen in many neurodegenerative diseases could arise to a disruption of these regulatory mechanisms.

1168

Local regulation of neurofilament transport by myelinating cells.

P. C. Monsma[1], Y. Li[1], P. Jung[1], A. Brown[1]; [1]Ohio State University, Columbus, OH

Two basic mechanisms by which animals increase axonal conduction velocity are to increase axonal diameter and to insulate axons by myelination. Intriguingly, the growth of axon caliber during vertebrate development is triggered by myelination; most unmyelinated axons do not exceed ≈1μm in diameter, whereas most myelinated axons grow much larger. This radial growth is caused principally by an accumulation of neurofilaments, which are space-filling polymers that function to increase axonal cross-sectional area. Neurofilaments are transported along axons in a rapid, bidirectional and intermittent manner and their motile behavior is dominated by prolonged pauses. We propose that the balance of movements and pauses determines the average velocity, and that this in turn regulates axonal neurofilament content. Thus a slowing of neurofilament transport could contribute to the radial expansion of myelinated axons. To test this hypothesis, we established long-term myelinating co-cultures from rat dorsal root ganglia. After 4-6 weeks in culture, we co-transfected the neurons with photoactivatable neurofilament fusion protein (PAGFP-NFM) and mCherry, a diffusible red fluorescent protein, and analyzed the kinetics of neurofilament transport using the pulse-escape fluorescence photoactivation technique. To determine the effect of myelination on neurofilament transport, we took advantage of the discontinuous myelination in these cultures, which results in contiguous myelinated and unmyelinated regions along many axons. On average we observed a 40% accumulation of neurofilaments in myelinated regions compared to contiguous unmyelinated regions along the same axons, and a 47% expansion of axonal cross-sectional area (n=27, $p<0.05$ and $p<0.001$, respectively; paired t-test). The kinetics of neurofilament departure from both the myelinated and unmyelinated activated regions were biphasic, indicative of distinct long- and short-term pausing states, as we have described previously. However, the filaments departed the myelinated regions more slowly. On average, 34% of the neurofilaments remained in the unmyelinated activated regions after 2 hours compared to 47% in the myelinated activated regions, and this difference was statistically significant (n=27, $p<0.001$; paired t-test). Computational modeling revealed that this change in the decay kinetics can be explained by a 40% decrease in the neurofilament transport velocity, which would be sufficient to explain the observed neurofilament accumulation. Thus the local neurofilament accumulation in myelinated axonal segments can be explained by a local slowing of neurofilament transport. These data indicate that myelinating cells locally regulate axonal morphology by modulating the kinetics of neurofilament transport.

1169

Neurofilaments are transported along axons in an unfolded and fully extended conformation.

N. J. Taylor[1], L. Wang[2], A. Brown[2]; [1]Ohio State University, Columbus, OH

Live-cell imaging studies in cultured nerve cells have demonstrated that neurofilament polymers move intermittently along microtubule tracks in both anterograde and retrograde directions, powered by kinesin and dynein motors. The instantaneous velocity is fast but the average velocity is slow because the movements are interrupted by long pauses. We have reported previously that the moving neurofilaments typically average about 5-10μm in length, with some as long as 40μm or more, and that they appear to be very flexible. We do not know how motors interact with neurofilaments, but the length and flexibility of these polymers has interesting implications for the site of this interaction. For example, if a motor binds to one end of a filament, it will pull the filament behind it in a fully extended conformation. However, if a motor binds away from the ends, the filament will be pulled from the somewhere in the middle, causing it to fold back on itself like an uneven hairpin with both ends trailing. To investigate the conformation of neurofilaments when they are moving, we transfected primary cultures of cortical neurons from newborn mice with GFP-tagged neurofilament protein M and then imaged the neurofilaments, which appear diffraction-limited in width, by time-lapse fluorescence microscopy. Our observations of 90 filaments revealed that the filaments are indeed very flexible and that they frequently exhibit complex and dynamic folding and unfolding behaviors, including hairpin loops, while they are pausing. Remarkably, however, when the neurofilaments move they almost always appear to be in a fully extended conformation. To test this quantitatively, we performed axial fluorescence intensity profiles along these filaments. Folding events were associated with a 2-3 fold increase in the fluorescence intensity along the folded portion of the filament, accompanied by a corresponding decrease in the filament length. To determine whether moving filaments ever show evidence of such folds, we analyzed 50 moving filaments, some anterograde and some retrograde. In all cases, the fluorescence was uniform along the filaments with no evidence of folding, even at the leading end. A statistical comparison of the fluorescence intensities in the leading, middle and trailing portions of the filaments revealed no significant difference. Thus we suggest that motors must bind to the ends of moving neurofilaments, regardless of their direction of motion, and this has intriguing implications for the mechanism by which motors interact with these cytoskeletal polymers.

1170

Interaction of neurofilaments with kinesin-1A and dynein/dynactin.

L. Wang[1], A. Uchida[1], A. Brown[1]; [1]Department of Neuroscience, The Ohio State University, Columbus, OH

Neurofilaments are synthesized in the nerve cell body and transported bidirectionally along axons by slow axonal transport. Direct observations of neurofilament transport in cultured neurons indicate that the slow rate is due to rapid movements interrupted by prolonged pauses. Previous studies suggest that the neurofilament motors include dynein/dynactin and kinesin-1A (KIF5A). However, while there is evidence for an interaction between neurofilaments and dynein/dynactin, there is no such evidence for kinesin-1A. Therefore, we examined the interaction of kinesin-1A and dynein/dynactin (p150 subunit) with neurofilaments using immunoprecipitation with magnetic beads. About 0.1% of the total kinesin-1A (average=0.08±0.05%; n=5) and about 0.5% of the total p150 (average=0.5±0.4%; n=6) immunoprecipitated with neurofilaments from mouse brain homogenate. In addition, about 0.1% of the neurofilament protein immunoprecipitated with kinesin-1A (average=0.13±0.1%; n=7), and about 0.7% with p150 (average=0.7±0.6%; n=5). These small percentages are expected

because (1) dynein and kinesin motors have multiple cargoes, (2) only a small proportion of neurofilaments are moving at any time, and (3) it is likely that a few motors are sufficient to move a single neurofilament. To test the specificity of the interaction, we designed a sequential immunoprecipitation approach, in which we first precipitated all the neurofilaments, and then we performed a second immunoprecipitation with the same antibody using the immuno-depleted supernatant from the first immunoprecipitation. We found that neurofilament antibody failed to precipitate kinesin-1A and p150 from the neurofilament-depleted supernatant in the second immunoprecipitation, even though both kinesin-1A and p150 were present in abundance. The reciprocal sequential immunoprecipitation experiment, using kinesin-1A or p150 antibody, yielded similar results. Finally, we found that kinesin-1A and p150 also co-purified and co-immunoprecipitated with neurofilaments from mouse and rat spinal cords. Together, these data suggest a specific interaction between neurofilaments and kinesin-1A and confirm the previously reported interaction between neurofilaments and dynein/dynactin.

1171

Presenilin and gamma-secretase control kinesin-1 and dynein motor activity in axonal transport.

S. Gunawardena[1]; [1]Biological Sciences, The State University of New York at Buffalo, Buffalo, NY

Neurons and other cells require intracellular transport of essential components for viability and function. Previous work suggested that the amyloid precursor protein (APP) can function as a kinesin-1 receptor during transport. However, how APP vesicle transport is regulated remains poorly understood. In this context we use genetic analysis and in vivo imaging in *Drosophila* to test the role of normal presenilin (PS) in APP transport. Our results show that reduction of PS suppresses axonal transport defects and blockages induced by excess human APP (hAPP). However, simultaneous reduction of PS and Drosophila APP-like protein (APPL) enhances axonal blockages induced by APPL loss. This PS-dependent enhancement is specific to APPL. No effect is seen with reduction of PS in the context of sunday driver (*syd*) mutants, which disrupt transport of a different class of vesicles. Further, increased velocities are observed for anterograde and retrograde APP vesicles in PS reduced axons. Strikingly, increased retrograde velocities can also be induced by pharmacological inhibition of gamma-secretase activity. These increased velocities require functional kinesin-1 and dynein motors. Our findings suggest that PS and gamma-secretase activity regulate APP intracellular transport by repressing kinesin -1 and dynein motor activity. Thus axonal transport defects induced by excess APP or loss of PS-mediated regulatory effects on APP vesicles could be a major cause of the neuronal defects observed in AD pathogenesis.

Vesicle Transport without Vesicle Motility: Firmly Attached Vesicles Take a Ride on Moving Microtubules.

V. Muresan[1], Z. Muresan[1]; [1]Pharmacology & Physiology, UMDNJ-New Jersey Medical School, Newark, NJ

Intracellular transport of vesicles over long distances – a process that occurs in all cells, but is particularly active in neurons - is powered by molecular motors, kinesins (plus-end movement) and cytoplasmic dynein (minus-end movement) that are recruited to, and move, individual vesicles along stationary microtubules. Yet, a fraction of intracellular vesicle trafficking may operate in a different, unexpected way. Earlier observations made by us while studying vesicle transport in squid axons and mammalian neurons suggest that some vesicles, rather than

recruiting molecular motors, appear steadily attached to short microtubules that glide over stationary cytoskeletal tracks. In this way, the vesicles take the ride by piggybacking on moving microtubule segments. Here, we present data in support of this novel form of vesicle transport. First, in proof of principle experiments, we found that in vitro generated vesicle-microtubule complexes move robustly over surfaces coated with active microtubule motors, kinesin-1, as well as cytoplasmic dynein. Second, video-enhanced DIC microscopy with extruded squid axoplasm often showed moving trains of vesicles, maintaining their relative interspacing, as if they were piggybacking on sliding microtubules; that this was the case was confirmed by observing the concerted movement of the clearly identifiable microtubule ends, and of the attached vesicles. Third, in cultured neuronal cells, we identified a specific set of vesicles that are likely transported in association with short, moving microtubules. These vesicles carry sAPP, a secreted polypeptide generated by proteolytic cleavage of the transmembrane protein, amyloid-β precursor protein (APP). We found that axonal transport of sAPP requires kinesin-1. Within neurites, sAPP – but not several other kinesin-1 cargo proteins - localizes exclusively to linear structures, with discontinuous distribution, which we identified as short, acetylated microtubules. With biochemical approaches, we found that, unlike the ATP-dependent binding of kinesin-1 to microtubules, the association of sAPP with microtubules is insensitive to ATP; this indicates that sAPP binding to microtubules does not involve motor proteins. The finding that, in axoplasmic spreads, anti-kinesin-1 antibodies heavily decorate microtubule segments, and not the attached vesicles, is consistent with our nonconventional model of vesicle transport by association with gliding microtubules. Overall, our data expand the current view on vesicle transport; we propose that, in addition to the long-accepted paradigm of individual vesicles moving independently along microtubules, molecular motors could transport en bloc trains of vesicles firmly attached to moving microtubules. GSK-3 negatively regulates bidirectional transport of APP and other cargos by altering the number of active molecular motors.

C. Leidel[1], C. Weaver[2], L. Szpankowski[2], N. M. Farley[1], L. S. B. Goldstein[2], G. T. Shubeita[1];
[1]Center for Nonlinear Dynamics, Department of Physics, The University of Texas at Austin, Austin, TX, [2]HHMI, Department of Cellular and Molecular Medicine, School of Medicine, The University of California, San Diego, La Jolla, CA

Alzheimer's disease is characterized by abnormal deposits of amyloid plaques which block important processes in neurons, leading to their deterioration. Deficient transport of the Amyloid Precursor Protein (APP) by kinesin-1 molecular motors has been linked to the development of these plaques. Uncovering the regulatory factors that enhance or inhibit axonal transport can lead to new targets for pharmaceutical treatments of neurodegenerative diseases. Glycogen Synthase Kinase 3 (GSK-3) , which has been linked to many aspects of the development of Alzheimer's disease, has also been proposed as a regulator of axonal kinesin-1. We use a combination of biophysical, biochemical and genetic techniques and analyses to examine the role GSK-3 plays in neuronal transport. Using *Drosophila* embryos and larvae with altered GSK-3 expression as our model system, we characterize motor transport of various cargos including APP using DIC microscopy, high-resolution video tracking, fluorescence, and force measurements made with optical tweezers. Comparing the forces, velocities, run lengths, and global distributions of cargos in environments with normal or deficient levels of GSK-3, we find that GSK-3 is a required negative regulator of *in vivo* transport by both kinesin-1 and cytoplasmic dynein, and that GSK-3 directly affects the motion of APP in larval axons and of lipid droplets in embryos. Stall force measurements indicate that GSK-3's regulatory role is not accomplished by weakening the motors, but by altering the number of motors that are actively

pulling at a given time. We find that motor-cargo binding is not affected by GSK-3, leading us to propose that its regulation occurs via a mechanism of changing motor-microtubule interactions.

1174

Cargo-Specific and Region-Dependent Axonal Transport Defects Induced by Tau.

M. Qiu[1], Y. Yu[1], G. Yang[1,2]; [1]Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, [2]Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA

Tau-mediated neurodegeneration has been identified as an important pathway for several human neurodegenerative diseases including Alzheimer's disease. It is thought that a possible mechanism of disease development is through tau induced axonal transport defects, which cause neuronal cell death. However, whether, and if so how, tau directly mediates transport defects *in vivo* remains controversial. In this study, we imaged and analyzed with high spatiotemporal resolution axonal transport *in vivo* in two tau transgenic *Drosophila* fly lines that express wild type human tau ($hTau^{WT}$) and a mutant human tau ($hTau^{R406W}$), respectively. To examine the effect of tau on cargoes carried by different motor proteins, transport of two types of vesicles were analyzed. Vesicles containing amyloid precursor protein (APP) tagged by yellow fluorescent protein (YFP) have been shown to be driven by kinesin-1, whereas vesicles containing sytaptotagmin (Synt) tagged with GFP have been shown to be driven by kinesin-3. Using the UAS/Gal4 system with a single neuron driver line, APP-YFP or Synt-GFP was expressed in several neurons in the ventral ganglion of Drosophila 3rd instar larvae. We collected and analyzed time-lapse movies of four equally spaced regions along the proximal-distal axis of axons within the segmental nerves. For APP-YFP vesicles in both tau transgenic animals, there was a significant increase in the fraction of stationary vesicles as well as significant decrease in anterograde velocity, whereas the retrograde transport was not affected. In contrast, transport of Synt-GFP vesicles was not significantly impaired in terms of their velocity, run length and pause frequency in either anterograde or retrograde direction. We then checked for any regional differences of axonal transport defects and found stronger impairment closer to the distal end. Surprisingly, both vesicles paused less frequently under the background of either type of tau in almost all regions along the axon. Together, our data revealed that tau induced cargo-specific and region-dependent axonal transport defects.

1175

The Schizophrenia-Related Protein, DISC1, Controls Production of Amyloid-β (Aβ), a Pathogenic Peptide Implicated in Alzheimer's Disease (AD), by Regulating Trafficking of Aβ Precursor Protein (APP) along Secretory, Endocytic, and Degradative Routes.

V. Muresan[1], Z. Muresan[1]; [1]Pharmacology & Physiology, UMDNJ - New Jersey Medical School, Newark, NJ

APP, a type-I transmembrane protein is proteolytically processed into N-terminal (NTFs) and C-terminal fragments (CTFs), and the 38-43-residue Aβ peptides. Overaccumulation of Aβ fragments in neurons is a risk factor for AD. The mechanisms that control the levels of Aβ in neurons are still elusive. We discovered that DISC1, the product of a susceptibility gene for schizophrenia, positively regulates the neuronal load of Aβ: decreased expression of DISC1 renders intracellular Aβ undetectable, whereas the neurons that express high levels of DISC1 accumulate high amounts of Aβ, in culture and in the AD brain. Since DISC1 binds the microtubule motors kinesin-1 and cytoplasmic dynein, we examined whether the transport function of DISC1 is required for accumulation of Aβ in neurons. We found that Aβ is generated through endocytic processes that begin in the soma, and continue during transport into the neurites. We also found that CTFs and Aβ, but not NTFs accumulate in the Rab11-positive, endosomal recycling compartment (ERC) in the soma, indicating that the proteolytic processing

of APP, and sorting of generated fragments begins in the early endocytic route. Within neurites, Aβ is detected within the Rab7-positive, late endosomes, with size and frequency increasing towards the terminals. This suggests that Aβ is generated from CTFs within the anterograde-moving endosomes. DISC1 precisely colocalizes with the CTFs and Aβ at ERC, and with Aβ at the Rab7-positive endosomes, indicating that it is implicated in the transport of endosomal vesicles, where Aβ is generated from CTFs. The inactivation of kinesin-1, by silencing expression of the light chains with siRNA, decreases accumulation of Aβ in neurites to 25%, suggesting that transport of the Aβ- and DISC1-containing late endosomes requires kinesin-1. Silencing DISC1, or impeding dynein function with Lis1 siRNA, decreases the level of Aβ in ERC, indicating that these treatments block APP processing upstream of ERC. These results suggest a model were generation of Aβ begins in early endosomes that progress into ERC by DISC1-, and dynein-mediated transport, and continues in late endosomes, transported by kinesin-1 into neurites. DISC1 facilitates both transport events by recruiting dynein to the APP-containing endocytic vesicles moving toward ERC, and kinesin-1 to ERC-derived endosomal vesicles, carrying Aβ and CTFs, which gradually mature into late endosomes as they advance into neurites. Thus, DISC1 could modulate neuronal levels of Aβ by participating in generation and clearance of Aβ, as part of the molecular complex regulating the transit of APP species through the compartments where Aβ is generated and degraded. These data implicate DISC1 – a schizophrenia-related protein – in the pathogenic mechanism of AD. Supported by NIH awards AG039668 (Z.M.), GM068596 (V.M., Z.M.).

BDNF mediates competitive interactions between individual cortical neurons.

C. N. English[1], A. J. Vigers[1], K. R. Jones[1]; [1]Molecular, Cellular, and Developmental Biology, University of Colorado, Boulder, CO

Reduced expression of Brain Derived Neurotrophic Factor (BDNF) is observed in many neurological disorders, including Alzheimer's, Huntington's, and Parkinson's diseases and may contribute to neurodegeneration. We previously reported that the loss of forebrain BDNF in conditional knockout mice recapitulates aspects of these diseases including shrinkage of associated brain regions, smaller neuron soma size, decreased dendritic arbor complexity, and reduced dendritic spine density. A variety of evidence indicates that BDNF can be expressed and secreted both pre- and post-synaptically by cortical neurons. The relevance of the associated anterograde and retrograde signaling pathways to features of cellular neurodegeneration has not been described at the single cell level. To determine if BDNF is cell autonomously required for the formation and maintenance of dendritic spines, the structural site at which most excitatory synapses in the mammalian brain occur, we injected visual cortex of mice that were heterozygous or homozygous for a floxed BDNF transgene with Adeno-associated virus with cre (AAV-Cre). AAV-Cre infects isolated cortical neurons, and analysis of the resulting isolated mutant layer 2/3 neurons demonstrated a cell-autonomous requirement for BDNF. Dendritic spine density was reduced in isolated mutant neurons, when these isolated neurons were surrounded by cells with higher levels of BDNF. In contrast mutant neurons surrounded by cells with lower BDNF levels did not show the same reduction of spine density. This comparison amongst genotypes provides strong evidence for an essential requirement for BDNF in mediating competitive interactions that determine dendritic spine density. Furthermore, these data demonstrate that isolated BDNF mutant neurons cannot be rescued by their wild-type neighbors, indicating that BDNF signals at the level of individual neurons in the cortex. These data support a model in which the formation and/or stabilization of some cortical excitatory synapses relies upon competition for a post-synaptic supply of BDNF.

Amyloid-beta oligomers induce tau-independent disruption of fast axonal transport via calcineurin in cultured hippocampal neurons.

E. M. Ramser[1], K. J. Gan[2], E. Y. Fan[1], M. A. Silverman[1,2]; [1]Dept. of Biological Sciences, Simon Fraser University, Burnaby, BC, Canada, [2]Dept. of Molecular Biology and Biochemistry, Simon Fraser University, BC, Canada, Burnaby, BC, Canada

Emerging evidence suggests that fast axonal transport (FAT) defects are early pathological manifestations of Alzheimer's disease (AD). We have previously shown that soluble amyloid beta oligomers (AβOs), a causative agent of AD, impede FAT of dense core vesicles (DCVs) in cultured hippocampal neurons. AβOs induce hyperphosphorylation of the axonal microtubule-associated protein, tau; however, it remains unclear how this modification disrupts transport. To determine whether tau is required for AβO-induced transport defects, we treated hippocampal neurons from wildtype (WT) and tau knockout (KO) mice with nanomolar concentrations of AβOs. We subsequently assessed DCV transport by live cell imaging of fluorescently-tagged brain-derived neurotrophic factor (BDNF). AβOs reduced DCV bidirectional transport similarly in WT and tau KO neurons, suggesting that tau is not initially involved in AβO-induced DCV transport defects. To investigate whether tau-independent FAT disruption results from changes in microtubule modifications and stability, we assessed tubulin acetylation, tyrosination and polymerization by immunocytochemistry and immunoblotting. In WT and tau KO neurons, AβOs did not induce significant changes in these characteristics. Thus, transport defects may result from dysregulation of intracellular signaling cascades that are implicated in AD pathogenesis. We hypothesized that AβO-disrupted transport results from tau-independent dysregulation of intracellular signaling cascades that activate calcineurin (CaN) and protein phosphatase 1 (PP1). PP1 is inhibited by protein phosphatase inhibitor-2 (I-2) and activated by CaN, a calcium/calmodulin-dependent phosphatase that is upregulated in the presence of AβOs. CaN inhibition using FK506 in cultured neurons from WT and tau KO mice not only rescued, but reversed AβO-induced FAT defects. Moreover, overexpression of I-2 prevented AβO-induced transport defects in hippocampal neurons from WT and tau KO mice. Our results indicate that AβO-induced FAT disruption is independent of tau and microtubule destabilization, and that this dysregulation is mediated by CaN. Work is ongoing to investigate novel roles for aberrant calcium signaling in motor protein inhibition and AD pathogenesis.

1178

Autophagosome biogenesis in primary neurons occurs distally followed by maturation during transport to the cell soma.

S. Maday[1], K. Wallace[1], E. Holzbaur[1]; [1]Department of Physiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA

Autophagy is an essential lysosomal degradation pathway in neurons. To determine the spatial and temporal dynamics of autophagosome biogenesis in primary neurons, we isolated dorsal root ganglion neurons from transgenic mice expressing the autophagosome marker GFP-LC3. Live-cell imaging of GFP-LC3 revealed the robust, constitutive initiation of autophagosomes in the distal end of the neurite. GFP-LC3 is incorporated into ring-like structures an average of 813 ± 23 (± SEM) nm in diameter. Multiple rings accumulate within a single bulbous region at the neurite tip. We used FRAP to analyze the origin of these autophagosomes and observed *de novo* formation of rings, while pre-existing rings did not recover their GFP-LC3 fluorescence indicating stable incorporation of LC3. While the distal population of GFP-LC3 rings exhibited bidirectional motility, autophagosomes that escaped from this compartment moved in a robust retrograde manner over hundreds of microns to the cell soma. 82 ± 2 (± SEM) percent of autophagosomes were minus end-directed, moving along microtubules at an average velocity of

0.45 ± 0.01 (± SEM) µm/sec with few pauses or reversals in direction. This motility is driven by cytoplasmic dynein and was blocked by expression of the dynein inhibitor CC1. To observe the maturation of autophagosomes along the axon, we expressed the dual reporter construct mCherry-GFP-LC3; the GFP is preferentially quenched in acidic environments. Distal organelles were positive for both markers, but we observed an increasing gradient of red-only organelles along the axon. Proximal to the cell body 69 ± 5 (± SEM) percent of LC3-puncta were positive for mCherry only. These results suggest that autophagosomes mature as they move distally to proximally along the axon. This maturation was accompanied by a shift in motility from robust retrograde movement toward more bidirectional motility characteristic of lysosomes. Bidirectional autophagosomes proximal to the cell body were positive for the lysosomal marker LAMP-1, consistent with maturation into autolysosomes. Taken together, these results support a model in which autophagosomes originate distally and mature into autolysosomes during transport toward the cell soma in primary neurons.

1179

A kinesin-II tail guides the diffusive flow of choline acetyltransferase in *Drosophila* axons.

A. Sadananda[1], R. Arif[1], S. Jana C[1], H. Doodhi[1], M. Girotra[1], D. Ghosal[1], V. Kumar[2], K. Ray[1], G. Menon[2]; [1]Dept. of Biological Sciences, Tata Institute of Fundamental Research, Mumbai, India, [2]The Institute of Mathematical Sciences

More than 200 soluble proteins are transported at about 2-10 mm/day in the axon, which is far slower than the transports of membrane-bound cargoes. The underlying mechanisms are mostly unknown. For instance, choline acetyltransferase (ChAT), a soluble enzyme that catalyzes acetylcholine synthesis, is produced in the neuronal cell bodies and transported to the presynaptic compartments at 1.25 mm/day, which is perceived to be diffusion based. Previous studies showed that the process requires heterotrimeric kinesin-II family motor comprising KLP64D, KLP68D and DmKAP in *Drosophila*. Soluble ChAT also coprecipitates with kinesin-II subunits. Here, we show that both endogenous ChAT and Green Fluorescent Protein (GFP)-tagged recombinant ChAT (GFP:ChAT) associate with kinesin-II through a specific and direct binding to KLP64D tail, which is essential for its transport in the axons. In addition, the apparently diffusive propagation of GFP:ChAT has an anterograde bias in the axons for a limited period. Altogether, these evidences suggest that direct interactions of soluble proteins with motors could actively regulate diffusive movements in cytoplasm.

Mutation of a Zinc Finger Polyadenosine RNA Binding Protein Causes Autosomal Recessive Intellectual Disability in Humans and Neuronal Dysfunction in a Drosophila Model: A Critical Role for Control of Poly(A) Tail Length.

A. H. Corbett[1], C. Pak[1,2], M. Garshasbi[3], K. Kahrizi[4], C. Gross[2], L. H. Apponi[5], J. J. Noto[1,2], S. M. Kelly[2], S. W. Leung[1], Y. Feng[5], S. Sanyal[2], G. J. Bassell[2], H-H. Ropers[3], H. Najmabadi[4], K. H. Moberg[2], A. Kuss[3,6]; [1]Biochemistry, Emory University School of Medicine, Atlanta, GA, [2]Cell Biology, Emory University School of Medicine, [3]Human Molecular Genetics, Max-Planck Institute for Molecular Genetics, [4]Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, [5]Pharmacology, Emory University School of Medicine, [6]Human Genetics, Ernst Moritz Arndt University

We have identified the first gene encoding a polyadenosine RNA binding protein, ZC3H14, which is mutated in inherited nonsyndromic autosomal recessive intellectual disability. ZC3H14 is a member of a novel class of tandem zinc finger polyadenosine RNA binding proteins. The polyadenosine RNA binding module in these proteins consists of tandem CCCH zinc fingers

such as those found in the essential Saccharomyces cerevisiae Nuclear poly(A)-Binding protein 2 (Nab2) and human ZC3H14. Studies of ZC3H14 in higher eukaryotes are extremely limited. Most information about this class of proteins thus far comes from studies of S. cerevisiae Nab2. Although Nab2 mutants have defects in poly(A) RNA export from the nucleus and control of poly(A) tail length, neither the precise molecular function of Nab2 nor the function of this class of proteins in higher eukaryotes is known. We present here the first studies aimed at understanding the function of ZC3H14. We show that ZC3H13 is located in nuclear speckles and also targeted to axons of cultured primary neurons supporting a role in post-transcriptional regulation of gene expression. Behavioral studies in a dNab2 mutant fly model confirm a critical role for dNab2 in neurons consistent with the nonsyndromic form of intellectual disability seen in patients. Taken together, results from these studies show that this class of zinc finger polyadenosine RNA binding proteins is required for proper development and brain function.

1181

Transport of mRNA in the Projections of Maturing Hippocampal Neurons.

G. Pathak[1], J. Love[2], J. Chetta[2], S. Shah[3]; [1]University of Maryland, Burtonsville, MD, [2]University of Maryland, [3]UCSD

Introduction: Translation of mRNA in axons and dendrites enables a rapid supply of proteins to specific sites of localization within the neuron. Distinct populations of mRNA-containing cargoes, including granules and mitochondrial mRNA, are transported with neuronal projections. The distributions of these cargoes appear to change during neuronal development, but details on the dynamics of mRNA transport during these transitions remain to be elucidated. The goal of this project is to characterize transport of mitochondrial and non-mitochondrial mRNA in neuronal projections during the development of hippocampal neurons.

Materials and Methods: Hippocampal neurons of one day old rat neonates were cultured on poly-lysine-coated glass cover slips. The neurons were co-labeled with dyes (Invitrogen) marking mRNA and mitochondria, to distinguish mRNA from mitochondrial mRNA. Live fluorescence imaging were performed on three different days, corresponding to different stages of development: **day 4,** when neurons have differentiated, but do not contact other neurons, **day 7**, when they form immature synaptic contacts, and **day 12** when they form mature synapses. Maturity of the neurons was determined via immunolabeling with PSD95, a post-synaptic marker. Immunolabeling with SMI-31, an axon-specific marker, was performed to differentiate axon and dendrites. Parameters of mRNA trafficking were quantified via kymograph (graph of spatial position over time). Statistical analysis was performed by Kolmogorov-Smirnov (K-S) test and ANOVA : Tukey.

Results and Discussion: The results suggest differences in the transport pattern of mitochondrial and non-mitochondrial mRNA, and also indicate significant differences in transport parameters at different time points. Higher mRNA velocity in growing neurons compared to mature neurons was observed. In addition, the mRNA flux increases during growth as it forms mature synapse, presumably because local protein synthesis is essential for long term potential.

Conclusions: The results suggest significance of local protein synthesis during growth of the neurons. To better understand the logic underlying altered mRNA transport, we are currently exploring transport mechanism of mRNA, and its importance in regeneration. This work has important implications for the regulation of neuronal plasticity during neuronal development and in response to neuronal injury.

The effects of oxygen concentration on mitochondrial function and morphology in SH-SY5Y cells.

L. M. Tiede[1], L. M. Villaneuve[1], H. Fox[1]; [1]Pharmacology and Exp Neuroscience, University of Nebraska Medical Center, Omaha, NE

Neurodegeneration is a high-priority matter facing the aging population. Recent research has identified mitochondrial function as critical in the development of neurodegenerative disorders. As such, mitochondria have been extensively studied with loss of mitochondrial integrity being linked to disease progression. While oxygen levels are tightly regulated in vivo, neurons grown in vitro are commonly exposed to atmospheric oxygen levels which is up to 10-fold higher than in tissues. On this basis, we hypothesized that culturing SH-SY5Y cells, a neuroblastoma cell line, at atmospheric oxygen levels detrimentally impacts mitochondrial homeostasis when compared to culturing at physiological oxygen levels. To test this hypothesis, quantitative imaging techniques were utilized. Through the use of a combination of mitochondrial dyes including JC-1, dihydrorhodamine 123, and Mitotracker Red, the contribution of oxygen level to mitochondrial polarization, reactive oxygen species production, and mitochondrial morphology was identified. Furthermore, the impact of oxygen level on mitochondrial markers such as Mfn1, Mfn2, the oxidation-phosphorylation complexes, DRP1, SOD2, Pink1, and GAPDH was evaluated through immunoblotting. Our results show that SH-SY5Y cells cultured at 5% oxygen, an oxygen level similar to the level found in the brain, exhibited a higher mitochondrial potential, a lower production rate of reactive oxygen species, a larger cytosolic fraction of mitochondria, and a more extensive mitochondrial network than neurons cultured at 2% or 21% (atmospheric) oxygen. Furthermore, the expression of several subunits of complexes in the oxidation-phosphorylation cycle were altered in SH-SY5Y cells cultured at 5% oxygen compared to those cultured in higher or lower oxygen, suggesting a correlation between mitochondrial protein expression and mitochondrial structure/function under optimal oxygen levels. Further tests of the effects of these changes in expression on mitochondrial polarization and cellular ATP production were conducted using inhibitors of the various mitochondrial complexes. These data indicate that neuronal cultures in vitro require close regulation of oxygen levels to properly mimic in vivo systems.

1183

Impaired Mitochondrial Function, Axonal Transport and Morphology in the Neurons of *PINK1* Mutants of *Drosophila.*

S. Devireddy[1], E. Garland-Kuntz[1], L. Pallanck[2], P. J. Hollenbeck[1]; [1]Biological Sciences, Purdue University, West Lafayette, IN, [2]Genome Sciences, University of Washington, Seattle, WA

Parkinson’s disease is a common neurodegenerative disease that can be caused by loss-of-function mutations in the mitochondrial serine/threonine kinase *PINK1* and the E3 ubiquitin ligase *Parkin*. Studies in cultured cells suggest that these proteins play roles in the mitochondrial quality control system that targets depolarized mitochondria for autophagic degradation. To explore the role of PINK1 in the intact nervous system, we used live imaging of the intact larval nervous system of *Drosophila PINK1* mutants to examine mitochondrial function, behavior and morphology. We observed substantially diminished mitochondrial membrane potential in the neurons of *PINK1*^{B9}mutants compared to wild type. Analysis of mitochondrial transport parameters in motor neurons of segmental nerves (SNs) of *PINK1*^{B9} mutants showed that mitochondrial velocities were decreased in both anterograde and retrograde directions and mitochondrial duty cycles were also reduced, with a higher percentage of time being stationary. In addition, we observed an increase in the lengths of the stationary pool of mitochondria in motor axons of SNs of *PINK1*^{B9}mutants compared to wild type. These

results suggest that the cellular neuropathology of *PINK1* mutants involves not just mitochondrial turnover, but also defects in mitochondrial function, transport and morphology.

1184

Expression of Mitochondrial Molecular Motors in Substantia Nigra Before Neurodegeneration-Related Protein Aggregation. A Study in Primary Cell Cultures and Aged Rats.

T. Q. Melo[1], R. S. Chaves[1], A. M. D'Unhao[1], K. L. Farizatto[1], M. F. Ferrari[1]; [1]Departamento de Genetica e Biologia Evolutiva, Instituto de Biociencias, Universidade de Sao Paulo, Sao Paulo, Brazil

Neurodegeneration is often accompanied by intra- and extracellular protein aggregation found throughout the central nervous system. However whether the aggregation is the cause or consequence for cell physiology impairment remains to be determined. The better understanding of the relationship between mitochondria trafficking and protein aggregation is an important step to clarify many aspects of neurodegeneration. In view of this the objective of the present study is to analyze the expression of synthaphilin, kinesins 1 and 5, dynein C1H1 and dynactin which are related to anchoring, anterograde and retrograde traffic of mitochondria. This study was performed before protein aggregation promoted by low doses of rotenone. METHODS: Primary cell cultures from substantia nigra (SN) of newborn Lewis rats were exposed to 0.1, 0.3 or 0.5nM of rotenone during 48h. Twelve-month old Lewis rats received continuous subcutaneous infusion of rotenone (1mg/kg/day) through minipumps during 4 weeks. Cells and age-matched rats were exposed to DMSO as control. Extracted protein from SN (cultures and rats) was analyzed through Western Blot. Experiments were performed in triplicates and evaluated by Student's t-test or one-way ANOVA. RESULTS: Rotenone decreased the expression of syntaphilin in SN cultured cells in a dose-dependent manner, and increased it by 200% in SN of aged rats exposed to 1mg/kg/day of rotenone. Kinesin 1 was 150% up-regulated in vitro after 0.5nM of rotenone, while it was observed a decrease in its expression in aged rats. Rotenone decreased (30%) the expression of kinesin 5 at the concentration of 0.1nM; and increased it (50%) after 0.5nM in cultured cells. Aged rats did not show any change in kinesin 5 expression after 1mg/kg/day of rotenone. In vitro dynein expression slightly decreased after 0.3nM and increased 30% after 0.5nM of rotenone. Aged rats presented decreased expression of dynein C1H1 in SN after rotenone. Dynactin expression was 50% decreased after 0.1nM and increased 30% after 0.3nM of rotenone in cultured cells. Aged rotenone-exposed rats showed a 2-fold increase in dynactin expression. CONCLUSION: Overall the results suggest that mitochondrial traffic may be altered before protein aggregation in SN, and the in vivo results may be comparable to cultured cells exposed to 0.3nM of rotenone. The present findings add to the understanding of the pathophysiology underlying neurodegenerative diseases.

Analysis of competition between cargo motor receptors during active transport in the squid giant axon: Evidence for a hierarchy of motor-affinities.

P. E. Seamster[1], E. L. Bearer[1,2], Z. Harris[3], M. Loewenberg[4], J. DeGiorgis[5,6], V. Cristini[7,8]; [1]Department of Pathology, University of New Mexico, Albuquerque, NM, [2]Cancer Center, University of New Mexico, [3]Department of Chemical and Nuclear Engineering, University of New Mexico, [4]Department of Chemical Engineering, Yale University, [5]Marine Biological Laboratory, [6]Providence College Department of Biology, [7]University of New Mexico, [8]University of New Mexico Cancer Center

Transport of membrane bound organelles requires microtubule tracks and molecular motors such as the kinesins and dynein to carry cargo. To attach vesicular cargo to specific motors requires binding sites on the cargo which we have identified as peptide zipcodes. We first described a 15 amino acid sequence within the carboxyl-terminus of APP uniquely sufficient to mediate transport of 100 nm plastic beads in the squid giant axon, and now report a 14 amino acid sequence from the JIP-1 MAPK scaffolding protein as another cargo-motor receptor. This adds to two other already known cargo motor receptors, negative charge and the lipid, phosphatidyl insotide. While JIP-1, APP-C and negative charge all display similar velocities consistent with fast axonal transport, they display markedly different biophysical properties such as run length, frequency of pauses, and pause durations. JIP-1 is significantly more efficient in these properties than APP-C and negative charge. All of these cargo motor receptors are competitive with each other for transport machinery. As analyzed by non-parametric statistical algorithms such as cumulative probabilities and Kolmogorov-Smirnov null hypothesis, these differences are highly significant ($P<0.004$). We are applying multiscale mathematical modeling using partial differential equations combined with individual motor-cargo dynamics informed by vector-based analysis of peptide-bead trajectories to predict and characterize behaviors of these cargo motor receptors. Three-dimensional immunofluorescence analysis of the squid axonal cytoskeleton is used to produce dimensions for inter-microtubule distances necessary to predict transit time between microtubule tracks. This powerful combination of engineered cargo dynamics, biophysical measurements and mathematical modeling will enable us to better understand how cargo motor receptors recruit and compete for transport machinery. Supported by NS062184; NS046810 and P5OGM08273 (ELB), DGE-0549500 (P.E.S.) and 1U54CA143837 (V.C.)

1186

Mechanistic logic behind intracellular trafficking of cytosolic cargoes - a new trafficking paradigm.

S. Roy[1], D. Scott[2], U. Das[2], Y. Tang[2]; [1]Neurosciences, UCSD, La Jolla, CA, [2]UCSD

Proteins vital to axonal and presynaptic function are synthesized in the neuronal perikarya and delivered into synapses via two modes of axonal transport. While membrane anchoring proteins are conveyed in fast axonal transport via motor-driven vesicles, cytosolic proteins travel in slow axonal transport via mechanisms that are poorly understood. We found that in cultured axons, populations of cytosolic proteins tagged to photoactivatable GFP (PAGFP) move with a peculiar slow motor-dependent anterograde bias distinct from both vesicular trafficking and diffusion of untagged PAGFP (1, see fig.). The overall bias is likely generated by an intricate particle kinetics involving transient assembly and short-range vectorial spurts; qualitatively and quantitatively distinct from classical modes of axonal transport. In vivo biochemical studies reveal that cytosolic proteins are organized into higher order structures within axon-enriched fractions that are largely segregated from vesicles. Data-driven biophysical modeling best predicts a scenario where soluble molecules dynamically assemble into mobile supramolecular

structures. We propose a model where cytosolic proteins are transported by dynamically assembling into multiprotein complexes that are directly/indirectly conveyed by motors. As cytosolic protein mobility is seen in all cells, this is likely a conserved mechanism for such transport, and we will show some evidence supporting that. We will also present MudPIT-MS data identifying the members of cytosolic protein complexes.

Jip3-Jnk interaction mediates retrograde axonal transport and axon health.

C. M. Drerup[1], G. Banker[1], A. Nechiporuk[1]; [1]Oregon Health & Science Univ, Portland, OR

Neural circuit assembly and maintenance requires active, axonal transport of proteins and organelles away from (anterograde) and towards (retrograde) the neuronal cell body. This transport is driven by conserved, microtubule-based motors of the Kinesin and Dynein families. Abnormalities in axon transport have been implicated in numerous neurodegenerative and neurodevelopmental diseases but, to date, a vertebrate system in which to analyze this process *in vivo* during development and maintenance of a neural circuit had not been developed. We have developed the posterior lateral line system of the zebrafish for this purpose. The posterior lateral line nerve is comprised of a small number of long, superficial, and planar axons whose stereotyped development has been thoroughly characterized. Additionally, as larval zebrafish are optically transparent, we can visualize transport of fluorescently tagged cargo of interest, expressed under the control of neuron-specific promoters, in these superficial axons without the use of invasive techniques. We used this new approach in conjunction with an ENU-based forward mutagenesis screen to identify zebrafish mutants with abnormalities in axon transport. One of these mutants, *rogue*^{nl7}, carries a loss-of-function mutation in *jnk-interacting protein 3* (*jip3*). Jip3 has been shown to interact with both the light and heavy chains of the Kinesin-1 molecular motor, components of the Dynein complex, and the Jnk signaling module. *rogue*^{nl7}mutant axons displayed large swellings at axonal terminals and, surprisingly, accumulation of activated Jnk (pJnk). *In vivo* analysis of Jnk transport utilizing our newly developed technique revealed a specific decrease in the frequency of retrograde transport of Jnk though distance and velocity traveled by motile puncta were normal. Similarly, general membrane-bound cargo also displayed decreased frequency of retrograde movement and accumulation in the terminal swellings. Immunolabeling experiments indicated that endogenous dynein motor components, Dynein Heavy Chain and p150^{glued}, were distributed normally at *rogue*^{nl7}axon terminals, indicating that retrograde transport was not globally disrupted in the absence of Jip3. Importantly, exogenous expression of Jip3 lacking the Jnk binding domain rescued neither retrograde transport deficits nor axonal swellings. This implicates Jip3-Jnk interaction specifically in retrograde Jnk transport and the generation of axonal swellings. In summary, our results reveal a novel role for Jip3 in the retrograde transport of an active kinase, which in turn affects retrograde transport of other cargo and subsequent axon health.

1188

The vesicular SNARE Synaptobrevin is required for Semaphorin 3A axonal repulsion.

K. Zylbersztejn[1], M. Petkovic[1], A. . Burgo[1], M. Deck[2], S. Garel[2], S. Marcos[3], E. Bloch-Gallego[3], F. Nothias[4], G. Serini[5], D. Bagnard[6], T. Binz[7], T. Galli[1]; [1]Institute Jacques Monod, Paris, France, Metropolitan, [2]IBENS, Paris, France, Metropolitan, [3]Institute Cochin, Paris, France, Metropolitan, [4]University Pierre and Marie Curie, Paris, France, Metropolitan, [5]University of Torino School of Medicine, Torino, Italy, [6]INSERM U682, Strasbourg, France, Metropolitan, [7]Institute of Biochemistry, Medizinische Hochschule Hannover, Hannover, France, Metropolitan

Attractive and repulsive molecules such as Semaphorins (Sema) trigger rapid responses which control the navigation of axonal growth cones. The role of vesicular traffic in axonal guidance is still largely unknown. We set out to address the potential role in axonal guidance of exocytic vesicular SNARE Synaptobrevin 2 (Syb2). Here, we took advantage of clostridial neurotoxins and genetic invalidation to demonstrate that Syb2 is required for Sema3A-dependent repulsion but not Sema3C-dependent attraction in cultured neurons and in the mouse brain. Further, more we have shown that Syb2 associates with Neuropilin 1 and Plexin A1, two essential components of the Sema3A receptor, via its juxta-transmembrane domain and Sema3A receptor and Syb2 colocalize in endosomal membranes. Moreover, upon Sema3A treatment, Syb2 deficient neurons fail to collapse and transport PlexinA1 to cell bodies. Reconstitution of Sema3A receptor in non-neuronal cells revealed that Sema3A further inhibits the exocytosis of Syb2. Therefore, Sema3A-mediated signalling and axonal repulsion require Syb2-dependent vesicular traffic.

Possible Protein Interaction between Maspardin and ALDH18A1 in Mast Syndrome.

M. A. Mason[1], M. C. Hanna[1]; [1]Biological and Environmental Sciences, Texas A&M University-Commerce, Commerce, TX

Hereditary Spastic Paraplegias (HSPs) are a family of neurological disorders characterized by weakness and spasticity of the lower limbs and sensory impairment. Mast syndrome is a complicated, autosomal recessive form of HSP exhibiting symptoms of dementia, thinning of the corpus callosum, white matter abnormalities, and spastic paraperesis. Patients with Mast syndrome carry a mutation along their SPG21 gene producing a frame shift and premature stop codon. Thus, Mast syndrome is likely due to loss of functional maspardin protein. Previous studies demonstrate maspardin interacts with ALDH16A1 and following maspardin deletion aldehyde dehydrogenase ALDH18A1, another member of the ALDH superfamily, was upregulation 1.66 fold suggesting an interaction between ALDH18A1 and maspardin may occur. Previous studies indicate patients with a missense mutation, R84Q, along the ALDH18A1 gene have reduced activity of both isoforms thus causing deficiencies of proline, arginine, and ornithine. Since other enzymes are dependent on the correct production of these amino acids, homeostasis throughout the body is also disturbed. Patients with this mutation exhibit progressive neurodegeneration, joint laxity, and bilateral subcapsular cataracts suggesting a link between ALDH18A1 and other neurodegeneration diseases. Interactions between ALDH18A1 and maspardin are being studied using numerous molecular, genetic, and cellular techniques. Correct ALDH18A1 gene and Myc tag vector have been identified and a PCR reaction performed amplifying ALDH18A1 insert. Dephosphorylation of vector, purification of vector and insert, ligation, and transformation of vector and insert into E. coli cells have also been executed. Successful cloning of insert and orientation has been confirmed. In vitro and in vivo immunoprecipitation analyses suggest an interaction occurs, whether this is interaction is direct or indirect will be determined as well as the interaction domains.

1190

Possible Contribution of Kinesin-1 to Mast syndrome.

S. Brookins[1], M. Hanna[1]; [1]Biological Sciences, Texas A&M University-Commerce, Commerce, TX

The hereditary spastic paraplegias (HSPs) are a group of neurological disorders characterized by progressive lower-limb spasticity and weakness. One autosomal recessive form of HSP, Mast syndrome (SPG21; MIM 248900), is caused by mutation in the SPG21 gene, which encodes a protein, maspardin, of unknown function. Studies suggest that normal functions of maspardin include protein sorting in the late endosomal/lysosomal pathway and mediating changes in intracellular protein targeting. We will investigate this function by studying the interaction of maspardin and a family of kinesin-1 motor proteins. The kinesin-1 proteins are microtubule motors involved in transport of membranous organelles down the axon and include Kif5a, Kif5b, and Kif5c. Another form of HSP, SPG10, is caused by mutations in Kif5a. In addition, it was revealed through gene chip analysis that Kif5b was upregulated 2.70 fold in the absence of maspardin, which suggests a possible interaction exists. Immunoprecipitation confirmed an interaction between maspardin and kinesin-1 protein, however there was no distinction between the Kif5 isoforms. The various Kif5 isoforms have been cloned into a pGW1-myc-tagged mammalian expression vector, and overexpressed in cell culture. Following SDS-PAGE, isoforms are detected using anti-myc monolclonal antibodies via western analysis. Direct interaction is supported by GST-fusion pull down. We hypothesize that a Kif5 isoform interacts with maspardin and disruption of this interaction contributes to neuropathogenesis. Therefore investigation into subcellular localization and changes following protein deletion between maspardin and Kif5a, Kif5b, and/or Kif5c have commenced.

Host Pathogen/Host-Commensal Interactions II

Mechanisms of endothelial cell infection by *Listeria monocytogenes.*

M. Rengarajan[1], J. A. Theriot[1,2]; [1]Biochemistry Department, Stanford University, Stanford, CA, [2]Microbiology and Immunology, Stanford University

The ubiquitous food-borne bacterium *Listeria monocytogenes*, though ordinarily an agent of gastroenteritis, causes sepsis in pregnant women and meningitis in immune-compromised hosts. The interaction of *L. monocytogenes* with the mammalian gut epithelium has been extensively studied, but less is understood about how *L. monocytogenes* spreads from the digestive tract to infect distal sites, such as the placenta or the central nervous system. Generally, upon entering a host cell, the bacterium harnesses that cell's actin machinery to move within individual cells and from one cell to another, without exposure to the extracellular space. In particular, the bacterium expresses the protein ActA, which activates Arp2/3 to polymerize actin at the bacterial surface; polarized actin polymerization propels the bacterium through the cytoplasm.

We are examining how *L. monocytogenes* is able to subvert cellular barriers during systemic infection; we are primarily focused on its subversion of the vascular endothelium, a single layer of cells that lines the blood vessels and represents a significant barrier to bacterial spread to organs distant from the gut. The most likely mechanisms of bypassing the barrier properties of the endothelium include: direct infection of endothelial cells, infection of endothelial cells via cell-to-cell spread from infected circulating immune system cells, and transmigration of infected

immune system cells across an uninfected endothelium. We have demonstrated that *L. monocytogenes* in infected macrophages can robustly infect monolayers of HUVEC via direct heterotypic cell-to-cell spread, in an ActA-dependent manner. Additionally, we have used fluorescence microscopy to confirm that *L. monocytogenes* can also directly invade a monolayer of human umbilical vein endothelial cells (HUVEC). In the latter case, experiments with an *ΔactA* strain have revealed that while a small fraction of cells (<5%) are directly invaded by *L. monocytogenes*, most infected cells in a sheet are infected by homotypic cell-to-cell spread of bacteria from previously infected HUVEC. Furthermore, we have determined that infected HUVEC divide normally; this process likely contributes to bacterial spread in a sheet. Using time-lapse microscopy, we have observed the *L. monocytogenes* life cycle in infected HUVEC and determined that intra-cytoplasmic bacteria form long filaments in HUVEC that we did not see with epithelial or endothelial cell lines. We are currently exploring how the specific cytoplasmic milieu of endothelial cells influences the bacterial life cycle.

1192

Defensins Enable Macrophages to Inhibit the Intracellular Proliferation of *Listeria monocytogenes.*

E. Arnett[1], W. Lu[2], S. Seveau[1]; [1]Departments of Microbiology and Internal Medicine, Center for Microbial Interface Biology, Ohio State University, Columbus, OH, [2]Institute of Human Virology, Department of Biochemistry and Molecular Biology, University of Maryland School of Medicine, Baltimore, MD

Listeria monocytogenes is an intracellular pathogen that infects a wide range of host cells including macrophages. To avoid the phagosome microbicidal environment, *L. monocytogenes* secretes the pore-forming toxin listeriolysin O (LLO) that disrupts the phagosomal membrane allowing for bacterial proliferation in the cytoplasm. In this work, we hypothesized that the defensin HNP-1, which is an antimicrobial peptide abundantly found in infected tissues, could protect macrophages from infection by *L. monocytogenes*. We found that *L. monocytogenes* did not grow in murine and human macrophages (RAW 264.7 cells, bone marrow-derived macrophages, and PMA differentiated THP-1 cells) incubated with HNP-1 before or during infection. Using fluorescence microscopy based invasion assays, we observed that HNP-1 did not alter the efficiency of phagocytosis, but markedly enhanced *L. monocytogenes* entrapment in LAMP-1 positive phagosomes and inhibited intracellular proliferation. Concentrations of HNP-1 that did not affect bacterial viability efficiently inhibited the release of LLO as determined by western blotting analysis of proteins precipitated from bacterial culture supernatants. In addition, HNP-1 inhibited LLO perforation of macrophage membranes as evidenced by measuring the incorporation of a small fluorescent nuclear dye into macrophages. These anti-LLO activities likely account for the inhibition of *L. monocytogenes* escape from the phagosome. We tested a second defensin, retrocyclin-1 (RC-1) that is a proposed therapeutic tool to treat bacterial and viral infections. Similar to HNP-1, RC-1 prevented *L. monocytogenes* intracellular growth and exerted anti-toxin activities. Also, RC-1 was a more potent anti-listerial peptide than HNP-1. In conclusion, the cooperation between antimicrobial peptides, such as HNP-1, and macrophages at the site of infection likely plays a critical role in the innate immune defense against *L. monocytogenes*. This is a property that could be exploited in novel therapeutic treatments against intracellular pathogens.

1193

The listeria P60 protein coopts the inflammasone in mature DCs to stimulate NK cell activation.

R. Schmidt[1], J. Lemon[1], H. Filak[1], L. Lenz[1]; [1]Immunology, National Jewish Health, Denver, CO

The intracellular pathogen Listeria monocytogenes (Lm) activates the inflammasome in host cells, leading to downstream innate immune responses, including IFNγ; production by activated natural killer (NK) cells. Activated NK cells enhance Lm growth at early times after systemic infection. We have shown that NK cell IFNγ; production requires IL-18 produced by infected dendritic cells (DC), yet the roles of specific bacterial factors in DC/NK cell activation are poorly defined. We previously reported the NK response is weakened in mice infected with an Lm strain lacking expression of the secreted virulence protein p60. In this study, we hypothesized that the released p60 protein interacts with DCs to enhance NK cell stimulation.
We employed a co-culture system in which bone marrow-derived DCs (BDCs) were infected with Lm prior to the addition of naïve NK-enriched splenocytes. We found that wildtype Lm-infected BDCs produced robust levels of the inflammasome-processed cytokines IL-18 and IL-1β;. However, production of these cytokines was significantly reduced in BDCs infected with Δp60 mutant Lm strains. The reduced IL-18 correlated with decreased amounts of IFNγ; secretion from NK cells co-cultured with the infected BDCs. Highly purified, endotoxin-free p60 protein stimulated processing of IL-18 and IL-1β in treated mature BDCs. The addition of p60 to BDC/NK co-cultures was also sufficient to induce IFNγ; from NK cells. Using DCs from *NLRP3*$^{-/-}$ and *IL-18*$^{-/-}$ mice, we demonstrated that p60 elicits processing of IL-18 by the NLRP3 inflammasome, and that such IL-18 production was essential for NK activation in response to p60. Inflammasome and NK cell activation by p60 were independent of its putative endopeptidase catalytic activity and mapped to an N-terminal LysM-domain containing region of the protein, termed L1S. L1S bound to the surface of DCs and was sufficient to stimulate NK cell activation both in co-culture and when administered to naïve animals. These data support the model that the N-terminal region of the secreted p60 protein promotes Lm pathogenicity by binding DCs to stimulate pro-bacterial NK cell activation. The mechanism for such immune subversion involves processing of IL-18 by the NLRP3 inflammasome in infected, or perhaps bystander, DCs. Our data reveal a mechanism by which an Lm virulence factor appears to intentionally elicit activation of the NLRP3 inflammasome, arguing against the assumption that inflammasome activation is universally protective for the host during infections. Furthermore, our findings suggest that p60 or L1S may prove useful for stimulation of innate immune responses in experimental and possibly therapeutic contexts.
This work was supported by NIH grants AI065638 and AI055701 to LL. RS was supported in part by NIH training grant T32-AI-074491.

1194

The Pore-Forming Toxin Listeriolysin O Mediates a Novel Entry Pathway of L. monocytogenes into Host Cells.

S. Vadia[1], E. Arnett[1], A-C. Haghighat[1], E. M. Wilson-Kubalek[2], R. K. Tweten[3], S. Seveau[1]; [1]Department of Microbiology, Ohio State University, Columbus, OH, [2]Cell Biology, The Scripps Research Institute, La Jolla, CA, [3]Microbiology and Immunology, University of Oklahoma Health sciences Center, Oklahoma City, OK

Despite the diversity of bacterial virulence factors promoting host cell invasion, only two mechanisms of entry have been observed. First, bacterial invasins bind to host cell receptors to activate signaling cascades that orchestrate the internalization of the bacterium. Second, some pathogens bypass the requirement for a host receptor by utilizing a secretion system that injects effectors into the host cell to activate bacterial uptake. Using Listeria monocytogenes as a

model intracellular pathogen, we have discovered a novel mechanism of entry that involves host cell attack by a pore-forming toxin. Several virulence factors are known to play critical roles in L. monocytogenes intracellular lifecycle. Two surface invasins -InlA and InlB- induce L. monocytogenes internalization into nonphagocytic cells and the pore-forming toxin listeriolysin O (LLO) facilitates bacterial escape from the internalization vesicle. We demonstrate that in addition to InlA and InlB, LLO is a critical invasion factor required for efficient internalization of L. monocytogenes into human hepatocytes (HepG2). Surprisingly, we found that LLO is sufficient to induce the internalization of noninvasive Listeria innocua or polystyrene beads into host cells in a concentration-dependent fashion including the concentrations produced by L. monocytogenes. As shown by electron scanning and fluorescence microscopy, LLO-coated beads stimulate the formation of plasma membrane extensions that ingest the beads into an early endosomal compartment. This pathway requires the activity of host tyrosine kinase(s), the Rho GTPase Rac1, and leads to F-actin polymerization at the entry site. To decipher how LLO could induce these events we constructed and characterized novel LLO variants that bind to the host cell membrane but are unable to form oligomers or that oligomerize but are unable to form pores. Our data demonstrate that membrane perforation is a key event required for F-actin polymerization and bead entry. In conclusion, this is the first demonstration that host cell attack by a pore-forming protein can be used by a bacterial pathogen as an invasive strategy.

1195

Invasion of Lung Epithelial Cells By Filamentous Legionella pneumophila.

A. Prashar[1], C. Duncan[2], S. Bhatia[3], D. E. Low[2,3], R. A. Garduno[4], C. Guyard[2,3], M. Terebiznik[3];
[1]Biological Sciences, University of Toronto at Scarborough, Toronto, ON, Canada, [2]Ontario Agency for Health Protection and Promotion, Toronto, ON, Canada, [3]University of Toronto at Scarborough, Toronto, ON, [4]Dalhousie University, Halifax, NS

The term Legionellosis is used to define a group of respiratory illnesses that vary in severity from mild flu like symptoms to fatal pneumonia. It is estimated that Legionellosis is responsible for 8,000 to 18,000 hospitalizations annually in the United States. The severe form of the disease known as Legionnaires' disease has a high mortality rate of upto 80% in immuno-suppressed patients.
Legionella is the etiological agent responsible for Legionellosis. It is an opportunistic pathogen that is found ubiquitously in association with protozoan hosts in natural and engineered water systems as well as in multispecies biofilms. Human infection is established upon inhalation of aerosolized water contaminated with the bacteria. Once internalized the bacteria can evade phagosomal clearance and establish a replicative niche inside macrophages.
Legionella exhibits pleomorphism and while the filamentous forms of the bacteria are present in sputum, bronchoalveolar lavage and alveolar tissue from infected patients and in biofilms, their role in the infectious process in not well studied. Our work is aimed at investigating the mechanisms used by these filaments to infect host epithelial cells.

Our results show that L.pneumophila filaments as long as 80 μm can invade epithelial cells and survive intracellularly. A membrane rich zipper structure forms around attached bacteria causing their internalization. Using various microscopy and biochemical approaches we have elucidated the cellular processes that mediate the internalization of bacterial filaments into cells. We have determined that L.pneumophila exploits both E-cadherin and β1 Integrin receptors on host cells to attach to them. Engagement of these receptors activates intracellular signaling that leads to bacterial internalization through a process that depends on
actin polymerization and the activity of actin motor myosin II. Additionally, we have demonstrated a role for Rab11 GTPase dependent receptor recycling in the progression of the zippers and consequently in bacterial internalization.

The invasion of macrophages by Legionella has been extensively studied, however 95% of the human lung surface consists of epithelial cells. As a result, these cells provide an important niche for bacterial infection. The ability of the filamentous form of the L.pneumophila to invade lung epithelial cells presents additional challenges for the host that have not been addressed in literature so far. Our work examines two important and previously under-studied factors that potentially play a significant role in Legionella pathogenesis.

1196

Invasion of Polarized Epithelial Cells by Filamentous *Legionella Pneumophila.*

Z. Tabatabaeiyazdi[1], A. Prashar[1], C. Duncan[2], C. Guyard[2,3], M. Terebiznik[4,5]; [1]Department of Cell and System Biology, University of Toronto, Toronto, ON, Canada, [2]Ontario Agency For Health Protection and Promotion (OAHPP), Canada, [3]Department of Laboratory Medicine and Pathobiology, University of Toronto, Canada, [4]Department of Cell and System Biology, University of Toronto, Canada, [5]Department of Biological Sciences, University of Toronto at Scarborough, Canada

Legionella pneumophila (Lp.) is an emerging respiratory pathogen that inhabits natural as well as engineered aquatic environments. *Lp.* causes two distinct illnesses; mild flu like Pontiac fever and a severe pneumonia called Legionnaires' disease. *Lp.* is a pleomorphic bacteria and although filamentous forms have been documented in biofilms and tissue/sputum from infected patients, they are not well studied. The ability of bacteria to invade and survive inside mammalian cells is crucial for *Lp.* infection. This process has been very well studied in macrophages, where it is considered to resemble the life cycle of Legionella in its natural host, amoeba. However, the invasion of lung epithelial cells by *Lp.* has been less studied and consequently is poorly understood.
Preliminary data from our laboratory indicate that filamentous *Lp.* attaches to and invades non-polarized cultured lung epithelial cells. This invasion process is mediated by cell surface receptors E-cadherin and ß1-integrin. While these receptors are available at the apical surface in non-polarized epithelia, in polarized epithelial cells tight junctions keep them segregated to the basolateral membrane. The objectives of our research are to investigate the invasion of polarized epithelial cells by filamentous *Lp.*
In order to study *Lp.* infections in polarized epithelial cells, we have utilized two well-established cell models, 16HBE14o- and MDCK cells. 16HBE14o- cells are polarized lung epithelial cells while MDCK cells are widely used as models of highly polarized epithelial cells. Following 7-10 days of differentiation after seeding, polarized cells are infected with late exponential phase *Lp.* and analyzed by fluorescent microscopy. Our results show that Lp. attachment to epithelial cells depends on the level of cell polarity with highly polarized cells being less susceptible to *Lp.* infection. We have also shown that in highly polarized MDCK and 16HBE14o- cells E-cadherin and ß1-integrin receptors are not exposed for *Lp.* attachment. However, wounding the cells can expose more receptors, leading to *Lp.* attachment and invasion.
These results suggested that intact tight junctions in polarized epithelial cells obstruct *Lp.* attachment and inhibit their internalization. However, *Lp.* can take advantage of exposed receptors in non-polarized or wounded epithelia in order to attach or invade epithelial cells. This may also be the case in patients with underling disease or injuries, which are reported to be more susceptible to Legionellosis. These data indicate that tight junctions may play an important role in regulating *Lp.* infection and generate knowledge on the poorly studied but important basic cellular microbiological aspects of *Lp.* pathogenesis.

1197

The Role of Protein Kinase C in Coxiella burnetii infection.

S. K. Hussain[1], J. G. Graham[2], D. E. Voth[2]; [1]Microbiology and Immunology, University of Arkansas for Medical Sciences, Little Rock, AR, [2]University of Arkansas for Medical Sciences

Coxiella burnetii, the agent of human Q fever, is an environmentally stable, Gram-negative bacterium that infects humans via contaminated aerosols. The acute form of Q fever includes flu like symptoms and less prevalent chronic disease typically presents as endocarditis. *C. burnetii* targets alveolar macrophages *in vivo* where the organism generates a phagolysosome-like parasitophorous vacuole (PV) for replication. The lengthy growth cycle of *C. burnetii* makes PV formation and maintenance critical for survival. Using a panel of pharmacologic compounds, we previously found that inhibition of 11 kinases and 2 phosphatases prevented proper PV formation. Five inhibitors from this panel targeted protein kinase C (PKC), suggesting a critical role for this protein during *C. burnetii* intracellular growth. In the present study, we further examined the role of classical, novel, and atypical PKC isoforms for their role in PV generation. In cells treated with isoform-specific PKC inhibitors, individual bacteria were harbored in tight-fitting phagolysosomes, as confirmed by CD63 (LAMP-3) and cathepsin D labeling, indicating *C. burnetii* replication was halted. Phosphorylation levels of myristoylated alanine-rich C-kinase substrate (MARCKS), a specific downstream substrate of PKC, remained elevated through 120 hpi, indicating continual stimulation of PKC signaling by *C. burnetii*. Phosphorylation of the classical isoform PKC-α and the novel isoform PKC-δ was observed from 24-96 hpi, indicating activation of both isoforms during infection. Furthermore, Immunofluorescence microscopy demonstrated differential trafficking of PKC-α to the plasma membrane at 48-72 hpi similar to artificial activation by phorbol myristoyl acetate treatment. Together, our current results suggest PKC signaling is critical for proper PV formation and *C. burnetii* replication. Elucidation of isoform-specific consequences will further our understanding of this unique host-pathogen interaction.

1198

Host PKA Activity is Required for Coxiella burnetii Parasitophorous Vacuole Formation and Replication.

L. J. Broederdorf[1], R. C. Kurten[2,3], D. E. Voth[1]; [1]Microbiology/Immunology, University of Arkansas for Medical Sciences, Little Rock, AR, [2]Physiology/Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR, [3]Arkansas Children's Hospital Research Institute

Coxiella burnetii is a highly infectious intracellular bacterial pathogen that causes the zoonotic disease Q fever. *In vivo*, the organism replicates in a unique phagolysosome-like parasitophorous vacuole (PV) within human alveolar macrophages. Establishment of this intracellular niche is required for replication and survival and necessitates regulation of numerous host cell signaling pathways, presumably via the activity of a specialized Dot/Icm type IV secretion system. We recently showed that a commonly used inhibitor of cAMP-dependent protein kinase (PKA) reversibly impairs typical PV formation, suggesting *C. burnetii* regulates this versatile cascade throughout infection. In the current study, we further probed the role of PKA during infection using more specific inhibitors and downstream readouts of kinase activity. Using a cAMP analog, we found that specific pharmacologic inhibition of PKA activation antagonized PV formation and replication. PKA phosphorylation, indicative of activation, increased through 96 hours post-infection. Downstream PKA substrates were differentially phosphorylated during infection, and inhibition of bacterial protein synthesis abrogated these changes. Interestingly, the prototypical PKA substrate cAMP response element-binding protein was not differentially phosphorylated during infection. However, increased phosphorylation of Bad and p105 was observed, suggesting *C. burnetii* regulates specific PKA substrates related to

apoptosis and the host immune response. Additionally, we investigated cAMP-dependent changes in host transcription and found expression of several downstream PKA targets was altered at three days post-infection. Importantly, PKA was also activated during virulent *C. burnetii* infection of primary human alveolar macrophages, indicating the importance of this signaling cascade in natural infection. We are also currently investigating the role of Dot/Icm in mediating these events. Our results collectively suggest PKA activity is required for *C. burnetii* infection, and the pathogen triggers activation of distinct downstream targets with important implications for host cell responses.

1199

Chlamydia trachomatis infection induces anchorage independence in a 3T3 soft agar assay.

A. E. Knowlton[1], R. K. Patel[1], H. M. Brown[1], S. S. Grieshaber[1]; [1]Oral Biology, University of Florida, Gainesville, Fl

Chlamydiae are gram negative, obligate intracellular bacteria, and *Chlamydia trachomatis* is the cause of the most commonly reported sexually transmitted disease in the United States. *Chlamydiae* undergo a unique life cycle that takes place inside a vacuole termed an inclusion. Chlamydial infections have been epidemiologically linked to increased rates in cervical cancer in patients simultaneously infected with human papillomavirus (HPV). Our lab has previously shown that a chlamydial infection induces supernumerary centrosomes and multipolar spindles inhibiting accurate chromosome segregation during mitosis. Many studies indicate that centrosome abnormalities, spindle defects, and chromosome segregation errors can lead to tumors. The soft agar assay is a commonly used technique to detect *in vitro* cellular transformation by measuring anchorage independence. We hypothesize that a chlamydial infection may lead to transformation of 3T3 cells by induction of centrosome abnormalities, spindle defects, and chromosome segregation errors. Here we demonstrate that *Chlamydia trachomatis* is, in fact, able to transform 3T3 cells in soft agar resulting in increased colony formation compared to uninfected 3T3 cells. These results contribute to a growing body of research implicating a role for *Chlamydia* in cervical cancer development.

Salmonella enterica Typhimurium associated with enterocyte extrusion in an in vivo bovine enteric infection model.

R. C. Laughlin[1], L. A. Knodler[2], H. R. Payne[3], R. B. Mouneimne[3], O. Steele-Mortimer[2], L. G. Adams[1]; [1]Veterinary Pathobiology, Texas A&M University, College Station, TX, [2]Rocky Mountain Laboratories, National Institutes of Health, Hamilton, MT, [3]Veterinary Intigrative Biosciences, Texas A&M University, College Station, TX

Salmonella enterica Typhimurium is a major food-borne zoonotic agent with a broad host range causing high morbidity enteritis and low to moderate mortality. The Gram-negative bacterium invades and replicates within a membrane bound niche in several cell host cell lineages, including enterocytes, macrophages and neutrophils. A recent report observed *S.* Typhimurium hyper-replicating in the cytosol of colonic epithelial cells *in vitro* and murine gall bladder epithelial cells *in vivo*. Interestingly, the cytosolic bacteria were expressing the SPI-1 invasion-associated gene profile and induced inflammatory cell death and extrusion. The objective of this study was to further analyze and compare the previous observations in an *in vivo S.* Typhimurium bovine ileal loop model. *S.* Typhimurium harboring conditional expression of destabilized GFP- driven by either the *invF* promoter, a SPI-1 associated gene, or the *ssaG* promoter, a SPI-2 associated gene, were injected into ligated bovine ileum. Following incubation for 2 or 8 hours, ileal sections were excised and biopsies collected for morphological and

molecular analyses. Histological, confocal and transmission electron microscopy confirmed the presence of extruding bovine enterocytes containing multiple *S.* Typhimurium positive for P*invF*-GFP[LVA] fluorescence. Laser-capture microdissection and subsequent molecular analysis of infected extruding cells confirmed expression of a SPI-1 invasion-associated gene profile and host cell inflammatory cell death. These *in vivo* data confirm in the gut the recently described novel survival and dissemination strategies of *S.* Typhimurium.

1201

The Giant Phosphoprotein AHNAK is Required for Salmonella Invasion of Non-Phagocytic Cells.

C. Jolly[1], S. Winfree[1], O. Steele-Mortimer[1]; [1]LICP, NIH/NIAID/RML, Hamilton, MT

During invasion of non-phagocytic cells, the Gram-negative bacterium Salmonella enterica uses a type III secretion system (T3SS) to deliver bacterial effector proteins into the host cell cytosol. Once inside the cytosol, these effectors drive actin polymerization at the invasion site. Rapid rearrangement of the actin cytoskeleton leads to the formation of prominent ruffles on the surface of the host cell, macropinosome formation, and internalization of the bacteria. While several components of this process are well understood, particularly actin remodeling, the role of membrane trafficking in ruffle formation has not been well studied. Using a proteomics approach we identified the giant phosphoprotein AHNAK (700 kDa) as a host cell protein that is localized to the plasma membrane in response to Salmonella invasion. AHNAK is a membrane-associated protein that has been implicated in vesicle-mediated membrane repair processes, can interact with actin, and act as a scaffolding protein during membrane signalling events. Using fluorescence microscopy we found that AHNAK is recruited to the Salmonella invasion site in HeLa cells. siRNA mediated knockdown of AHNAK results in a significant decrease in Salmonella invasion. To confirm this data we also examined Salmonella invasion in wild-type and AHNAK-null mouse embryonic fibroblasts and determined that AHNAK is required for efficient Salmonella invasion. AHNAK is known to complex with Annexin A2/p11 at the plasma membrane and this interaction has been implicated in cortical actin organization. siRNA mediated knockdown of Annexin A2 and p11 also result in a significant decrease in Salmonella invasion. Together these results suggest that the AHNAK/Annexin A2/p11 complex is required for efficient Salmonella invasion.

1202

Selective targeting of Rab29 by an effector protein distinguishes the intracellular compartment of human-adapted and broad-host Salmonella.

S. Spanò[1], X. Liu[1], J. E. Galán[1]; [1]Yale University School of Medicine, New Haven, CT

Unlike other *Salmonella enterica* serovars (e.g., *Salmonella* Typhimurium), *Salmonella* Typhi can only infect humans, where it causes typhoid fever, a life-threatening disease. The objective of this work is to identify the molecular and cellular bases for different pathogenic properties of human-adapted and broad-host-range *Salmonella* serovars. Here through an RNAi screen to identify Rab GTPases involved in the transport of Typhoid toxin, a unique virulence factor of *Salmonella* Typhi, we found that Rab29 (Rab7L1) is recruited to the *Salmonella* Typhi-containing vacuole but not to the vacuole containing the broad-host serovar *Salmonella* Typhimurium. We observed that in *Salmonella* Typhimurium-infected cells Rab29 is specifically cleaved by the proteolytic activity of GtgE, a novel type III secreted bacterial effector that is absent from *Salmonella* Typhi. We also found that a *Salmonella* Typhi strain engineered to express GtgE and therefore able to cleave Rab29 exhibited increased intracellular replication in human macrophages. These findings indicate fundamental differences in the intracellular biology of human adapted and broad host range *Salmonella enterica* serovars and have

implications for the understanding of *Salmonella* Typhi's ability to cause systemic infection. These results also show how subtle differences in the assortment of type III secreted effector proteins encoded by highly related pathogens can have a major impact in their biology.

1203

Visualizing Salmonella effectors in host cells and characterizing the intracellular niche.

S. McQuate[1], I. Brown[1], S. Van Engelenburg[1], A. Palmer[1]; [1]Biochemistry, University of Colorado, Boulder, CO

Salmonella species are gram-negative enteropathogenic bacteria that cause diseases in humans ranging from enteritis to typhoid fever. In order to successfully invade the host, *Salmonella* use two type three secretion systems (T3SSs 1 and 2) to secrete bacterial effector proteins into the host cell. Effector proteins secreted from T3SS1 and T3SS2 are called SPI-1 and SPI-2 effectors, respectively. These effector proteins are responsible for hijacking the host cell machinery to allow for bacterial engulfment and uptake into the host cells (SPI-1 effectors) as well as promoting bacterial replication and furthering *Salmonella* infection (SPI-2 effectors). Our lab has developed a split GFP system to image the localization and dynamics of SPI-2 effectors in real time in live cells. Using this methodology, we have labeled a number of different effector proteins and tracked their localization between 4 hours and 24 hours post invasion. Although numerous effectors localize to the *Salmonella* containing vacuole and tubules that emanate from the vacuole, we observe distinct populations of tubules that colocalize with different pools of host cell markers. We also observe significant perturbation of host cell organelles such as the Golgi apparatus. We are determining which host cell organelles are involved in the formation of the tubules in order to characterize the biochemical composition of these tubules and their role in the overall infection cycle.

1204

Alternative Mating Type Configurations (a/α versus a/a or α/α) of *Candida albicans* Result in Alternative Biofilms, One Pathogenic and the Other Sexual, That Are Regulated By Different Pathways.

K. J. Daniels[1], N. Sahni[1], S. Yi[1], K. L. Lu[1], T. Srikantha[1], G. Huang[1], D. R. Soll[1]; [1]Biology & Developmental Studies Hybridoma Bank, University of Iowa, Iowa City, IA

Similar multicellular structures can evolve within the same organism that may have different evolutionary histories, be controlled by different regulatory pathways and play similar but non-identical roles. In the human fungal pathogen *Candida albicans*, a quite extraordinary example of this has occurred. Depending upon the configuration of the mating type locus (**a**/α versus **a/a** or α/α), *C. albicans* forms alternative biofilms that appear similar morphologically, but exhibit dramatically different characteristics and are regulated by distinctly different signal transduction pathways. Biofilms formed by **a**/α cells have all of the characteristics expected of a pathogenic biofilm. They are impermeable to molecules in the size range of 300 Da to 140 kDa, are poorly penetrated by human polymorphonuclear leukocytes (PMNs) and are resistant to antifungals. In contrast, **a/a** or α/α biofilms are permeable to molecules in this size range, are readily penetrated by PMNs and are susceptible to antifungals. Moreover, they facilitate mating between mating competent opaque cells, suggesting that they represent sexual biofilms. By mutational analyses, pathogenic **a**/α biofilms are demonstrated to be regulated by the Ras1/cAMP pathway that includes Ras1→Cdc35→cAMP(Pde2—)→Tpk2(Tpk1)→Efg1→Tec1→Bcr1, and sexual **a/a** biofilms by the MAP kinase pathway that includes Mfá→ Ste2→Ste4, Ste18, Cag1)→Ste11→Hst7→Cek2(Cek1)→Tec1. The permeable, sexual biofilm can be made impermeable by overexpression of the transcription factor Bcr1. These observations suggest the hypothesis that while the upstream portion of the newly evolved

pathway regulating sexual **a/a** and α/α cell biofilms was derived intact from the upstream portion of the conserved pheromone-regulated pathway for mating, the downstream portion was derived through modification of the downstream portion of the conserved pathogenic pathway for **a**/α biofilm formation. *C. albicans* therefore forms two alternative biofilms, one pathogenic and one sexual, depending upon the configuration of the mating type locus.

1205

Investigation of Candida albicans adhesion to endothelial cell monolayers under controlled shear flow.

C. Conant[1], M. Schwartz[2]; [1]Fluxion Biosciences, San Francisco, CA, [2]Fluxion Biosciences

Candida albicans is an important pathogen in several biological niches which are constantly irrigated by biological fluids such as saliva or blood. One important step to dissemination of organisms during a septic infection is adhesion to endothelial cells. To approximate the vascular niche more closely, we developed an in vitro model of endothelial cell culture under flow in microfluidic channels. We used these model monolayers to examine adhesion rate and strength of C. albicans yeast and hyphal forms to the monolayers under variable flow. We then tested adhesion rate and strength in monolayers stimulated with TNF-alpha. Under conditions of maximal adhesion, we tested adhesion inhibition with anti-PECAM, anti-VCAM, anti-vitronectin and anti-ICAM. We found maximum rapid adhesion with yeast forms at lower flow rates. However, we found that filamentous forms adhered under the strongest shear forces(in excess of 20dyn/cm2) . Inhibition of adhesion by filamentous forms on unstimulated endothelial cells was noted using anti-PECAM, anti-VCAM-1, anti-ICAM-1, and anti-vitronectin. This model is further extensible to the study of downstream events related to C. albicans pathogenesis such as transmigration.

1206

Host factor screening cleaved by hepatitis C virus protease using wheat cell-free system.

M. Arimoto[1], S. Takahama[2], A. Muroi[1], S. Miyajima[3], Y. Endo[1,2], T. Sawasaki[1,2]; [1]Cell-free Science and Technology Research Center, Ehime University, Matsuyama, Japan, [2]The Venture Business Laboratory, Ehime University

Hepatitis C virus (HCV) causes acute and chronic hepatitis and leads hepatocellular carcinoma. After infection with HCV, it is not easy to be cured although there are effective anti-viral medicines such as PEG-interferon and NS3/4A protease inhibitor. Thus, new drug targets are required to eliminate HCV. In general, a virus exploits proteins in the host cells for replication, and HCV is also known to use some host factors. Because drugs targeting viral proteins largely produce resistances, recent studies consider possibility that the host proteins are good candidates as drug target. We have an idea that HCV protease may provide an appropriate environment for viral growth by cleavage of host proteins. In this study, we challenged to identify new host factors that are cleaved by HCV protease.

We constructed N- and C-terminally tagged protein libraries consisting of protein kinases and single transmembrane proteins by the wheat cell-free translation system, and monitored the cleavage of these proteins by a HCV protease, NS3/4A, by AlphaScreen system. As a result, we identified 12 human proteins that were cleaved by HCV protease in vitro, and their cleavage sites. Now, we are investigating whether these candidate proteins are cleaved by HCV protease in the infected cells and the cleavage effects on HCV growth.

1207

The effects of hepatitis C virus NS3-4A protein on stress-induced apoptosis.

S. C. Chang[1], Y-C. Lin[2], H-Y. Wu[1], S-H. Pan[1], M-F. Chang[3]; [1]Microbiology, National Taiwan University College of Medicine, Taipei, Taiwan, [2]Microbiology, National Taiwan University College of Medicine, Taiwan, [3]Biochemistry and Molecular Biology, National Taiwan University College of Medicine

Hepatitis C virus (HCV) NS3 functions as a viral protease that together with the NS4A cofactor promotes the viral polyprotein processing. We have previously demonstrated an internal NS3 cleavage activity and its association with an enhanced transforming activity of NS3. In this study, an inducible cell line HepG22-NS3-4A was established. Expression of the NS3-4A polyprotein upon induction and its further processed into individual NS3 and NS4 protein in the cell line were evident. Immunostaining assay demonstrated distribution of the NS3/4A complex to the mitochondria. In addition, expression of the NS3-4A protein alleviated a reduced mitochondria membrane potential caused by deoxycholic acid (DCA). Furthermore, DCA-induced releasing of mitochondria cytochrome C into cytoplasm can be alleviated by overexpression of the NS3-4A polyprotein. Reduced sub-G1 population in DCA treated, NS3-4A expressing 293 cells suggested a role of the NS3-4A polyprotein in protecting cells from DCA-induced apoptosis. This study implies the anti-apoptotic effect of NS3-4A protein involving in HCV tumorigenesis.

1208

Isolation of a hepatitis C virus mutant adapted to mouse CD81 in hepatic cell culture system.

M. Fukasawa[1], R. Anai[1,2], Y. Shirasago[1,2], K. Saito[1], Y. Murakami[3], H. Fukazawa[3], T. Suzuki[4], T. Wakita[5], J. Chiba[2], K. Hanada[1]; [1]Department of Biochemistry and Cell Biology, National Institute of Infectious Diseases, Tokyo, Japan, [2]Department of Biological Science and Technology, Tokyo University of Science, Japan, [3]Department of Bioactive molecules, National Institute of Infectious Diseases, Tokyo, Japan, [4]Department of Infectious Diseases, Hamamatsu University School of Medicine, [5]Department of Virology II, National Institute of Infectious Diseases, Tokyo, Japan

Infection of hepatitis C virus (HCV) is a rapidly increasing global public health problem, with approximately 170 million people infected worldwide. HCV infects only humans and chimpanzees naturally, which has restricted development of animal models for HCV. Although molecular determinants responsible for the narrow host range of HCV are not well-defined, cell surface CD81 as well as occludin at least contributes to the species tropism at the entry step. From human hepatic Huh7.5.1 cell clones resistant to HCV infection, we isolated a CD81-defective cell clone, designated as 751r. The 751r cells stably expressing human CD81 or mouse CD81 (named 751r/hCD81 and 751r/mCD81, respectively) were also established. In consistent with previous observations, 751r/hCD81cells were permissive to the HCV-JFH1 strain, but both 751r and 751r/mCD81 cells were not. Interestingly, the HCV-JFH1 variant strain with two adaptive mutations (K74T/I414T), which we reported as a highly infectious HCV mutant at the last meeting, however, significantly infected 751r/mCD81 cells. Then we tried to isolate HCV mutants more adapted to mouse CD81. By repeated infections of naïve 751r/mCD81 cells (and Huh7.5.1 cells or 751r/hCD81 cells) with the HCV-JFH1 (K74T/I414T) variant, we finally obtained a HCV-JFH1 mutant showing similar infectivity toward 751r/mCD81 and 751r/hCD81 cells. Sequencing analysis of the mutant virus genome revealed that there are five additional mutations in the structural protein region: F172C in the core protein; N234D, V293A, and T331S in the E1 protein; and V402A in the E2 protein. Since its infectivity and all these mutations were preserved after further repeated infections, the phenotype of the mutant was very stable and the

mutation sites would be important for adaptation to mouse CD81. These results suggest that the adapted mutations in the structural proteins contribute to overcome the CD81-mediaed species-specific restriction of HCV entry into cells. In the future this study should lead to the development of a mouse model permissive to HCV.

1209

Dynamics of ESCRT protein recruitment during retroviral assembly.

N. Jouvenet[1], P. Bieniasz[1,2], S. M. Simon[3]; [1]Aaron Diamond Aids Research, New York, NY, [2]Lab of Retrovirology, Rockefeller University, New York, NY, [3]Rockefeller University, New York, NY

The assembly of retroviruses is the dependent upon the interaction of various components encoded both by the virus and the host cell. The separation of retroviral particles from host membranes is promoted by the cellular ESCRT (Endosomal Sorting Complex Required for Transport) complexes and associated proteins. The ESCRT complexes and associated proteins mediate other membrane scission reactions, such as multi-vesicular body formation and the terminal stages of cytokinesis. These proteins are believed to be sequentially recruited to the site of membrane scission, and then complexes are disassembled by the ATPase Vps4A. However these events have never been observed in living cells and their dynamics are unknown. Characterizing the relative time course of these molecules is complicated in cells where each virion is in a different state of assembly. To characterize the dynamics of these molecules, we studied the assembly of individual virions. By quantifying the recruitment of several ESCRT and associated proteins during the assembly of two retroviruses, EIAV and HIV-1, we show that Alix progressively accumulated at viral assembly sites, coincident with the accumulation of the major viral structural protein, Gag, and was not recycled after assembly. In contrast, ESCRT-III and Vps4A were only transiently recruited when the accumulation of Gag was complete. These data suggest that the rapid and transient recruitment of proteins that act late in the ESCRT pathway and carry out membrane fission is triggered by prior and progressive accumulation of proteins that bridge viral proteins and the late-acting ESCRT proteins.

1210

Sub-localization of Murine Norovirus proteins and its genome RNA.

T. Shimoike[1], H. Takagi[2], T. Oka[1], K. Murakami[1], T. Wakita[1], K. Katayama[1]; [1]Virology II, National Institute of Infectious Diseases, Musashi-Murayama, Japan, [2]Boisafety Control and Reseach, National Institute of Infectious Diseases, Musashi-Murayama, Tokyo

Human norovirus (HuNoV), a member of the family Caliciviridae, is the dominant agent of acute gastroenteritis. HuNoV replication is difficult to study because there is no cell culture system or small animal model. However murine norovirus (MNV) was recently found to replicate in RAW264.7 cells. To understand MNV life cycle in cells, we used immunofluorescence deconvolution microscopy to visualize MNV proteins (VPg, RNA dependent RNA polymerase: RdRp, NTPase, and structural proteins VP1 and VP2), double stranded viral RNA (dsRNA), and newly synthesized viral RNA (nsRNA) during replication in RAW264.7 cells. At 12 hours post infection, the dsRNA was observed at the perinuclear region. The small amount of nsRNA was also localized with the dsRNA at the perinuclear region, however most of the nsRNA were spread diffusely throughout the cytoplasm. The RdRp, NTPase and VPg proteins were localized at the perinuclear region, indicating that MNV replicates at perinuclear region, and the replication complex is composed of dsRNA, RdRp, NTPase, VPg and a small amount of nsRNA. The structural protein, VP1, was detected in the cytoplasm and appeared to co-localize with nsRNA, suggesting that virion assembly, which involved nsRNA and VP1, was at a different site to the replication complex. The other structural protein, VP2 was detected in the cytoplasm

in particle forms, but interestingly it was not co-localized with any viral proteins (RdRp, NTPase, and VPg) and with any genome RNA (nsRNA and dsRNA).

Defining Therapeutic Targets and New Therapeutics

1211

Transduced Tat-Frataxin protein ameliorates MPTP-induced Parkinson′s disease mouse model.

M. Kim[1], D. Kim[1], E. Ahn[1], S. Kwon[1], Y. Kim[1], H. Kim[1], T-C. Kang[2], D-S. Kim[3], O-S. Kwon[4], H. Hwang[1], J. Park[1], W. Eum[1], S. Choi[1]; [1]Biomedical Science and Research Institute of Bioscience and Biotechnology, Hallym University, Chuncheon, Korea, [2]Anatomy, and Neurobiology, College of Medicine, Hallym University, [3]Anatomy, College of Medicine, Soonchunhyang University, Cheonan-Si, Korea, Dem People's Rep, [4]Biochemistry, Kyungbook National University, Taegu, Korea, Dem People's Rep

Frataxin is an essential mitochondrial protein which deficiency causes increased reactive oxygen species (ROS), and deficit of iron-sulphur cluster, and mitochondrial dysfunctions. Parkinson's disease (PD) is a progressive neurodegenerative disorder, characterized by selective loss of dopaminergic neurons in the substantia nigra pars compacta and it is associated with ROS. Thus, we investigated the protective effects of Tat-Frataxin protein on neuronal cell death in vitro and in vivo. Tat-Frataxin protein showed a protective effect on 1-methyl-4-phenylpyridinium ion (MPP+)-induced SH-SY5Y neuronal cell death by reduction of ROS and caspase-3 activation. Furthermore, a histological analysis indicated that transduced Tat-Frataxin protein markedly protects against dopaminergic neuronal cell death in 1-methyl-4-phenyl-1,2,3,6,-tetrahydropyridine (MPTP)-induced PD mouse models. These results strongly suggest that Tat-Frataxin may provide a useful therapeutic strategy for the prevention of progressive neurodegenerative disorders such as PD.

Keywords: Antioxidant, MPP+, Parkinson disease, Protein transduction, Reactive oxygen species (ROS), Tat-Frataxin protein.

1212

PEP-1-heat shock protein 27 protects from neuronal damage in cells and in a Parkinson′s disease mouse model.

S. Kwon[1], D. Kim[1], Y. Lee[1], H. Kang[1], E. Sohn[1], M. Kim[1], H. Kim[1], S. Woo[1], J. Hwang[1], D-S. Kim[2], D. Kim[3], K. Suk[3], J. Park[1], W. Eum[1], S. Choi[1]; [1]Biomedical Science and Research Institute of Bioscience and Biotechnology, Hallym University, Chuncheon, Korea, [2]Anatomy, College of Medicine, Soonchunhyang University, Korea, [3]Internal Medicine, Chuncheon Sacred Heart Hospital, Hallym University, Chun Cheon, Korea

Heat shock proteins (HSPs) are induced in response to a variety of cellular responses including reactive oxygen species (ROS). HSP27 is a chaperone protein with the ability to increase cell survival in response to oxidative stress. Parkinson's disease (PD) is a neurodegenerative disorder characterized by loss of dopaminergic neurons. Although the mechanism of PD remains unclear, oxidative stress is known to be important in the pathogenesis of PD. This study investigated the protective effects of PEP-1-HSP27 on neuronal damage induced by 1-methyl-4-phenyl pyridinium (MPP+) in SH-SY5Y cells and a 1-methyl-4-phenyl-1,2,3,6,-tetrahydropyridine (MPTP)-induced PD mouse model. PEP-1-HSP27 rapidly entered the cells and protected them against MPP+-induced toxicity by inhibiting the ROS levels and DNA fragmentation.

Furthermore, transduced PEP-1-HSP27 prevented dopaminergic neuronal cell death in the substantia nigra of MPTP-induced PD mouse models. These results demonstrate that PEP-1-HSP27 protects against neuronal cell death in vitro and in vivo, and suggest that PEP-1-HSP27 may have therapeutic potential in preventing or delaying progression of PD, and utility as a therapeutic agent for various human diseases related to oxidative stress, including PD.
Keywords – PEP-1-HSP27; ROS; Protein transduction; Parkinson's disease; Protein therapy.

1213

Tat-proline rich Akt substrate 40 (Tat-PRAS40) attenuates MPP+-induced dopaminergic neuronal cell death in a mouse model of Parkinson′s disease.

M. Shin[1], D. Kim[1], H. Jeong[1], E. Sohn[1], M. Kim[1], E. Ahn[1], H. Jo[1], D-S. Kim[2], T-C. Kang[3], O-S. Kwon[4], S-W. Cho[5], J. Park[1], W. Eum[1], H. Hwang[1], S. Choi[1]; [1]Biomedical Science and Research Institute of Bioscience and Biotechnology, Hallym University, Chun Cheon, Korea, [2]Anatomy, College of Medicine, Soonchunhyang University, Korea, [3]Anatomy and Neurobiology, College of Medicine, Hallym University, Korea, [4]Biochemistry, Kyungbook National University, Korea, [5]Biochemistry and Molecular Biology, University of Ulsan College of Medicine, Korea

Parkinson's disease (PD) is caused mainly due to loss of dopaminergic neurons in the substantia nigra (SN), leading to accumulation of Lewy bodies inside nerve cells. Primary characteristic symptoms include tremors, bradykinesia, rigidity and postural instability. Phosphatidylinositol 3-kinase/AKT/mammalian target of rapamycin signal pathways play crucial roles in controlling cell growth, survival and apoptosis. Proline-rich Akt substrate (PRAS40) is implicated in negative regulation of mTORC1 activity through binding to the raptor-mTORC1 complex. In this study, we examined whether Tat-PRAS40 fusion protein could protect dopaminergic neuronal cells from 1-methyl-4-phenylpyridinium (MPP^+)-induced oxidative stress, *in vitro* and *in vivo*, thereby increasing survival of dopaminergic neuronal cells. Transduced Tat-PRAS40 effectively suppressed MPP^+-induced ROS production and attenuated apoptosis to a considerable extent in SH-SY5Y cells. Also, in a MPTP-induced mouse model of PD, cresyl violet staining and tyrosine hydroxylase immunostaining demonstrated that Tat-PRAS40 could readily and effectively cross the blood-brain barrier and protect dopaminergic neuron cells in the SN. The collective results suggested that Tat-PRAS40 could be utilized as a potent therapeutic agent against oxidative stress-induced PD.
Keywords: Apoptosis, Mammalian target of rapamycin, Oxidative stress, Parkinson's disease, Proline-rich Akt substrate 40, Protein transduction domain.

1214

Chronic central administration of valproic acid increased pro-survival proteins and growth cone signaling without altering rat behavior.

R. Bates[1], B. Stith[2], K. Stevens[3]; [1]Medical Research Service, VA Medical Center; Integrated Biology, University of Colorado Denver; Psychiatry, Anschutz Medical Campus, Aurora, CO, [2]Integrated Biology, University of Colorado Denver, [3]Medical Research Service, VA Medical Center; Psychiatry, Anschutz Medical Campus

Valproic acid (VPA) is the most widely prescribed antiepileptic drug due to its ability to treat a broad spectrum of seizure types. Direct delivery of VPA intracerebroventricularly (ICV) could circumvent the toxic effects normally seen with the oral route of administration. ICV use would maximize VPA brain concentration which may ameliorate neuron and astrocyte death associated with seizures. After ICV administration of VPA in the Sprague Dawley rat, near-infrared fluorescence was used to image coronal brain tissue slices and analyze brain lysates. Immunopositive complexes of VPA were localized to the periventricular zone in tissue slices and pro-survival phospho-proteins pAkt-Ser473, pGSK3β-Ser9 and growth cone protein 2G13p were

also increased in this area of the brain slice (compared to chronic saline injection; significance determined by ANOVA and Scheffe a posteriori). In regional tissue lysates, there were increases in pro-survival pAkt-Ser473, pAkt-Thr308, pGSK3β-Ser9, pErk1/2-Thr202/Tyr204 and growth cone associated protein GAP43 (Western blotting). However, ICV administration of VPA did not change the total protein amount of doublecortin, NeuN, synaptotagmin, and synaptophysin. This lack of change could be due to dilution during tissue extraction or stalled growth cone formation. Elevated VPA concentration (3 mM) may have induced hydrocephaly through higher drug viscosity which would decrease ciliary flow of the CSF. VPA did not alter animal anxiety or drugged behavior as analyzed by open field (no change in percent time against the wall of the field, or distance traveled in region), and elevated plus mazes (no change in percent time in the elevated open arms). Analysis of brain slices from the cortical region showed high levels of VPA that had traveled from the ventricle along an incipient space formed by the insertion of the cannula. Future studies will examine whether VPA conjugated to high molecular forms of poly(ethylene glycol) (PEG) will significantly decrease diffusion and concentrate the drug to minimize leak from the CSF into the peripheral blood.

1215

Gene Expression Profiling of Oxidative Stress on Vascular Tissue in Diabetic Patients.

E. Albino-Rodriguez[1], E. Soltero[2], L. Ferder[3], J. Dutil[1]; [1]Biochemistry Department, Ponce School of Medicine, Ponce, PR, [2]Cardiovascular Surgery, Damas Hospital, Ponce, PR, [3]Physiology & Pharmacology Department, Ponce School of Medicine, Ponce, PR

Diabetes Mellitus is a worldwide epidemic and the main risk for coronary artery disease. Diabetes is the third leading cause of death in Puerto Rico and it contributes to the major cause of mortality, coronary artery disease (CAD). Diabetic patients with advanced, symptomatic CAD are usually referred for coronary artery bypass grafting (CABG). High blood sugar levels causes generation of free radicals that leads to oxidative stress in several tissues. We hypothesize that Puerto Rican diabetic patients undergoing coronary artery bypass grafting comprise molecular differences compared to normal patients who experienced identical surgery. The aim of this study is to evaluate the molecular differences in the left internal thoracic artery and saphenous vein conduits in diabetic Puerto Rican patients undergoing coronary artery bypass grafting. Mammary artery (MA) and saphenous vein (SV) tissues from 10 patients undergoing CABG surgery were provided. RNA was extracted and the gene expression levels were compared between diabetic and non-diabetic patients using the super array for 84 genes of oxidative stress. Our results show that the expression level of the Glutathione peroxidase 1 (GPX1) gene is significantly higher in conduits of diabetic patients with respect to non-diabetic patients. This suggest that oxidative stress modulates certain antioxidant defense in type 2 Diabetes, improving our understanding of the molecular pathways that are modulated in the conduits of diabetic patients undergoing CABG. Moreover, this information will help to develop new treatments to improve the long-term prognosis of diabetic patients undergoing CABG.

Amelioration of ischemic neuronal cell damage by transduced Tat- glyoxalase fusion protein.

E. Ahn[1], D. Kim[1], Y. Lee[1], H. Jeong[1], M. Shin[1], S. Kwon[1], Y. Kim[1], H. Kim[1], S. Kim[1], D-S. Kim[2], K. Han[1], J. Park[1], W. Eum[1], S. Choi[1]; [1]Biomedical Science and Research Institute of Bioscience and Biotechnology, Hallym University, Chun Cheon, Korea, [2]Department of Anatomy, College of Medicine, Soonchunhyang University, Cheonan-Si, Korea

Methylglyoxal (MG), a metabolite of glucose, is the major precursor of protein glycation and induces apoptosis. MG is associated with neurodegeneration including oxidative stress and

impaired glucose metabolism, and is efficiently metabolized to S-D-lactoylglutathione by glyoxalase (GLO). Although GLO has been implicated as being crucial in various diseases including ischemia, its detailed functions remain to be elucidated. To this end, we investigated the protective effect of GLO in neuronal cells and an animal model of ischemia using cell-permeable Tat-GLO fusion proteins. Purified Tat-GLO was efficiently transduced into neuronal cells and protected cells against MG-induced cell death, DNA fragmentation, and activation of caspase-3 and mitogen-activated protein kinase. Gerbils injected intraperitoneally with Tat-GLO displayed delayed neuronal cell death in the CA1 region of the hippocampus compared with control cells. Those results demonstrate that transduced Tat-GLO protects neuronal cells by inhibition MG-mediated toxicity. Therefore, Tat-GLO could be useful as a therapeutic agent for various human diseases related to MG including oxidative stress.
Keywords - Methylglyoxal (MG), Glyoxalase (GLO), Oxidative stress, Protein therapy, Ischemic damage.

1217

Tat-DJ-1 protein protects against oxidative stress and ischemic injury in gerbils.

H. Jeong[1], D. Kim[1], E. Sohn[1], M. Shin[1], S. Woo[1], S. Kim[1], H. Jo[1], S-W. Cho[2], D-S. Kim[3], Y-J. Cho[4], J. Park[1], W. Eum[1], S. Choi[1]; [1]Biomedical Science and Research Institute of Bioscience and Biotechnology, Hallym University, Chun Cheon, Korea, [2]Biochemistry and Molecular Biology, University of Ulsan College of Medicine, [3]Anatomy, College of Medicine, Soonchunhyang University, [4]Neurosurgery, Hallym University Medical Center

Reactive oxygen species (ROS) have been implicated in the pathogenesis of various human diseases including ischemic brain injury. Although the exact mechanism remains elucidated, oxidative stress plays critical roles in the pathogenesis of ischemic insult. DJ-1 is widely distributed and is highly expressed in the brain. DJ-1 has an antioxidant and chaperone. However, the protective effect of DJ-1 in brain ischemic injury is unclear. Therefore, we investigated the protective effects of transduced Tat-DJ-1 protein against cell death and ischemic insult. Tat-DJ-1 protein efficiently transduced into astrocytes and protected them against oxidative stress-induced neuronal cell death by reduced intracellular ROS and apoptosis. In addition, we found that Tat-DJ-1 protein prevented neuronal cell death in the CA1 region of the hippocampus when Tat-DJ-1 protein intraperitoneally injected into gerbils.
These results demonstrate that transduced Tat-DJ-1 protein is a tool for the treatment of ischemic insult and it can be used as protein therapy for various disorders related to ROS, including stroke.

Key words: Antioxidant; Cell viability; Ischemic damage; Oxidative stress; Protein therapy; Tat-DJ-1

1218

Anti-inflammatory effect of transduced PEP-1-Cyclophilin A in Raw 264.7 cells and 12-O-tetradecanoylphorbol-13-acetate-induced mice.

E. Sohn[1], D. Kim[1], M. Lee[1], H. Jeong[1], M. Shin[1], H. Kang[1], E. Ahn[1], S. Kwon[1], Y. Kim[1], M. Won[2], J. Kim[3], S-W. Cho[4], T-C. Kang[5], K. Han[1], J. Park[1], W. Eum[1], S. Choi[1]; [1]Biomedical Science and Research Institute of Bioscience and Biotechnology, Hallym University, Chun Cheon, Korea, [2]Neurobiology, School of Medicine, Kangwon National University, Korea, [3]School of Life Science and Biotechnology, Korea University, Korea, [4]Biochemistry and Molecular Biology, University of Ulsan College of Medicine, Korea, [5]Anatomy and Neurobiology, College of Medicine, Hallym University, Korea

Cyclophilin A (CypA) is an immunophilin that acts as a receptor for the immunosuppressant drug cyclosporine A (CsA). CypA has emerged as a potential drug target for several inflammatory diseases, although the details of its mechanism are not unclear. To elucidate the protective effects of CypA on inflammation in Raw 264.7 cells and animal models, a human CypA gene was fused with a protein transduction domain, PEP-1 peptide, to construct a cell permeable PEP-1-CypA fusion protein. Transduced PEP-1-CypA protein markedly inhibited lipopolysaccharide- and 12-O-tetradecanoyl phorbol-13-acetate-induced expression levels of cyclooxygenase-2 as well as pro-inflammatory cytokine levels *in vitro* and *in vivo*. Furthermore, transduced PEP-1-CypA protein resulted in a significant reduction in the activation of nuclear factor-kappa B (NF-*k*B) and mitogen-activated protein kinase (MAPK). The results indicate that PEP-1-CypA inhibits inflammatory response cytokines and enzymes by blocking NF-*k*B and MAPK activation upon stimulation of inflammation *in vitro* and *in vivo*. PEP-1-CypA protein may potentially be used as a therapeutic agent against skin diseases-related inflammation.
Keywords: Cyclophilin A, Inflammation, NF-*k*B, Mitogen-activated protein kinase, Protein therapy.

Investigation of Superparamagnetic Iron Oxide Nanoparticles across Scales in the Inner Ear.

M. Thaler[1], R. Soumen[2], A. Fornara[3], M. Bitsche[4], J. Qin[3], M. Muhammed[3], W. Salvenmoser[5], G. Rieger[6], A. Schrott-Fischer[4], R. Glueckert[4]; [1]University of Innsbruck, Austria, Institute of Zoology; Carl Zeiss NTS GmbH, Oberkochen, Germany, Oberkochen, Germany, [2]Department of Otolaryngology, Medical University of Innsbruck, Austria, [3]Division of Functional Materials, Royal Institute of Technology, Stockholm, Sweden, [4]Department of Otolaryngology, Medical University of Innsbruck, Innsbruck, Austria, [5]Institute of Zoology, University of Innsbruck, Austria, [6]University of Innsbruck, Austria, Institute of Zoology; Medical University of Innsbruck, Austria, Department of Otolaryngology

Today, there is enormous potential for therapeutic innovations for organs which are difficult to access by systemic drug application such as the inner ear. One challenge is to identify suitable multifunctional nanoparticles for drug delivery. This includes the demand for better visible and traceable nanoparticles.
Imaging properties of nanoparticles should enable visualization and analysis across scales down to sub-cellular localization within the target cells.

Objective of this work was to evaluate superparamagnetic iron oxide nanoparticles (SPIONs) within a novel thermo-sensitive copolymer for future pharmacological treatment of hearing loss and drug delivery to the inner ear.

We reported successful application of this ferrogel. SPIONs were tested in two model systems of the inner ear. Results from organotypic explant culture from mouse and human temporal bones are presented.
Distribution and localization of SPIONs in the tissue was visualized by light microscopy and energy filtered transmission electron microscopy (EF-TEM).

We conclude that iron oxide is a powerful imaging agent in multifunctional nanoparticles which can be used for multiscale evaluations especially in inner ear studies. Novel SPIONs have a great potential for traceable targeted drug delivery into inner ear.

1220

Protective effects of p53 in a mouse model of progressive hereditary kidney disease Alport syndrome.

R. Fukuda[1,2], K. Koyama[1,2], T. Koga[1,2], Y. Kai[1,2], M. A. Suico[1,2], T. Shuto[1,2], H. Kai[1,2]; [1]Graduate School of Pharmaceutical Science, Kumamoto University, Kumamoto, Japan, [2]Global COE "Cell Fate Regulation Research and Education Unit", Kumamoto, Japan

Alport syndrome (AS) is one of the hereditary, progressive kidney diseases caused by mutations in the genes encoding type IV collagens such as *COL4A3, 4* or *5*. These collagens compose the glomerular basement membrane (GBM), a key component of the filtering unit in the kidney. Mutation in *COL4* genes causes aberrant GBM structure that results in podocyte detachment from GBM and proteinuria leakage, which are responsible for the symptoms such as chronic inflammatory and fibrotic phenotypes in the kidney of AS. To ameliorate the symptoms and phenotypes of AS, identification of molecules other than COL4 proteins that modulate disease progression could provide novel therapeutic approach for AS. Here, we identify p53, a stress responsive transcriptional factor known to regulate various genes expression, as an inhibitory molecule of the progression of renal symptoms in a mouse model of AS (*Col4a5* mutation). A p53 heterozygosity in AS mice ($p53^{+/-}$ AS mice) caused rapid progression of proteinuria increasing rate compared with $p53^{+/+}$ AS mice. Furthermore, expression of inflammatory cytokine genes in the kidney of $p53^{+/-}$ AS mice was significantly increased, and glomerular injury score and fibrotic phenotype were more exaggerated in $p53^{+/-}$ AS mice compared with $p53^{+/+}$ AS mice. Moreover, survival rate of $p53^{+/-}$ AS mice was significantly lower than that of $p53^{+/+}$ AS mice, suggesting that p53 has a protective role against renal symptoms in AS. Finally, expression analysis of p53 in the kidney of $p53^{+/+}$ AS mice proved that renal expression of p53 is decreased during progression of AS, supporting the idea that induction and maintenance of p53 expression in the kidney may contribute to its protective effects against AS. Collectively, our data demonstrate the critical role of p53 in a mouse model of AS.

1221

Cleavage of the Polycystin-1 cytoplasmic tail: pathogenic and proper modulation of STAT3.

J. J. Talbot[1,2], J. M. Shillingford[1,2], S. Vasanth[1,2], N. Doerr[1,2], T. Weimbs[1,2]; [1]University of California Santa Barbara, Santa Barbara, CA, [2]Neuroscience Research Institute, Santa Barbara, CA

Autosomal-dominant polycystic kidney disease (ADPKD) is a common genetic disorder that frequently results in renal failure by midlife. Functional nephrons are progressively replaced by non-filtering cysts and fibrous tissue. Mutations in *polycystin-1* (PC1) underlie ~95% of ADPKD cases, but the function of PC1 has remained poorly understood. PC1 is a multi-pass integral membrane protein, which has been implicated in the regulation of multiple signaling pathways

including the JAK/STAT pathway. PC1 protein levels are high during development and acute renal injury but drop with maturity and the resolution of injury. Unexpectedly, PC1 levels are also high in ADPKD patients.

Similar to cancer, the “loss of heterozygosity” sets the stage for disease. However, it is an environmental “third hit” that induces cystogenesis, leading to the growth of clonal cysts, which differ in their geneotypes due to unique mutations in each PC1 allele. We report here two mechanisms by which PC1 can regulate STAT3 activity. The first is characteristic of wild type PC1 and critical for development and acute injury response, the second characteristic of ADPKD and executed by a pathogenically cleaved PC1.

We show that, as in a normal kidney, membrane-anchored PC1 tyrosine-phosphorylates STAT3 in a JAK2-dependent manner, leading to its nuclear translocation and activating transcriptional activity. We show that the cleaved PC1 tail accumulates in ADPKD kidneys, including a unique ~15-kDa fragment (P15). Cleavage of the P15 fragment from the PC1 cytoplasmic tail abolishes the ability of PC1 to activate STAT3. Additionally, patient mutations in the PC1 tail affect its ability to activate STAT3.

Also, a ~30kDa cleavage product (P30) is enriched in ADPKD kidneys. The cleaved P30 PC1 product readily undergoes nuclear translocation. The P30 fragment co-activates STAT3 by a mechanism requiring phosphorylated STATs, which are activated by auto- or paracrine secretion of cytokines/growth factors. This leads to an exaggerated cytokine/growth factor response and amplified levels of STAT3 signaling.

STAT3 is strongly activated in cyst-lining epithelial cells in human ADPKD, and orthologous and nonorthologous polycystic mouse models compared to normal kidneys in which it is barely detectable. STAT3 is also activated in developing, postnatal kidneys but inactivated in adult kidneys.

Altogether, these results indicate that PC1 can differentially regulate STAT3 signaling depending on the state of PC1 cleavage, and on the local cytokine environment. Normally, PC1 may integrate mechanical and chemical signals to direct the appropriate cellular response of renal epithelial cells. In disease, the cleaved PC1 tail hypersensitizes cells to STAT3-dependent cytokine signaling. We believe that STAT3 signaling is a driving factor for renal epithelial proliferation during normal renal development and during cyst growth.

1222

The Structural Investigation of Protective Role of Antiepileptic Vigabatrin in Epilepsy Treatment by FTIR Spectroscopy and Neural Networks.

S. Turker[1], M. Severcan[2], S. Komsuoglu[3], F. Severcan[4]; [1]Biology, Kocaeli University, Kocaeli, Turkey, [2]Electrical and Electronics Engineering, Middle East Technical University, Ankara, Turkey, [3]Medical School, Dept. of Neurology, Kocaeli University, Kocaeli, Turkey, [4]Biological Science, Middle East Technical Univ., Ankara, Turkey

Epilepsy is a well-known neurological disorder affecting 1-2 % of the population of the world, however; epileptic seizures remain uncontrollable in at least 30% of all the cases. Clinical studies have been carried out to improve new antiepileptic drugs. Vigabatrin (γ-vinyl-GABA) is a newer well-characterized antiepileptic, which differs from old drugs due to high rate of metabolic transformation. In the current study, the therapeutic role of VGB on PTZ-induced epileptic rat brain cell membrane was investigated at molecular level by using Fourier Transform Infrared Spectroscopy (FTIR) together with Neural Network (NN) analysis.

Animals were divided as control (n=6), PTZ (n=5) and PTZ-VGB (n=6). Whilst PTZ group was administrated by 60 mg/kg pentylenetetrazol, PTZ-VGB group received first 100 mg/kg VGB and 4 hours later 60 mg/kg pentylenetetrazol injection. The isolated rat brain plasma membrane samples were studied in FTIR spectroscopy in 4000-1000 cm-1 frequency range with 2 cm-1 resolution. The variations in the secondary structure of membrane proteins upon VGB treatment were determined by NN and second derivative analysis of Amid I band. Based on spectral variations cluster analysis was applied to different spectral regions which provided successful differentiation of control, epileptic and VGB-treated groups.
In epileptic group, there are significant ($p<0.05^*$) changes in the spectral parameters of lipid bands e.g. the bandwidth of the CH2 asymmetric and symmetric, the C=O band frequency, olefinic band area and also the lipid to protein ratio (the ratio of the total areas under CH2 asymmetric and symmetric stretching bands to the total areas under Amid I and II bands). With the application of VGB to PTZ group, these alterations approached to control group values, however; the C=O, the PO2 asymmetric and symmetric band areas related to phospholipid molecules and the secondary structure of membrane proteins were significantly ($p<0.05^*$) different from control group.
The results revealed that VGB protects some of the epilepsy-induced alterations such as the decrease in membrane fluidity, membrane disorganization, protein degradation, lipid to protein ratio and lipid peroxidation. However, it was observed that VGB had no positive effects to prevent phospholipid degradation and changes in the secondary structure of proteins.

1223

Light and Electron Microscopic Examination of The Effects of Long Term-Low Dose CyclosporinA (CsA) and Its Combination with Prednisolone on Hematopoietic Cells.

R. G. Aktas[1], F. Ercan[2], S. Altaner[3]; [1]Histology&Embryology, School of Medicine, Koc University, Istanbul, Turkey, [2]Histology&Embryology, School of Medicine, Marmara University, Istanbul, Turkey, [3]Pathology, School of Medicine,Trakya University, Edirne, Turkey

Objective:
A very potent immunosuppressive agent, CsA, is a common drug after transplantations. The side effects of CsA at high doses after short term applications have been examined in previous studies. However; many immunosuppressive treatment protocols contain long term-low dose CsA administration. There are concerns about the side effects of the vehicle of CsA, Cremophore-EL. Some protocols also include low dose Prednisolone, which might cause additional side effects.
The current study focuses on the effects of long term immunosuppressive therapy on hematopoietic cells. It was aimed to analyse the morphologic effects of CsA, Cremophor-EL and Prednisolone on bone marrow both at light and electron microscope level.
Methods:
The study included four experimental groups: 1st group was control, 2nd group had oral form of CsA(4mg/kg/day) for 10 weeks. 3rd group had i.v. form of CsA(4mg/kg/day) for 10 weeks. This form contains Cremophor-EL. Finally, 4th group had i.v. form of CsA(4mg/kg/day) and prednisolone(1 mg/kg/day) for 10 weeks. 24 female Sprague Dawley rats had been used for the study: Bone marrow specimens from these animals were embedded in Araldite. Semi-thin sections were stained with toluidine blue and examined under Axioscope. Thin sections were stained with uranyl acetate and lead citrate. They were examined under Jeol 1200 FX.
Results:
Bone marrow specimens from control group included myelomonocytic cells, erythroid cells, and megakaryocytic cells. There were also lymphocytes, plasma cells, connective tissue cells and stromal cells. Myeloid to erythroid ratio (ME ratio) was about 3:1.. After long term application of either oral or intravenous form of CsA; cellularity was slightly decreased. Distribution of

precursor cells was different from control group. Additional therapy with Prednisolone caused significant increase at the number of adipocytes.

Conclusions:

These morphologic results suggest that long term-low dose CsA therapy has impact on hematopoiesis. Long term effects of the drug differs from the results after short term-high dose applicatons. Cremophore EL does not cause any additional microscopic changes on bone marrow cells. The most drammatic changes are observed after the application of CsA with Prednisolone.

1224

Novel therapeutic strategy for the inhibition of pseudorabies virus (PRV) infection in C57BL/6 mouse by recombinant nuclease catalytic antibody.

S. Cho[1], G. Lee[2], J. Park[1], J. Chae[1], E-J. Kil[1], S. Kang[1], E. Ji[1], D. T. Tran[1], K. Roh[1], P. M. Hoang[1], T-K. Lee[2], S. Lee[1]; [1]Sungkyunkwan University, Suwon, Korea, [2]Korea Ocean Research and Development Institute

3D8 scFv is a recombinant monoclonal antibody with nuclease activity originally isolated from autoimmune-prone MRL mice. Previously, we have demonstrated that HeLa cell lines expressing 3D8 scFv conferred resistance to HSV-1 and PRV by nuclease activity of 3D8 scFv. In this study, we show that 3D8 scFv can be delivered to the target tissues and cells by intraperitoneal injection and have a therapeutic effect against PRV. Intraperitoneal injection of 5 μg and 10 μg 3D8 scFv did not develop any noticeable toxicity. C57BL/6 mouse showed 9% survival rate after $10LD_{50}$ PRV intramuscular infection. By contrast, 3D8 scFv injected C57BL/6 mouse exhibited 57% (5 μg; group E) and 47% (10 μg; group F) survival rates. This therapeutic effect of 3D8 scFv against PRV was also supported by qRT-PCR, southern hybridization, and immunohistochemistry. Comparative mRNA expression data using several chemokines (iNOS and CXCL10) revealed that the antiviral mechanism on C57BL/6 mice was due to the nuclease activity of 3D8 scFv. Therefore, our results indicated that the nuclease activity of 3D8 scFv can be utilized as an effective antiviral agent on several animal models.

1225

Binding Affinity of a Phosphopeptide Analogue of Heat Shock Protein β6 to Various Isoforms of 14-3-3.

D. H. Eng[1], D. N. Derkach[1], K. B. Perkins[1], M. R. Sheller[1]; [1]Capstone Therapeutics, Tempe, AZ

AZX100, a phosphopeptide mimetic of Heat Shock Protein β6 (HSPβ6 or HSP20) containing a protein transduction domain, has been previously shown to bind to 14-3-3γ. In cells expressing 14-3-3γ, AZX100 binding results in the displacement and dephosphorylation of cofilin. Upon dephosphorylation, cofilin dismantles actin, leading to reduced contractility and migration of fibroblasts. AZX100 has also been shown to reduce filamentous actin and change cell shape in both 3T3 fibroblasts and keloid fibroblasts (KF).

Since the binding motif for phosphoserine peptides is conserved across all 14-3-3 isoforms, the ability of AZX100 to bind to 14-3-3β, –ε, and –σ was investigated via Surface Plasmon Resonance (SPR) measurements conducted with the Biacore® 2000. Peptides were coated on a CM5 chip and various concentrations of each 14-3-3 isoform were flowed over the chip surface. Binding affinities were calculated from the measured binding curves. AZX100 bound to all isoforms of 14-3-3; however, the binding affinity was highest to 14-3-3γ. AZX100 binding affinity to 14-3-3γ was 157 ± 24.9 nM, whereas AZX100 binding affinity to 14-3-3β, -ε, and –σ was 1702 ± 135, 607.9 ± 66.3, 2192 ± 60, respectively. Small variations in the binding pocket of

the 14-3-3 isoforms for phosphoserine peptides could account for the differences in binding affinity.

Additional experiments with peptide variants of AZX100 were measured with SPR to determine important residues associated with binding. Variants W12A, L13A, and L23A did not significantly reduce binding to 14-3-3γ (215 ± 33.5, 177 ± 16.5, and 218 ± 29.4 nM, respectively). These variants also bound to 14-3-3β, -ε, and –σ with similar binding affinity as AZX100. However, a single amino acid substitution at P19A abolished all binding to 14-3-3γ, -β, and -ε. Interestingly, P19A bound to 14-3-3σ with a binding affinity of 1832 ± 480 nM. Therefore, further optimization can be conducted at the 12, 13, and 23 positions in AZX100 that may lead to improved binding and specificity.

1226

Development of a novel antiviral mouse model harboring a nuclease antibody against pseudorabies virus (PRV) infection.

J. Chae[1], G. Lee[2], S. Cho[1], J. Park[1], E-J. Kil[1], E. Ji[1], D. T. Tran[1], K. Roh[1], P. M. Hoang[1], S. Cho[1], T-K. Lee[2], S. Lee[1]; [1]Sungkyunkwan University, Suwon, Korea, [2]Korea Ocean Research and Development Institute

In the previous experiments, recombinant 3D8 scFv, isolated from an autoimmune-prone MRL mice, showed antiviral effects. HeLa cell lines expressing 3D8 scFv conferred the resistance to HSV-1 and PRV by nuclease activity of 3D8 scFv and then 3D8 scFv can be utilized as an effective antiviral agent on C57BL/6 mice. In this Paper, we identified preventive effect on 3D8 scFv transgenic C57BL/6 mice against PRV. STG90 mouse (3D8 scFv transgenic mouse line 90) exhibited high mRNA expression of 3D8 scFv by qRT-PCR in muscle and brain. Wild type C57BL/6 mouse showed 0% survival rate after PRV challenging while STG90 have a 56% survival rates after PRV intramuscular infection. Preventive effect against PRV on 3D8 scFv TG mouse was verified by qRT-PCR, southern hybridization, and immunohistochemistry. These results demonstrated that 3D8 scFv transgenic C57BL/6 mice showed preventive effect by nuclease activity and will exhibit antiviral effects against DNA and RNA virus.

1227

Calretinin Interacts with Mutant Huntingtin and Suppresses Its Cytoxicity in Cell Culture.

K. Gross[1], G. Dong[2], E. Callegari[2], H. Wang[2]; [1]Department of Biology, Mount Marty College, Yankton, SD, [2]Division of Basic Biomedical Sciences, University of South Dakota Sanford School of Medicine

Huntington's disease (HD) is a fatal neurodegenerative disorder and is caused by an abnormal expansion of polyglutamine repeats in the Huntingtin (Htt) protein. Abnormal mutant Htt-protein interactions have been implicated in the pathogenesis of HD. To identify novel proteins that interact with mutant Htt, we employed the approach of tandem affinity purification and discovered that Calretinin (Cr), a calcium-binding protein, interacts with mutant Htt. This was confirmed by co-immunoprecipitation. Overexpression of Cr reduced mutant Htt-induced cytotoxicity in both non-neuronal and neuronal cell models of HD, whereas knockdown of Cr expression in the cells facilitates mutant Htt-caused cell death. These data taken together suggest that Cr might be a novel therapeutic target for treating HD and other polyglutamine disorders.

1228

Mechanistic studies of fibronectin peptide P12: a co-factor of PDGF-BB.

J. Zhu[1], M. Mctigue[1], F. Lin[1], R. Clark[1]; [1]Stony Brook Univeristy, East Setauket, NY

Objective: P12 is a small cationic peptide derived from the first type III repeat of human fibronectin based on its growth factor binding activity. P12 has shown promise limiting injury progression in both rat and porcine burn injury models. The overall goal is to investigate the mechanism of P12 to promote cell survival by in vitro models created to mimic the ischemic condition in the peri-burn tissue. This is a logical extension of previous biochemical experiments demonstrating P12 has synergistic effects with platelet derived growth factor-BB (PDGF-BB) to prolong cell survival. The hypothesis is that P12 functions through augmenting PDGF-BB survival signals as a PDGF-BB co-factor. Results: P12 in the presence of PDGF-BB promoted adult human dermal fibroblast (AHDF) cell metabolism and survival under nutrient deprivation stress as measured by XTT and TUNEL assay. P12 modulated PDGF-BB signaling in AHDF under nutrient deprivation stress on both serum coated and collagen coated surfaces. Compared to PDGF alone or PDGF with scrambled P12, authentic P12 prolonged Akt phosphorylation at Ser473 for 2hs on both surfaces. It also reduced JNK and ERK1/2 phosphorylation to control level on serum coated surfaces. It did not change p38 phosphorylation and eIF4e protein level. P12 showed efficient binding to PDGF-BB and penetrated AHDF as a protein transduction domain. Briefly, P12 labeled by Alexa Fluor 488 entered human dermal fibroblast in a temperature and energy dependent manner as measured by confocal microscopy and FACS. P12 entry is also partially blocked by removing cell surface glycosaminoglycans. Conclusion: P12 promotes cell survival by augmenting survival signals from PDGF-BB and possibly by affecting PDGF-BB/PDGFR internalization/trafficking.

Signaling from the PM/Cytoplasm to the Nucleus

1229

IFN-γ and TNF-α induced GBP-1 inhibits epithelial cell proliferation through suppression of β-catenin/TCF signaling.

C. T. Capaldo[1], N. Beeman[1], R. Hilgarth[1], P. Nava[1], N. Louis[1], E. Naschberger[2], M. Sturzl[2], C. Parkos[1], A. Nusrat[1]; [1]Emory University, Atlanta, GA, [2]Molecular and Experimental Surgery, University of Erlangen-Nuremberg, Erlangen, Germany

Proinflammatory cytokines induce Guanylate Binding Protein 1 (GBP-1) protein expression in intestinal epithelial tissues. GBP-1 has been described as influencing a number of cellular processes important for epithelial homeostasis, including cell proliferation. However, the role of GBP-1 in intestinal mucosa remains incompletely understood. We therefore sought to investigate the function of proinflammatory cytokine induced GBP-1 during intestinal epithelial cell proliferation. Through the use of complementary GBP-1 overexpression and siRNA-mediated knockdown studies, we now show that GBP-1 acts to inhibit pro-mitogenic β-catenin/ T cell factor (TCF) signaling. Interestingly, proinflammatory cytokine induced GBP-1 was found to be a potent suppressor of β-catenin protein levels and β-catenin serine 552 phosphorylation. Neither GSK3-β nor proteasomal inhibition alleviated GBP-1-mediated suppression of cell proliferation or β-catenin/TCF signaling, indicating a non-canonical mechanism of β-catenin inhibition. Together, these data show that cytokine-induced GBP-1 retards cell proliferation by forming a negative feedback loop that suppresses β-catenin/TCF signaling.

1230

The mechanism of IL-33-induced Th2 cytokine production in natural helper cells.

J-I. Furusawa[1,2], K. Moro[1,3], S. Koyasu[1]; [1]Department of Microbiology and Immunology, Keio University School of Medicine, Tokyo-to, Japan, [2]Research fellow of the Japan Society for the Promotion of Science, Tokyo-to, Japan, [3]PRESTO, Japan Science and Technology Agency (JST), Japan

We have previously identified novel IL-2R$^+$IL-7R$^+$IL-25R$^+$IL-33R$^+$ lymphocytes named 'natural helper (NH) cells' in mouse, rat and human adipose tissues. NH cells produce large amounts of Th2 cytokine such as IL-5, IL-6 and IL-13 by IL-33 stimulation. The ability of NH cells to produce Th2 cytokine is much higher than mast cells and basophils. IL-33 is a member of IL-1 family cytokine, which is known to localize in the nucleus of epithelium and endothelium cells. During helminth infection, allergy and other diseases, IL-33 is released by necrotic cells in injured tissues. In this study, we aimed to clarify why NH cells can produce such large amounts of Th2 cytokines compared to other cells by focusing on IL-33 signaling pathways. NH cells and bone marrow derived mast cells (BMMC) were stimulated with IL-33, and examined the kinetics of Th2 cytokine production at protein levels by ELISA. In NH cell, production of IL-5, IL-6 and IL-13 was significantly accelerated 48 hrs after IL-33 stimulation, leading to the production of more than 10 ng of these cytokines by 5,000 NH cells. In contrast, BMMC produced IL-6 from 3 hrs and peaked at 24 hrs after IL-33 stimulation but total amounts were less than 3% of NH cells. Only small amounts of IL-5 and IL-13 (~200 pg) were produced by BMMC. Western blot analysis revealed that IL-33 stimulation of NH cells activated NFκB and MAPK pathways more strongly than in BMMC. The activation of NFκB and MAPK signaling pathways were sustained even 48 hrs after IL-33 stimulation. To clarify what signaling molecules are important for IL-33-induced Th2 cytokine production in NH cells, we examined the effect of several inhibitors of signaling pathways. Intriguingly, a p38 inhibitor, SB203580 markedly inhibited IL-33-induced IL-5, IL-6 and IL-13 production in NH cells. Taken together, these results suggest that NH cells produce high amounts of IL-5, IL-6 and IL-13 through p38 mediated signal transduction pathways downstream of IL-33 receptor. Now, we are analyzing more detailed mechanisms of p38 mediated Th2 cytokine production in NH cells.

1231

In Situ Calcium Imaging During Mechanical Shear Applied to Articular Cartilage.

A. E. Mercado[1], J. T. Henderson[2], C. P. Neu[2]; [1]Biomedical Sciences, University of Puerto Rico Aguadilla Campus, San Sebastián, Puerto Rico, [2]Biomedical Engineering, Purdue University

Osteoarthritis is a degenerative disease of articular cartilage in the joint that affects over 27 million people in the US alone (Lawrence, 2008). Cartilage cells (chondrocytes) are influenced by mechanical loading which in turn regulates a variety of biochemical responses, including Ca2+ concentrations. Recent studies have shown how intracellular Ca^{+2} concentrations in chondrocytes change in response to different mechanical loading such as shear flow. Many studies of this type involve isolated cells in monolayer cultures, but the role of the surrounding three-dimensional extracellular matrix in delivering the mechanical stimuli has been widely discarded from such studies. When shear stress is applied to cartilage, deformation of the extracellular matrix and consequently of the pericellular matrix occurs, changing the environment that surrounds the cell and initiating signal transduction pathways. To study how the application of shear stress affects the intracellular concentrations of calcium, we carried out calcium imaging using the ratiometric dye Fura-2 AM in cells in their native environment, i.e. in explants (plugs) obtained from bovine articular stifle joints. A dual piezoelectric device was used to deform the cartilage explants every 30 seconds during imaging. In one of the experiments ionomycin was added after 10 minutes and EGTA was added after 16 minutes while applying

compression. Results show that 340/380 nm ratio intensity increases steadily in calcium-free media while applying compression to the explants. These results indicate that biochemical responses to mechanical loading can be measured *in situ* in chondrocytes, and they further enable the study of potentially altered cell responses to disease states in articular cartilage.

1232

Increased expression of Aquaporin 9 in inflammatory cells as a response to LPS.

A. Holm[1], T. Karlsson[1], J. Wetterö[2], V. Loitto[1], K-E. Magnusson[1]; [1]Department of Clinical and Experimental Medicine: Medical Microbiology, Linköping University, Linköping, Sweden, [2]Department of Clinical and Experimental Medicine: Rheumatology, Linköping University

The aquaporins (AQPs) are a family of water channels involved in volume regulation through water transport in and out of the cell and are thereby of importance in a number of cellular events. The aquaglyceroporin, AQP9 has been suggested to play a pivotal role in inflammatory cell migration, differentiation and metabolism. Thus, we wanted to investigate the role and regulation of AQP9 in human primary inflammatory cells in response to inflammatory stimuli and inhibitors especially the effects of lipopolysaccharide- (LPS) and TNF-alpha-stimulation as analyzed with molecular and imaging techniques,.
qPCR analyses of human primary macrophages obtained from healthy blood donors showed an increase of the mRNA expression of AQP9 upon LPS stimulation. Protein analyses with Western blot further confirmed this effect at the protein level. Moreover, preliminary data from human primary neutrophils indicated similar responses.
These results implicate a role of AQP9 in inflammatory cell responses to LPS and are in line with a suggested role of AQP9 in inflammatory cell motility. AQP9 could thus have crucial effects on cell functions at sites of infection and bacterial antigen deposition, like their volume regulation, motility and metabolism. Here we present a hypothetical model for AQP9 upregulation that is dependent on bacterial agents and inflammatory mediators.

1233

Regulation of p21 in urothelial carcinoma cells.

N. Yohn[1], C. Bingaman[1], L. Yoo[2]; [1]Denison University, [2]Denison University, Granville, OH

Background
The PTEN/Phosphatidylinositol 3’-kinase (PI3-kinase) growth factor signaling pathway plays a critical role in epithelial tumor development in a multitude of tissue types. Deletion of the Pten tumor suppressor gene in murine urothelial cells in vivo results in upregulation of cyclin-dependent kinase inhibitor p21. We have previously shown in mice that p21 expression blocks an increase in urothelial cell proliferation due to Pten deletion. In this study, we utilized human urothelial carcinoma cells UMUC-3 and UMUC-14 to identify the signaling pathways downstream of PI3-kinase that regulate p21.
Methods
Cells were treated with a combination of PI3-kinase stimulating growth factors and kinase inhibitors, or transfected with exogenous genes in order to identify the signaling events that are necessary for p21 induction. Mice with conditional deletion of Pten in bladder urothelium were also examined for evidence of PI3-kinase pathway signaling events that affect p21 expression.
Results
When cells were treated with PI3-kinase activating growth factors EGF or PDGF, we found that p21 levels increased, in a manner similar to that observed in mice. We used the inhibitors LY294002, Akti-1/2, and rapamycin, to show that p21 induction is dependent upon PI3-kinase and AKT activity, and partially dependent on mTOR. We treated the cells with proteasome inhibitor MG-132 and found that p21 may be degraded in the proteasome to regulate protein

levels. Importantly, our findings show that GSK-3β plays a role in diminishing p21 levels in cells. Treatment of cells with the GSK-3β inhibitor SB-216763 increased p21 levels, while exogenous expression of GSK-3β caused a decrease in p21, indicating that GSK-3β actively reduces p21 levels. We found that a combined treatment of LY294002 and SB-216763 improved the cytotoxic effect against UMUC-3 and UMUC-14 carcinoma cells over LY294002 alone, suggesting potential therapeutic uses for GSK-3β inhibitors. Immunohistochemical staining in bladders from wild-type and Pten-deleted mice indicated that GSK-3β inhibitory phosphorylation increases when Pten is deleted.
Conclusion
PI3-kinase and AKT cause an upregulation of p21 by suppressing GSK-3β activity and activating mTOR in both cultured human urothelial carcinoma cells and mouse urothelial cells in vivo.

Regulation of β-distroglycan nuclear localization by ezrin.
A. Vasquez-Limeta[1], A. Ortega[1], D. A. Jans[2], B. Cisneros[1]; [1]Genetica y Biologia Molecular, CINVESTAV-IPN, Mexico, D.F., Mexico, [2]Biochemistry and Molecular Biology, Monash University, Melbourne, Australia

Dystroglycan is a protein member of the Dystrophyn-Associated Protein Complex (DAPC). DAPC is composed of extracellular, transmembrane and cytoplasmic proteins, and has central role in muscular integrity. Dystroglycan subcomplex comprises the extracellular subunit α–dystroglycan and the transmembranal protein β-dystroglycan (β-DG); the latter links to α-dystroglycan by its N-terminus domain, and to different intracellular proteins (dystrophin, actin, ERK, MAPK, Grb2, and ezrin) through its C-terminus domain. Nuclear presence of β-dystroglycan has been recently demonstrated in different cell lines, and a functional nuclear localization sequence (NLS) that is recognized by importins α and β was identified within the cytoplasmic domain. It is worth to note that the NLS of β-DG also serves as an ezrin-binding site, making possible that ezrin and importins compete each other for binding to the same motif on β-DG. Therefore, the aim of this study was to analyze the influence of ezrin on the nuclear localization of β-DG, we showed that ezrin over-expression increases rather than decreases the nuclear levels of endogenous β-DG. Furthermore, we revealed that over-expression of an ezrin variant that mimics its phosphorylated state (ezrinT567D) favors even more the nuclear accumulation of β-DG. On contrary, over-expression of a nonphosphorylable variant of ezrin (ezrinT567A) causes a marked decrease in the nuclear levels of β-DG. In consistency, induction of ezrin phosphorylation by LPA treatment increased the nuclear levels of β-DG, while inhibition of ezrin phosphorylation by C3-transferase exotoxin treatment reduces the nuclear accumulation of β-DG. Altogether, our results suggest that phosphorylation of ezrin favors the nuclear import of β-DG, likely by ezrin-mediated cytoskeleton remodelation.

1235
Pathway Selection by Nod1 and Nod2.
A. Ver Heul[1], S. Ramaswamy[2], R. Piper[3]; [1]Biochemistry, University of Iowa, Iowa City, IA, [2]inStem, NCBS, Bangalore, India, [3]Molecular Physiology and Biophysics, University of Iowa, Iowa City, IA

Defects in both Nod1 and Nod2 signaling pathways are associated with human disease. Perhaps most notably, polymorphisms in Nod2 and ATG16L are strongly associated with susceptibility to Crohn’s Disease. The two main effectors for Nod1 and Nod2 are Receptor-interacting serine/threonine-protein kinase 2 (Ripk2) and Autophagy-related protein 16 (ATG16L). Upon recruitment to the Nod1 or Nod2 signaling complex, the proinflammatory

effector Ripk2 is autophosphorylated and stimulates the canonical NF-κB pathway by activating the IKK complex. How ATG16L activates autophagy remains poorly understood, but recent evidence suggests that its recruitment by Nod1 or Nod2 signaling complexes to sites of intracellular bacterial invasion serves to enhance autophagocytosis of those bacteria.
NMR spectroscopy and affinity matrix binding assays were used to map protein:protein interactions between Nod1, Nod2, ubiquitin, Ripk2 and ATG16L. We found distinct but overlapping binding interfaces for Ripk2 and ubiquitin exist on Nod1. Accordingly, we show that ubiquitin binding is competitive with Ripk2 binding to both Nod1 and Nod2. Similarly to how Ripk2 binds Nod1 and Nod2, ATG16L binds the Caspase Activation and Recruitment Domains (CARDs) on Nod1 and Nod2.
The finding that ubiquitin competes with the interactions between Ripk2 and Nod1 and Nod2 suggests that ubiquitin plays a regulatory role in Nod1 and Nod2 signaling. In addition to our findings, recently reported results on the regulation of another innate immune receptor by poly-ubiquitin chains support a general role for ubiquitin:CARD interactions in modulating activity of innate immune receptors. Ongoing functional studies of ubiquitin- and Ripk2-specific binding mutants of Nod1 and Nod2 will determine the functional relevance of these interactions. As well, investigations into the role of ubiquitin in the interaction between ATG16L and Nod1 and Nod2 are underway. These studies will not only advance our understanding of the Nod1 and Nod2 pathways, but will also contribute to the broader field of cell biology and immunology.

Muscle Plasticity Is Regulated by a Process Involving ATP Release and Inositol Trisphosphate Production in Skeletal Myofibers.

G. Jorquera[1], G. Almarza[1], S. Buvinic[1], E. Jaimovich[1], M. Casas[1]; [1]Center for Molecular Studies of the Cell, ICBM, Faculty of Medicine, Universidad de Chile, Santiago, Chile

Introduction: In skeletal muscle, myofibers can be classified as slow- and fast-twitch depending on its metabolic and contractile properties. Transcription of specific gene programs is regulated by different electrical stimulation patterns, process known as muscle plasticity. We have previously described the presence of post-tetanic, inositol trisphosphate (IP_3)-dependent calcium signals that are frequency dependent in adult muscle fibers. We reported that extracellular ATP can act as an autocrine signal in primary myotubes, inducing intracellular calcium movements and regulating gene expression.
Objective: How myofibers can discriminate among different frequencies and activate specific gene programs? In the present work we propose a pathway for muscle plasticity is modulated by IP_3-dependent calcium transients, with ATP release as a key regulator.
Methods: We used adult myofibers obtained from both FDB and soleus muscles. Myofibers were stimulated at 20 and 90 Hz (270 pulses, 0.3 ms each). We analyzed gene expression (qPCR), ATP release (luciferase) and IP_3 production (ELISA).
Results: We found that ATP release from myofibers is different depending on stimulation frequency, with an important, biphasic release at 20 Hz with a peak 3-5 min after stimulation; this release is dependent on pannexin channels and dihydropyridine receptors because it is inhibited by fiber pre-incubation with 25 μM nifedipine. With this stimulation pattern we found two IP_3 increments, one immediately after stimulation another one 5 min after stimulation. We observed an increase in slow troponin I (TnIs) mRNA levels and a decrease in fast troponin I (TnIf) mRNA. These changes are inhibited by ATP release inhibitors (apyrase, carbenoxolone) and IP3R blockers (xestospongin B). We see an increase of citrate synthase mRNA and a decrease in those of enolase mRNA after 20 Hz stimulation, which are not inhibited by xestospongin B. At 90 Hz there was no significant ATP release and IP_3 production was much less evident. In these conditions there is an increase in TnIf mRNA levels and a decrease in TnIs, that was IP3R-independent.

Conclusions: We propose that both ATP release and IP_3 production are part of a frequency-dependent integrated process that activates the slow type muscle fiber program.

Hypertrophy Induced by Testosterone in Skeletal Muscle Cells: Not Only an Androgen Receptor Mediated Process.

C. E. Basualto-Alarcón[1], G. Jorquera[1], E. Jaimovich[1], M. Estrada[2]; [1]Center for Molecular Studies of the Cell, ICBM, Faculty of Medicine, Universidad de Chile, Santiago, Chile, [2]Program of Physiology and Biophysics, ICBM, Faculty of Medicine, Universidad de Chile, Santiago, Chile

Introduction: Since description of testosterone as the major male anabolic hormone in humans, questions about its action mechanism in skeletal muscle have arisen. Reports about rapid non genomic effects of this hormone raised the question about their impact in hypertrophy elicited by testosterone. We studied whether the classic androgen receptor was necessary to elicit hypertrophy in skeletal muscle myotubes. Concomitantly activation of classic hypertrophic pathways by testosterone and the potential relationship between the androgen receptor and these hypertrophic pathways was also studied.
Materials and Methods: Five to seven day old rat myotubes, obtained from neonatal rat hind limbs, were used. 100nM testosterone, a dose that produces oscillatory calcium transients and induces activation of ERK1/2, was utilized. Hypertrophy was measured by microscopy, western blot and qPCR. Activation of the putative pathways was studied by western blot and inhibitors. Androgen Receptor action was studied by western blot and small interference RNA (siRNA).
Results: Testosterone induced an increase in myotube cross sectional area (control=134,5μm^2±10,21; testosterone=181,9μm^2±14,41) and in α-actin protein levels at 12 hours. Morphological development of myotube sarcomerisation was more clearly established in testosterone stimulated myotubes at this time. Earlier times of testosterone stimulation showed increased transcription of α-actin gene, concomitantly with no changes in atrogenes (MAFfbx and MuRF-1) activity at 6 hours. Classic hypertrophy pathways were studied at short times: ERK1/2 and Akt showed an increase in phosphorylation status after testosterone at 5 and 15 minutes, respectively. p70S6K was phosphorilated at 60 minutes. This response was inhibited with LY294002, Akt-inhibitor-VIII and Rapamycin but not by PD98059. Similarly, the hypertrophic response at 12 hours was abolished with these inhibitors as well as partly by a siRNA against androgen receptor but not by PD98059.
Discussion: In this work we showed that testosterone activates the Akt/mTOR pathway at short times. Two selected parameters of hypertrophy showed an increase at 12 hours. Inhibition of Akt/mTOR pathway at 12 hours, demonstrated a direct relationship between the early hypertrophy response and the activation of mTOR pathway. siRNA to the androgen receptor also unveiled an important role of this receptor in the early hypertrophy response.

JNK1 inhibits GluR1 expression and GluR1-mediated calcium influx through phosphorylation and stabilization of Hes-1.

C-H. Lin[1], S-Y. Liu[1], H-Y. Lee[2]; [1]Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan, [2]Institute of Biomedical Sciences, Taipei, Taiwan

The GluR1 subunit of the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor plays an important role in excitatory synaptic transmission and synaptic plasticity in the brain, but the regulation mechanism for GluR1 expression is largely unknown. *Hairy* and *Enhancer of split 1* (Hes-1) is a mammalian transcription repressor that regulates neuronal

differentiation and development, but the role of Hes-1 in differentiated neurons is also less known. Here we examined the molecular mechanism in regulation of GluR1 expression in cultured cortical neurons from rat. We found that Hes-1 suppressed GluR1 promoter activity and decreased GluR1 expression through direct binding to the N box and through preventing Mash1/E47 from binding to the E box of GluR1 promoter. We also found that Hes-1 could be regulated by c-Jun N-terminal kinase (JNK1). JNK1 directly phosphorylates Hes-1 at Ser-263, and JNK1 phosphorylation of Hes-1 stabilized the Hes-1 protein and enhanced its suppressing effect on GluR1 expression. Moreover, this JNK1-mediated signaling pathway was found to inhibit AMPA-evoked calcium influx in cortical neurons and this regulation mechanism is Notch-independent. Further, JNK1 regulation of GluR1 expression is independent of GluR1 phosphorylation. Here we provided the first evidence that Hes-1 plays an important role in synaptic function in differentiated neurons. We also identified a novel JNK1-Hes-1 signaling pathway that regulates GluR1 expression involved in synaptic function in rat cortical neurons.
Keywords: JNK1, Hes-1, GluR1, phosphorylation, stabilization, calcium influx

The N-terminal Projection Domain of The Microtubule Associated Protein Tau Inhibits TNFa Signaling.

S. Debnath[1], P. Hannon[2], K. Toropova[2], N. N. Rodriguez[2], A. Alonso[3], J. E. Fata[4]; [1]Ph.D program in Biochemistry, The City University of New York, CSI, New York, NY, [2]Biology, The City University of New York, CSI, [3]Ph.D program in Biochemistry, Department of Biology, The City University of New York, [4]Ph.D program in Biochemistry, Department of Biology, The City University of New York, CSI

Tumor Necrosis Factor-alpha (TNFα) is a multifunctional pro-inflammatory cytokine implicated in inducing both tumor promotion and tumor inhibition. This paradoxical effect can be partly explained by the fact that TNFα acts as a regulator of both proliferation and apoptosis; however the mechanisms and factors associated with how or whether a tumor cell responds to a microenvironment rich in TNFα have not been fully resolved. Here we provide evidence that the microtubule associate protein Tau inhibits TNFα signaling through its N-terminal domain and implicate it as a novel regulator of the cellular response to this key cytokine. Our findings indicate that over-expression of Tau in the human breast cancer cell lines MCF7, SkBr3 and in the pheochromocytoma cell line PC12 suppresses TNFα-induced apoptosis evident in the control cells. TNFα-induced cell apoptosis in control cells is triggered as early as 6 hrs post-treatment with hallmark features of cell shrinkage, membrane blebbing, disruption of tubulin architecture and caspase-3 activation. While over-expression of wild type full length Tau isoform in these cell lines, completely abrogates all TNFα-associated apoptotic phenotypes. Aside from inhibiting TNFα-induced apoptosis, Tau over-expression also interferes with TNFα-induced NFKB activation. This is evident by a significant decrease in NFKB nuclear translocation in Tau over-expressed cells compared to controls. Suppression of TNFα-signaling by Tau is not associated with its tubulin interaction since a truncated N-terminal projection domain lacking all microtubule binding domains still provides resistance to TNFα-induced apoptosis and NFKB activation. These findings lead us to conclude that the functional domain of Tau that regulates TNFα response lies within its N-terminal region and current studies investigating regions within this domain

are ongoing. Our data provide direct evidence that the N-terminal domain of the microtubule associated protein Tau can inhibit TNFα signaling in tumor cells. These findings indicate a novel function for Tau and add to our knowledge of how a tumor cell responds to TNFα-signaling.

Substratum topography modulates Nesprin1,2 but not FAK or ROCK1 in corneal epithelial cells.

B. Dreier[1], V. K. Raghunathan[1], P. Russell[1], C. J. Murphy[1,2]; [1]Department of Surgical and Radiological Sciences, School of Veterinary Medicine, University of California Davis, Davis, CA, [2]Department of Ophthalmology and Vision Science, School of Medicine, University of California Davis, Davis, CA

Human corneal epithelial cells *in vivo* attach to the underlying stroma through a basement membrane that possesses a rich 3 dimensional topography. The impact of submicron and nanoscale topographic cues on fundamental cell behaviors including adhesion, shape, size, proliferation, and migration has been widely reported. However, the processes that allow the cells to identify and react to topographic features are still poorly understood. To study the impact of topographic cues on various cell types, our lab is using topographically patterned substrates with anisotropic features of parallel ridges and grooves in the biomimetic micron- and nanoscale range. Topographic cues appear to be transmitted from the outside of the cell to the nucleus resulting in changes in the cells' gene expression patterns. We therefore set out to investigate the effects of micron- through nanoscale topographic features on signaling events both proximal/near the extracellular matrix interface and distal/near the nucleus. One of the signaling molecules near the cell membrane is focal adhesion kinase (FAK), which has been proposed to serve as a mechanosensor. Perinuclear proteins, such as Nesprins, link the cytoskeleton to the nucleus via the LINC complex and can transfer forces to the nucleus hence influencing nuclear shape and signaling. To investigate the relevance of FAK as a signaling molecule, we depleted FAK in immortalized human corneal epithelial cells by siRNA transfection and studied their response to topographic cues. Our results indicate that FAK knockdown has no impact on the cells' ability to align to topographic cues. FAK depleted cells remain able to migrate along the ridges and grooves. Also, topography alone did not modulate the inherent expression of FAK or ROCK, a signaling molecule downstream of FAK, in corneal epithelial cells. However, qPCR analyses revealed that the expression levels of Nesprin 1 and 2 are altered by topographic cues. Interestingly, FAK depletion in corneal epithelial cells leads to an increased Nesprin 2 expression accompanied with decreased Nesprin 1 expression.

1241

Diarylheptanoid mediates GSK-3beta-dependent activation of Wnt signaling pathway.

K. Bhukhai[1], K. Suksen[1], A. Suksamrarn[2], P. Piyachaturawat[1], A. Chairoungdua[1]; [1]Department of Physiology, Faculty of Science, Mahidol University, Bangkok, Thailand, [2]Department of Chemistry, Faculty of Science, Ramkhamhaeng University, Bangkok, Thailand

Estrogen promotes growth in many tissues by activating Wnt/β-catenin signaling pathway. We recently isolated diarylheptanoids from *C.comosa* (compound-049) which contains phytoestrogens, is widely used as an alternative supplement for treatment of unpleasant symptoms in menopausal women. However, it is not clear whether these phytoestrogens act in a similar manner to that of estradiol. In the present study, we aim to investigate the mechanistic effect of compound-049, which exhibits the highest estrogen-like activity, on Wnt/β-catenin signaling pathway. By using a TOPFlash luciferase assay in HEK 293T cells, compound-049

rapidly activated β-catenin activity and induced a significant increase in β-catenin protein levels similar to those of estradiol. Moreover, immunofluoresence in CHO cells demonstrated that β-catenin was predominantly localized in the nucleus after treatment with E2 and compound-049. Treatment with LiCl, the specific inhibitor of GSK-3β, abolished the effect of compound-049 and E2 on the activation of the TOPFlash luciferase reporter assay. In addition, Wnt/β-catenin signaling stimulated by the constitutively active β-catenin mutant, S33Y, which is insensitive to GSK-3β, was not susceptible to activation induced by compound-049 and E2. Treatment of compound-049 and E2 induced the phosphorylation at serine 473 of Akt and serine 9 of GSK-3β, which in turn inhibited GSK-3β activity. Collectively, these results suggest that compound-049 and E2 activate the canonical Wnt/β-catenin signaling through a mechanism that is dependent of Akt and GSK-3β. Therefore, our results provide an important information required for further development of this natural compound as supplement for post-menopausal women.

1242

Grb7-mediated transcriptional regulation of EphA4 gene expression in cancer progression.

P-Y. Chu[1], T-L. Shen[1]; [1]Plant Pathology and Microbiology, National Taiwan University, Taipei, Taiwan

Signaling through Grb7, a multi-domain adaptor, has been shown in capable of transmitting EGF receptor family kinases- and/or integrin cell adhesion- dependent events. Conceivably, Grb7 involves in EGFR- and integrin-mediated tumor progression, such as invasion and metastasis. In this study, we found that Grb7 mediated STAT3 activation gives rise to the elevation of EphA4 gene expression in EGF dependent manner in both SK-Br3 breast cancer and A549 lung cancer cell lines. Moreover, the Grb7-mediated *EphA4* upregulation enhanced cancer invasion/metastasis in lung adenocarcinoma cells. Furthermore, EphA4 could involve in EGF-induced cytoskeleton reorganization as well as cell proliferation, migration and anchorage-independent growth. Our data suggest that a novel mechanism by which Grb7 regulates tumorigenesis through the formation of a novel EGF-triggered EGFR-Grb7-STAT3-EphA4-ERK1/2 signaling pathway, thereby highlighting the potential strategy of targeting Grb7 as an anti-lung cancer therapy.

1243

Insulin regulated expression of adiponectin receptors in muscle vs. fat cells.

A. A. Sattar[1]; [1]Internal Medicine, Wayne State Univ Sch Med, Detroit, MI

Adiponectin, an adipocyte secreted hormone, exerts its effect via its specific receptors, AdipoR1 and AdipoR2, in insulin sensitive cells in muscle, liver, and adipose tissues and plays an important role in lipid and glucose metabolism. The purpose of the current study was to investigate if the effect of insulin is also modulated through adiponectin receptor expression in muscle and fat cells. Differentiated fat (3T3-L1), skeletal muscle (L6), and vascular smooth muscle (PAC1) cells were serum starved and exposed to 100 nM insulin for 1-24 hours. AdipoR1 and AdipoR2 mRNAs and AdipoR1 protein expression were respectively monitored by real time PCR and Western blotting. The results demonstrate that insulin down regulates both AdipoR1 and AdipoR2 mRNAs levels with little or no changes at the protein level in L6 and PAC1 cells. On the other hand, insulin has little or no effect in the regulation of AdipoR1 expression (both mRNA and protein levels) in 3T3-L1 cells, while significantly up regulating AdipoR2 mRNA level in a biphasic manner. These data suggest that insulin differentially regulates expression of adiponectin receptors R1 and R2 in muscle (L6 and PAC1) vs. fat (3T3-L1) cells; and perhaps insulin regulated expression of the receptors is also dependent on the availability of the endogenous ligand such as adiponectin for AdipoR1 and R2 in fat cells.

1244

The LINC-anchored actin cap connects the extracellular milieu to the nucleus for ultrafast mechanotransduction.

A. Chambliss[1], S. Khatau[1], N. Erdenberger[1], D. Robinson[2], Y. Feng[3], D. Hodzic[4], D. Wirtz[1]; [1]Department of Chemical & Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, [2]Department of Biomedical Engineering, Oregon Health and Science University, Portland, OR, [3]Departments of Medicine and Cell Biology and Physiology and BRIGHT Institute, Washington University School of Medicine, St. Louis, MO, [4]Department of Ophthalmology, Washington University School of Medicine, St. Louis, MO

Cells continuously sense and respond to external mechanical forces through their cytoskeleton. Here we show that only a small subset of actin fibers, those forming the perinuclear actin cap that wraps around the nucleus, form in response to low physiological mechanical stresses. While conventional basal stress fibers form only past a threshold shear stress of 0.5 dyn/cm^2, actin-cap fibers are formed at shear stresses 50 times lower and within 30 s, orders-of-magnitude faster than biochemical stimulation with serum. This fast differential response is uniquely mediated by focal adhesion protein zyxin at low shear stress and by talin at high shear stress, actomyosin fibers of the actin cap, lamin A/C of the nuclear lamina, and linkers of nucleus to cytoskeleton (LINC) molecules Nesprin2giant and Nesprin3, which anchor actin cap fibers to the nucleus. These results map an interconnected physical pathway for mechanotransduction, from the extracellular milieu to the nucleus.

1245

Cell Adhesion and Spreading Regulate a Map Kinase/Ternary Complex Factor Transcriptional Switch to Control Proliferation.

M. Wozniak[1], C. Cheng[1], C. Shen[1], L. Gao[1], C. Chen[1]; [1]Bioengineering, University of Pennsylvania, Philadelphia, PA

Much of our understanding of adhesion-regulated proliferation is based on studies comparing suspended vs. adherent cells. However, these conditions do not recapitulate the changes in adhesion and spreading that occur *in vivo*. Using microcontact printing to control the degree of spreading and adhesion, we uncovered a previously undescribed mechanism by which these more subtle adhesive changes modulate cell proliferation through regulation of the map kinases (MAPKs) and the Serum Response Factor (SRF) cofactors, the ternary complex factors (TCFs). Increasing adhesion preferentially enhanced JNK activity while suppressing p38 activity. This switch in MAPK activity led to the exchange of the Sap-1 TCF for the Net TCF at the promoters of the immediate early genes *egr1* and *fos*. Modulation of MAPK signaling and knockdown of TCFs demonstrated that MAPK/TCF switching controlled both immediate early gene expression and proliferation. Proliferative regulation by the TCFs was conserved in an *ex ovo* model of angiogenesis, validating the physiological significance of this MAPK/TCF switch. These data highlight the pivotal role that cell spreading and adhesion play in the transcriptional regulation of proliferation and points to a novel mechanism by which this occurs.

1246

Oxygen signaling via the regulation of protein localization.

R. Ghosh Dastidar[1], R. Michael Henke[1], A. Shah[1], D. Cadinu[1], X. Yao[1], J. Hooda[1], L. Zhang[1]; [1]Department of Molecular and Cell Biology, Center for Systems Biology, University of Texas at Dallas, Richardson, TX

Oxygen provides a crucial energy source in eukaryotic cells. Hence, eukaryotes ranging from yeast to humans have developed sophisticated mechanisms to respond to changes in oxygen

levels. Regulation of protein localization, like protein modifications, can be an effective mechanism to control protein function and activity. We examine how hypoxia affects protein distribution on a genome-wide scale in the model eukaryote, the yeast *Saccharomyces cerevisiae*. We demonstrated, by live cell imaging, that hypoxia alters the cellular distribution of 203 proteins in yeast. These hypoxia-redistributed proteins include an array of proteins with important functions in various organelles. Many of them are nuclear and are components of key regulatory complexes, such as transcriptional regulatory and chromatin remodeling complexes. Under hypoxia, these proteins are synthesized and retained in the cytosol. Upon reoxygenation, they relocalize effectively to their normal cellular compartments, such as the nucleus, mitochondria, ER and cell periphery. The resumption of the normal cellular locations of many proteins can occur even when protein synthesis is inhibited. Further, we show that the changes in protein distribution induced by hypoxia follow a slower trajectory than those induced by reoxygenation. These results show that the regulation of protein localization is a common and potentially dominant mechanism underlying oxygen signaling and regulation. Experiments are underway to examine the time course characteristics of the relocalization of certain regulatory proteins and to determine their direct contributions to oxygen regulation.

1247

Probing the functional integration of mechanosignals to chromatin organization in living cells.

K. V. Iyer[1,2], G. V. Shivashankar[1]; [1]Department of Biological Sciences & Mechanobiology Institute, National University of Singapore, Singapore, Singapore, [2]National Center for Biological Sciences, Bangalore, India

Cells sense physical and chemical cues from their microenvironment and selectively transmit these cues to the nucleus – resulting in altered gene expression. However the underlying mechanisms are still unclear. In this work, we provide evidence for transduction of physical forces between the plasma membrane and the chromatin organization through the actin cytoskeleton. For this controlled forces are applied using an electromagnet on cell membranes adhered with magnetic beads. The effect of force and its transduction to the nucleus is visualized using high–resolution fluorescence anisotropy imaging of chromatin assembly within single living cells. Our studies evidence physical links anchoring cytoskeleton and the nucleus. Force induced disruption of these links relaxes the prestressed organization of the cell nucleus in a reversible manner. In addition cellular networks are shown to be correlated with 3D organization of chromosomes and their gene expression patterns. Taken together our results evidence a strong architectural coupling between physico-chemical networks and spatial organization of the chromosomes within the nucleus facilitating mechanotransduction.

Post-Translational Modifications in Signaling

1248

Stimulus-dependent ubiquitination of a G protein β subunit is required for proper cell polarization.

M. Zhu[1], M. P. Torres[2], J. B. Kelley[2], H. G. Dohlman[2], Y. Wang[1]; [1]Saint Louis University, Saint Louis, MO, [2]University of North Carolina

Ste4 is the β subunit of a heterotrimeric G protein that mediates mating responses in Saccharomyces cerevisiae. Here we show that Ste4 undergoes mono-ubiquitination in response to pheromone stimulation. Ubiquitination of Ste4 is dependent on the E3 ligase Rsp5. Disrupting the activity of Rsp5 abolishes ubiquitination of Ste4 in vivo, and recombinant Rsp5 is capable of ubiquitinating Ste4 in vitro. We find also that Lys340 is a major ubiquitination site on Ste4, as pheromone-induced ubiquitination of the protein is prevented when this residue is mutated to an arginine. Functionally, ubiquitination does not appear to regulate the stability of Ste4, as blocking ubiquitination has no apparent effect on either the abundance or the half-life of the protein. However, when presented with a concentration gradient of pheromone, $Ste4^{K340R}$ mutant cells polarize significantly faster than wild type, indicating that ubiquitination limits pheromone-directed polarized growth. Together, these findings reveal a novel stimulus-dependent post-translational modification of a Gβ subunit, establish Ste4 as a new substrate of the E3 ligase Rsp5, and demonstrate a role for G protein ubiquitination in cell polarization.

Hypoxia-Induced Estrogen Receptor Alpha Activation Is Mediated by Both the MAPK and PI3K Phosphorylation Pathways.

J. Park[1], Y. Lee[2]; [1]Bioscience and Biotechnology, Sejong University, Seoul, Korea, [2]Sejong University, Seoul, Korea

The estrogen receptor (ER) plays an important role in breast cancer development and progression. Hypoxia was shown to modulate the level of ERα expression and induce ligand-independent transcriptional activation of ERα, which may be intimately associated with the biology of breast carcinomas. Given that phosphorylation affects the transcriptional activity and stabilization of ERα, we examined the changes in phosphorylation of ERα under hypoxic conditions. Hypoxia induced phosphorylation of ERα at serine residues 118 and 167 in the absence of estrogen. Phosphorylation-defective ERα mutants with serine-to-alanine replacements at residues 118 and 167 had impaired hypoxia-induced ERα activation, showing that serine residues 118 and 167 are involved in hypoxia-induced ERα activation. The hypoxia-induced ERα-mediated transcriptional response was dependent on both the ERK1/2 MAPK and PI3K pathways, but not the p38 pathway, as assessed using chemical inhibitors. These data show that ERα phosphorylation via both the MAPK and PI3K pathways is one mechanism leading to ERα activation under hypoxia.

1250

Novel components of the SRR (Snf3/Rgt2/Rgt1) glucose sensing pathway of S. cerevisiae.

K. Simpson-Lavy[1], M. Johnston[1]; [1]Biochemistry and Molecular Genetics, University of Colorado School of Medicine, Aurora, CO

Novel components of the SRR (Snf3/Rgt2/Rgt1) glucose sensing pathway of *S. cerevisiae*
Kobi (Jamie) Simpson-Lavy and Mark Johnston

Introduction: *S. cerevisiae* cells undergo many transcriptional, proteomic and metabolic changes when glucose becomes available. Glucose is sensed at the cell surface by glucose receptors that activate Casein Kinase 1 (CK1) to cause degradation of Mth1 and Std1, (which collaborate with the Rgt1 DNA-binding protein to represses expression of *HXT* genes), leading to expression of glucose transporters. The AMP-activated protein kinase orthologue Snf1 opposes this process by an unknown mechanism.
Results: We discovered that SUMO is involved in this glucose-sensing pathway. The SUMO E3 ligase activity of Mms21 is required for degradation of Mth1 and induction of *HXT3* expression; overexpression of the Ulp1 deSUMOylase prevents these events. Mutations in *mms21* are suppressed by deletion of *STD1*, raising the possibility that Std1 is a (direct or indirect) target of SUMO. *STD1* dosage modulates both induction of *HXT* gene expression and Snf1 activity, and its deletion suppresses defects in glucose sensing caused by Snf1 hyperactivity.
Conclusions: SUMO E3 ligase activity of Mms21 is crucial for glucose sensing and expression of glucose transporter genes. This is intriguing because Mms21 provides a minor portion of total SUMO E3 ligase activity in *S. cerevisiae*, and all Mms21 substrates found to date are involved in genome maintenance and repair. Std1 is a key player in regulating glucose transporter expression, and may serve as a link between Snf1 and its regulation by glucose, SUMO, and glucose sensing though the glucose sensors and CK1.

1251
TNF-alpha alters microRNA expression profile in macrophages.
B. P. Clarke[1], H. Pan[2], S. Wickline[2]; [1]CD-BioRAP, Washington University School of Medicine, St. Louis, MO, [2]Washington University School of Medicine

The NF-κB signaling pathway is a pivotal mediator of the chronic inflammatory process that drives atherosclerotic plaque development, and has been proposed as a therapeutic target for clinical management. Additionally, microRNA species are rapidly being uncovered as equally prominent components of atherosclerosis, but little is known about the interplay between NF-κB signaling and microRNA in this context. We aim to define the interaction between NF-κB and microRNA in the macrophage, since it is an abundant inflammatory cell type in plaques. Tumor Necrosis Factor alpha (TNF-α) is a known stimulator of NF-κB signaling. Therefore, as the first step of this investigation, TNF-α was applied to induce alterations in microRNA expression, which were quantified by real time RT-PCR. RAW264.7 cells were treated with 10 ng/ml TNF-alpha for 15 min, 30min, 1hr or 2hrs, respectively. We found that the nuclear tranaslocation of NF-kB protein, p65, peaked at the 30 min treatment time. Therefore, we then treated RAW264.7 with 10 ng/ml TNF-alpha for 30 minutes and evaluated expression of 88 inflammation-related microRNAs. The microRNA expression profiles were dramatically altered, such that 14 out of 88 microRNAs had altered expression by more than 7 fold change, indicating a potent effect of TNF-α potentially operating both NF-κB signaling axis and microRNA system in macrophages. By far, we validated and optimized initial experimental conditions to study interplay between NF-κB and microRNA in macrophage.

PIAS1 SUMO ligase regulates apoptosis in response to UV damage.
R. Sudharsan[1], Y. Azuma[1]; [1]Molecular Biosciences, University of Kansas, Lawrence, KS

Cells respond to UV damage by activating damage repair responses and/or initiating apoptosis. The choice between survival and death is influenced by a number of factors, including post-translational modifications. Post-translational modification of proteins by SUMO has been known to alter both the localization and the stability of DNA repair factors and influence the activity of transcription factors. In addition, SUMO E3 ligases PIAS1 and PIASy have been implicated in

the DNA repair process by modifying double stranded DNA break foci with SUMO2/3 and SUMO1 respectively. However, the specific role for each member of the PIAS family of SUMO ligases in DNA damage response, specifically damage caused by UV irradiation, has not been elucidated. In order to understand the role of PIAS family of SUMO ligases in UV-induced DNA damage response, we ectopically expressed mCherry fused PIAS1, PIASXa, PIAS3 and PIASy in HeLa cells. Cells expressing PIAS1 show increased sensitivity to UV irradiation. Each of the PIASes shows distinct localization and SUMOylation profile, indicating PIAS1 modified substrates may have a specific role in UV-induced apoptosis. We identified Daxx as a possible downstream protein in PIAS1 mediated apoptosis based on its co-localization at PIAS1 foci. Daxx is a pro-apoptotic protein that localizes to heterchromatic regions and within PML bodies in the nucleus. It has two SUMO interacting motifs that enable it to bind SUMOylated proteins. Daxx is known to act as a co-repressor of a number of SUMO-modified transcription factors, including those required for production of anti-apoptotic proteins. Daxx is proposed to interact with only a subset of SUMOylated proteins; however the basis for this specificity is not clear. Using siRNA against Daxx, we show that PIAS1 induced cell death is mediated by Daxx. We hypothesize that Daxx interacts with PIAS1 specific substrates and suppresses production of anti-apoptotic factors. This may be the molecular mechanism by which ectopic PAIS1 expression sensitizes cells to genomic insults such as UV irradiation.

1253

Girdin/GIV's partner Rabenosyn-5 controls turnover of Akt.

L. Weng[1], A. Enomoto[1], M. Takahashi[1]; [1]Department of Pathology, Nagoya University Graduate School of Medicine, Nagoya, Japan

Background: Girdin/GIV is a substrate of Akt. Akt-mediated phosphorylation of Girdin is essential for cancer cell migration, postnatal angiogenesis and neuron development. The regulation between Girdin and Akt is reciprocal; Akt phosphorylates Girdin at serine-1416, whereas overexpression of Girdin enhances phosphorylation of Akt at threonine-308 and serine-473, which is partly due to Girdin's GEF function for Gαi3. However, the detailed mechanism underlying this regulation is still unclear.
Objective: To investigate the mechanism of Girdin-mediated enhancement of Akt signaling.
Methods: Mass spectrometry was used to find novel Girdin-interacting proteins. Immunoprecipitation and GST-pull down assays were applied to confirm the interaction and identify interacting domains between Girdin and Rabenosyn-5. Furthermore, overexpression and siRNA-mediated knockdown of Rabenosyn-5 were performed to check their effects on Akt signaling.
Results: We identified Rab5 effector Rabenosyn-5 as a Girdin partner by mass spectrometry. Endogenous interaction between Girdin and Rabenosyn-5 was confirmed in HeLa cells by immunoprecipitation. In COS7 cells, GST-fused Girdin fragments was transfected combining with myc-Rabenosyn-5. Girdin CT domain was found interacting with Rabenosyn-5. Furthermore, immunoprecipitation assays using lysates of COS7 cells transfected with T7-tagged Rabenosyn-5 fragments and Girdin CT domain revealed that C3 domain of Rabenosyn-5 is responsible for the interaction with Girdin. In addition, we found that knockdown of Rabenosyn-5 by siRNA decreases the expression level of total Akt. Interestingly, overexpression of Rabenosyn-5 increases the expression level of total Akt, which indicates the role of Rabenosyn-5 in Akt turnover or degradation. Further experiment is required to check the effect of Girdin-Rabenosyn-5 complex on Akt expression level and signaling.
Conclusion: Girdin's partner Rabenosyn5 may have a role in regulating expression level of Akt.

1254

SOX9 induces irreversible chondrogenic phenotypic change in diabetic nephropathy.

S. Kishi[1], H. Abe[1], K. Nagai[1], T. Tominaga[1], T. Doi[1]; [1]Nephrology, The Univ of Tokushima, Tokushima, Japan

Study's objective: Diabetic nephropathy (DN) is a most important chronic kidney disease. We have previously reported that SOX9, a master gene of chondrogensis, is ectopically induced and promotes glomerulosclerosis in mouse experimental nephritis and recently reported that BMP4-Smad1signaling pathway regulates the expression of extracellular matrix proteins in DN. Phenotypic changes of mesangial cells(MCs)are key pathologic findings which underlies the increased glomerular sclerosis seen in DN. Furthermore a recent report revealed that HIF-1α also could be important factors in DN. The aim of this study is to investigate that activation of HIF-1α,BMP4 and SOX9 is responsible for chondrogenic phenotypic change, a new potential of phenotypic switch in DN.
Methods and Results: In vitro cell cultures, when MCs were cultured under micromass culture method, sulfated proteoglycans and Col2 were confirmed. Activation of SOX9 and Col2 in response to BMP4 induction were confirmed. Chondrogenic potential of MCs, accompanied by activation of HIF1 α, BMP4, SOX9 and Col2, could also be induced under diabetic or hypoxic condition. Furthermore forced expression of SOX9 in MCs also induced ectopic expression of proteoglycans and Col2 in MCs.BMP4-Smad1 signaling pathway played a key role in phenotypic change in MCs.
In streptozotocin-induced diabetic model mice, the induction of SOX9 and Col2 in glomeruli were confirmed. In another diabetic model, transgenic mice expressing NOS2 constitutively in pancreatic βcells exhibited pathological change resembling an advanced stage of human DN. In this model, the induction of HIF1α, BMP4,SOX9 and Col2 were observed. Positivity of these proteins were detected in sclerotic lesions in the glomeruli and a major part of the positive staining area of SOX9 was coincided with the area of HIF1αand BMP4.
We have developed transgenic mice with inducible expression of BMP4 (BMP4 Tgm) by using thetamoxifen-regulated Cre/LoxP system. BMP4 Tgm exhibited an expanded mesangial area and a thickened glomerular basement membrane that remarkably resembles human DN. BMP4 Tgm also showed significant induction of glomerular expression of SOX9 and Col2 compared to the control mice. Furthermore, the heterozygous BMP4 knockout mice did not show the induction of SOX9.
Conclusions: Our present data provide a new aspects in the progression of glomerular injury, MCs have a chondrogenic potential. As chondrocytes are unique cells that locate at avascular and hypoxic condition, it makes sense that MCs acquire the chondrogenic phenotype mediated by ectopic BMP4 and SOX9 to operate a cellular protective mechanism for chronic pathological hypoxic stress in the kidney.

1255

Cytosolic CD38 Protein Forms Intact Disulfides and Is Active in Elevating Intracellular Cyclic ADP-ribose.

Y. Zhao[1], H. Zhang[1], M. Lam[1], Q. Hao[1], H. Lee[1]; [1]Physiology, HKU, HK, China

Cyclic ADP-ribose (cADPR) is a Ca^{2+} messenger molecule responsible for regulating a wide range of physiological functions from social behavior in mice to abscisic acid-dependent signaling in sponges and plants. Currently, no method is available for manipulating the cellular levels of cADPR, greatly impeding the mechanistic elucidation of its signaling function. We have now modified the native CD38 and engineered a soluble form for transfection into cells. The soluble CD38 efficiently used the cytosolic NAD as substrate and produced cADPR intracellularly. The activity of the engineered CD38 can be tuned downward by mutating the

catalytic residue, Glu226, and upward by a double mutation, E146A and T221F, which increased its cADPR synthesis activity by more than 11 folds. Remarkably, the engineered CD38 exhibited the ability to form the critical disulfide linkages required for its enzymatic activity. This was verified by using a monoclonal antibody generated against a critical disulfide, C254-C275. The specificity of the antibody was established by X-ray crystallography and site-directed mutagenesis. The engineered CD38 is thus a novel example challenging the general belief that cytosolic proteins do not possess disulfide. Functionally, the intracellular calcium was increased in HEK 293 cells by co-overexpressing this engineered CD38 (double mutant) and ryanodine receptor (RYR), which is the potential target of cADPR. This study has set the stage for *in vivo* manipulation of cADPR signaling pathway.

1256

Sumoylation-promoted enterovirus 71 3C degradation correlates with a reduction in viral replication and cell apoptosis.

S-C. Chen[1,2], H-M. Shih[1]; [1]Institute of Biomedical Sciences, Taipei, Taiwan, [2]Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan

Enterovirus (EV) 71, a member of the Picornaviridae family, may cause serious clinical manifestations associated with the central nervous system. Enterovirus 3C protease is required for virus replication and can trigger host cell apoptosis via cleaving viral polyprotein precursor and cellular proteins, respectively. While the role of the 3C protease in processing viral and cellular proteins has been established, very little is known about the modulation of EV71 3C function by host cellular factors. Here, we show that sumoylation promotes EV71 3C protein ubiquitination for degradation, correlating with a decrease of EV71 in virus replication and cell apoptosis. SUMO E2 conjugating enzyme Ubc9 was identified as an EV71 3C-interacting protein. Further studies revealed that EV71 3C can be SUMO modified at residue K52. Sumoylation downregulated 3C protease activity in vitro and also 3C protein stability in cells, in agreement with data suggesting 3C K52R protein induced greater substrate cleavage and apoptosis in cells. More importantly, the recombinant EV71 3C K52R virus infection conferred more apoptotic phenotype and increased virus levels in culture cells, which also correlated with a mouse model showing increased levels of viral VP1 protein in intestine and neuron loss in the spinal cord with EV71 3C K52R recombinant viral infection. Finally, we show that EV71 3C amino acid residues 45-52 involved in Ubc9 interaction determined the extent of 3C sumoylation and protein stability. In addition, sumoylation can further regulate 3C subcellular localization. We also demonstrate that 3C protein degradation is through ERAD (ER-associated degradation) pathway, and identify HRD1 is the 3C ubiquitin E3 ligase. Furthermore, USP14 is the 3C-deubiquitinating enzyme. More importantly, USP14 inhibitor IU1 treatment significantly reduced the protein half-life of EV71 3C and inhibited EV71 virus replication. Collectively, our results uncover a previously undescribed cellular regulatory event against EV71 virus replication and host cell apoptosis by sumoylation and ubiquitination at 3C protease.

1257

AOD2 and AOD5 localize to the nucleus and synergistically induce alternative oxidase in *Neurospora crassa.*

Z. Qi[1], F. Nargang[1]; [1]Biological Sciences, University of Alberta, Edmonton, AB, Canada

Alternative oxidase (AOX) provides an alternative respiratory pathway in plants, some other eukaryotes, and some prokaryotes. It functions as a terminal oxidase in the electron transport chain as it directly delivers electrons from ubiquinol to molecular oxygen and produce water as a final product. Production of the enzyme responds to various signals in different organisms including inhibition of the standard electron transport chain, increased production of reactive

oxygen species, temperature changes, and pathogen attacks. AOX serves as an excellent model to study mitochondrial retrograde signaling because it is encoded by a nuclear gene and can be induced by effects on mitochondrial function. So far, the mechanism(s) by which AOX is induced is poor elucidated. In *Neurospora crassa*, the induction of AOX requires two zinc binuclear cluster transcription factors, AOD2 and AOD5. Here, we report that both AOD2 and AOD5 are located in the nucleus under either normal conditions or conditions that result in induction of AOX. Furthermore, pulldown experiments suggest that they interact with each other *in vivo*, again under both normal and inducing conditions. Finally, both AOD2 and AOD5 are required for growth on poor carbon courses, suggesting a role in gluconeogenesis. Future studies are aimed at examining the two proteins under normal and inducing conditions for changes in protein modifications.

1258

Coordinated Regulation of Human GCM1 Activity by Phosphorylation and Desumoylation in Placental Cell Differentiation.

H. Chen[1], C-W. Chang[1]; [1]Institute of Biological Chemistry, Academia Sinica, Taipei, Taiwan

cAMP signaling and the placental transcription factor GCM1 regulate expression of syncytin-1 and -2 fusogenic proteins, which are critical for syncytiotrophoblast formation by trophoblast fusion. We recently revealed a cAMP/PKA/CBP signaling pathway that activates GCM1 by coordinating GCM1 phosphorylation and acetylation. In contrast, GCM1 activity is downregulated by sumoylation of Lys156. How GCM1 sumoylation is regulated was unknown. Here we identify a novel PKA-independent cAMP signaling pathway as the critical regulator of GCM1 sumoylation. We show that Epac1 and Rap1, in response to cAMP, activate CaMKI to phosphorylate Ser47 in GCM1. This phosphorylation facilitates the interaction between GCM1 and the desumoylating enzyme SENP1 and thereby leads to GCM1 desumoylation and activation. Using RNAi, we further demonstrate that 8-CPT-AM, an Epac activator, stimulates syncytin-1 and -2 gene expression and cell fusion of placental BeWo cells in a GCM1-dependent manner. Importantly, the cell fusion defect in GCM1-knockdown BeWo cells can be reversed and enhanced by the RNAi-resistant phosphomimetic GCM1S47D mutant. Our study has identified a novel cAMP/Epac1/CaMKI/GCM1 signaling cascade that stimulates trophoblast fusion through promoting GCM1 phosphorylation and desumoylation.

Modeling and Simulation Analysis of Insulin Secretory Functions of Pancreatic β-cells.

M. Kudo[1], A. Saito[2], M. Nagasaki[2], S. Miyano[2], Z. Naito[1]; [1]Nippon Medical School, Tokyo, Japan, [2]Institute of Medical Science, The Univeristy of Tokyo, Japan

BACKGROUND: Pancreatic β-cells secrete insulin in response to elevated plasma glucose levels, and the dysfunction of these cells is a major contributor to the development of diabetes. Diabetes is classified roughly into two types, type 1 diabetes (T1D) and type 2 diabetes (T2D). Usually, T1D onset is associated with an autoimmune reaction against pancreatic β-cell constituents, and T2D onset is associated with insulin resistance and insulin secretory dysfunction. Furthermore, genetic and environmental factors also play important roles in diabetes onset. The insulin secretory capacity of Asians including Japanese is relatively lower than that of western populations; thus, insulin secretory dysfunction, rather than insulin resistance, may play a more critical role in the development of T2D in Asians. Therefore, an

integrated understanding of the insulin secretory function of pancreatic β-cells is important for the study and therapy of diabetes. In systems biology, modeling and simulation analyses of biological pathways, such as metabolic pathways, gene regulatory networks, and cell signaling networks, are available using a computational approach. Cell Illustrator (CI), which is a graphic platform, implements the Hybrid Functional Petri net with an extension (HFPNe) theory suitable for the modeling and simulation of biological pathways and enables realistic modeling and simulation of biological pathways in silico. We developed a biological pathway model of insulin-secretion-related molecules in pancreatic β-cells, and the insulin secretory function, which is induced by glucose, incretin, and antidiabetic drugs, was simulated using CI. METHODS: To develop a computer simulation model of the insulin secretory function of pancreatic β-cells, we compiled and interpreted measurement data from the literature on insulin secretion of pancreatic β-cells using CI. RESULTS: A biological pathway model of the insulin secretory function was developed and was visually presented similarly to a pathway map. Glucose-induced time-dependent changes in β-cell secretory function parameters such as ATP/ADP ratio, membrane depolarization, Ca^{2+} oscillation, and biphasic insulin secretion were simulated successfully in the graph data form. CONCLUSION: This simulation model may be useful for providing a visually easy-to-understand explanation of the pathophysiology and treatments of diabetes to medical professionals and patients. Moreover, this model may contribute to the development of novel therapies and drugs for T2D.

Modeling the Interplay of Plasmin and Thrombospondin-1 in TGF-β1 Activation : A Bistable Switch *in Silico* and *in Vitro.*

L. Venkatraman[1,2], S-M. Chia[3], B. Narmada[3], L. Poh[3], J. White[1,4], S. Bhowmick[1,5], C. Dewey[1,4], P. So[1,4], H. Yu[1,2], L. Tucker-Kellogg[1,2]; [1]Singapore-MIT Alliance, Singapore, [2]Mechanobiology Institute, National Univ of Singapore, [3]National Univ of Singapore, [4]MIT, [5]NTU

Background: Transforming growth factor-β1 (TGF-β1) is a potent and influential cytokine that accumulates in the extra-cellular matrix as a latent, inactive complex. The bioavailabilty of TGF-β1 for cell signaling is controlled by its extracellular activation, for example by conformational change upon binding Thrombospondin-1 (TSP), by plasmin proteolysis, or by other activating factors. Although plasmin is a direct molecular activator of TGF-β1, animal experiments have paradoxically shown the opposite effect of the plasmin pathway toward TGF-β1.
Methods: We built a systems-level computational model using ordinary differential equations to represent the kinetics of TGF-β1 activation, mutual antagonism between plasmin and TSP, and gene expression feedback from TGF-β1. Model-based predictions were tested with hepatic stellate cells by adding plasminogen, the stable precursor of plasmin, to cell culture media. TGF-β1 was measured with an ELISA specific for the active form.
Results: Mathematical simulations predict that plasmin will decrease TGF-β1 activation in the presence of TSP-mediated activation, and increase TGF-β1 otherwise. Furthermore, simulations predict that the TGF-β1 activation system can exhibit cooperative, bistable switching between two distinct modes of TGF-β1 activation: a TSP-dependent mode with high activation of TGF-β1, and a plasmin-dependent mode with TSP suppressed and lower activation of TGF-β1.
In vitro experiments showed that increasing plasmin caused increased cleavage of TSP and decreased concentration of active TGF-β1, with a sigmoidal (cooperative) dose-response curve. In the presence of a specific inhibitor to block TSP-mediated TGF-β1 activation, plasmin was instead able to increase TGF-β1 activation. Bistability was demonstrated experimentally in the form of hysteresis.

Conclusion: Antagonistic interplay between plasmin and TSP is an important feature of our model, and is confirmed by our experiments. These results suggest novel mechanisms and hidden pitfalls for addressing TGFβ-related diseases.

1261

A new method for measuring intracellular dynamics reveals a negative feedback linking cell growth to proliferation in mammalian cells.

R. Kafri[1], S. Oh[1], M. B. Ginzberg[1], G. Lahav[1], M. W. Kirschner[1]; [1]Systems Biology, Harvard Medical School, Boston, MA

Intracellular dynamics are studied from either time course measurements on live cells (e.g. time lapse microscopy) or time course measurements on synchronized populations. Limitations of these two different techniques range from the unknown affects of synchronizing agents to the difficulty of probing live cells for both post-transcriptional modifications and bulk properties such as total cell mass. In this study we develop ergodic rate analysis (ERA) as a third independent path to investigate intracellular dynamics. ERA is based on the fact that in non-synchronized populations, rapid intracellular events are represented by fewer cells than slower events. By mathematically harnessing this point, ERA provides an interpretive framework transforming measurements made on large ensembles of fixed cells into information about cellular dynamics. Applying ERA to investigate cell growth dynamics reveals, at the G1/S transition, a negative feedback linking growth rate to cell size. We show that this feedback functions by cell-size dependent protein degradation and is regulated by the mTOR pathway. By affectively decreasing the cell-to-cell size variation, this feedback partly explains the relative homogeneity in cell-size in proliferating populations and, perhaps, in tissues.

1262

Novel graphical approaches to analyze phosphoproteomic data reveal signaling pathways activated in lung cancer and neuroblastoma.

M. Stokes[1], A. Guo[2], P. Shannon[3], M. L. Grimes[4]; [1]Cell Signaling Technology, Danvers, MA, [2]Cell Signaling Technology, [3]The Institute for Systems Biology, Seattle, WA, [4]Division of Biological Sciences, University of Montana, Missoula, MT

Phosphoproteomics, which identifies a large number of phosphorylated proteins from tumors and cell lines, has shown that individual cancerous tumors express different combinations of active tyrosine kinases, including multiple receptor tyrosine kinases. A major challenge is to sort out relationships between individual signaling pathways for targeted therapy. Hierarchical clustering dendrograms, heat maps, and network graphs have been employed to attempt to visualize patterns that may indicate functional relationships among different groups within data, but graphical visualization of large data sets rapidly becomes unwieldy and too often conveys little meaning. We developed new methods that combine statistical analyses (using R) and novel graphic approaches (using RCytoscape, Cytoscape, and PyMOL) to visualize the statistical structure of data. We applied these methods to phosphoproteomic data from lung cancer tumors and cell lines and neuroblastoma cell lines. Multidimensional scaling was used to translate Pearson and Euclidian distance into Cartesian coordinates in three dimensions, into a data structure that we call a Pearson Euclidian Distance (PED) graph. Proteins that are close to one another on this graph have similar phosphorylation patterns as measured by two independent statistical criteria. Groups selected from the data structure were plotted as networks using evidence for protein-protein interactions sought from String, GeneMANIA, and the kinase-substrate data from PhosphoSitePlus. The analysis supports the hypothesis that activation of one or more different receptor tyrosine kinases (RTKs) and/or SRC-family kinases (SFKs) occurs in different individual cancerous tumors. Remarkably, many regions of the data

structure appear to contain at least one RTK and/or SFK and known effector proteins thereof. The data-driven clusters suggest potential links between several different cancer driver pathways and proteins that have not previously been characterized. These clusters suggest strategies for more effective cancer treatments involving combinations of drugs tailored to individual tumors.

1263

EGFR Regulation of Epidermal Barrier Function.

Q. Tran[1,2], L. Kennedy[3], S. Leon Carrion[1], S. Bodreddigari[1,2], S. Goodwin[1,2], C. Sutter[1,2], T. Sutter[1,2]; [1]Biological Sciences, The University of Memphis, Memphis, TN, [2]W. Harry Feinstone Center for Genomic Research, The University of Memphis, Memphis, TN, [3]Chemistry, The University of Memphis

The epidermal growth factor (EGF) receptor (EGFR) plays an important role in keratinocyte terminal differentiation, a process that ultimately forms the epidermal barrier. Defective epidermal differentiation and disrupted barrier are primary features of many human skin diseases, including psoriasis and atopic dermatitis. Abnormalities in expression of the EGFR and its ligands are common features found in these diseases. Here, we explored the genome-wide effects of EGF, a ligand of the EGFR, on normal human epidermal keratinocytes undergoing density-induced differentiation. We identified 2,676 density-dependent EGF-regulated genes. Contrary to density effects, EGF inhibited expression of 91% of the density-induced genes and promoted that of 96% of the density-suppressed genes, suggesting that EGF plays a critical role in inhibiting epidermal differentiation. Specifically, EGF significantly reduced free fatty acid synthesis to half by suppressing expression of PTPLB and TECR, enzymes that form stearic and oleic acids, two major fatty acid components in the stratum corneum. EGF also inhibited mRNA levels of genes encoding enzymes in the *de novo* and salvage ceramide pathways, causing a decrease in ceramide 1, 3, 6, 7, 8, and acyl-glucosylceramides. Our expression and protein results strongly suggest that activation of EGFR signaling inhibits cornified envelope formation by altering levels of enzymes and structural proteins essential for the synthesis of this differentiated structure. Further, we showed that EGF caused a significant reduction in levels of tight junction proteins such as CLDN1 and TJP1, leading to an increase in paracellular permeability and disrupting tight junction barrier function. EGF impaired the epidermal barrier integrity as a whole by increasing the transepidermal water loss in organotypic culture. Finally, bioinformatics and statistical analyses revealed that genes associated with skin diseases were enriched in the set of EGF-regulated genes. Our work advances the current understanding of EGFR signaling in regulating epidermal barrier function. We identified many new EGFR-regulated genes and, more importantly, connected the function of these genes to major processes involved in epidermal differentiation. These findings provide a reference for subsequent studies of EGFR in the regulation of epidermal cell fate and homeostasis, and may lead to novel therapeutic approaches for the treatment of dermatological diseases.

1264

Differential Expression of Transcripts Linked to Wound Healing, Epithelial-Mesenchymal Transition (EMT), and Inflammation during Primary Explant Culture of Zebrafish Keratocyte.

K. J. Leyva[1], S. R. Gadagkar[2], A. S. Pascual[2], K. E. Cooper[2], E. E. Hull[2]; [1]Microbiology & Immunology, AZCOM, Midwestern University, Glendale, AZ, [2]Biomedical Sciences, Midwestern University, Glendale, AZ

Fish keratocytes derived from 1 – 3 day old explant cultures are routinely used to study mechanisms of cell motility. Significant cellular changes have been reported in a number of other systems during these initial stages of primary culture but 1) a systematic characterization of these changes is lacking and 2) it is uncertain if these effects are seen in the keratocyte system. Data presented here suggest that keratocytes undergo significant changes in gene expression patterns during primary explant culture including genes controlling processes involved in wound healing, epithelial-mesenchymal transition (EMT), and inflammation. Changes in gene expression begin as early as 12-hours after establishment of explant cultures. Additionally, our data show that 17.5% of the genome is differentially expressed between 1 and 7 days of explant culture. Cell motility and morphology appear to undergo little change within the initial 72-hours of explant culture, when changes in gene expression are significant and increasing, but are dramatically altered in 7-day cultures. The variability in the expression profile within a well-controlled, genetically-defined explant culture system provides an important contextual framework for interpretation of data from keratocyte primary explant cultures and other primary culture systems.

Animating Cell Biology: New Tools for Research and Communication.

J. Iwasa[1]; [1]Department of Cell Biology, Harvard Medical School, Boston, MA

In recent years, there has been a rapid growth in the use of animation as a means to communicate complex biological processes to a wide range of audiences. Using 3D animation software from the entertainment industry, it is possible to synthesize data from diverse sources to create a coherent and contextualized view of how molecular and cellular systems operate. These visualizations have served not only to make molecular concepts more accessible to students and the public at large, but have also proven to be extremely useful for researchers seeking to build and refine their hypotheses. In an effort to make animation tools more readily available to researchers, we have embarked on a project to create a novel molecular biology-centric 3d animation application created specifically for cell and molecular biologists.

The Open Microscopy Environment (OME): Informatics for Biological Imaging.

M. Linkert[1,2], C. Allan[3], J-M. Burel[3], J. Moore[1], C. Neves[1], C. Blackburn[3], B. Loranger[3], S. Loynton[3], D. MacDonald[3], W. Moore[3], A. Patterson[3], A. Tarkowska[3], S. Wells[3], C. T. Rueden[2], E. Hill[3], J. Swedlow[1,3], K. W. Eliceiri[2]; [1]Glencoe Software, [2]LOCI, University of Wisconsin, , Madison, WI, [3]University of Dundee

OME is a multi-site collaborative effort across academic laboratories and commercial entities that produces open tools to support data visualization, management, and analysis for biological microscopy and high content screening (HCS). All OME specifications and software are free, and all source code is available under GNU public "copyleft" licenses. With a strong foundation for biological light microscopy in place, OME has begun extending its coverage to HCS, electron microscopy, scanning probe microscopy, other emerging modes of biological imaging.

OME develops and releases:
-- The OME Data Model (http://ome-xml.org) provides a specification for saving and exchanging metadata in biological imaging.
-- The OME-TIFF file format (http://ome-xml.org/wiki/OmeTiff) and the Bio-Formats file format library (http://openmicroscopy.org/site/products/bio-formats) provide an easy-to-use set of tools for converting data from proprietary file formats into an open, accessible format.
-- OMERO (http://openmicroscopy.org/site/products/omero) is a Java-based server and client application suite that combines an image metadata database, a binary image data repository and high performance visualization and analysis. OMERO works as an image data management system for a laboratory, department or institution. For computational analysis of microscopy or HCS images, OMERO's standardised interface and Bio-Formats provide a single mechanism for accessing image data and metadata regardless of original file format. OMERO includes interfaces for Java, C++ and Python to support standard image processing tools like ImageJ, Matlab, and CellProfiler, a scripting facility for Python-based data processing, and custom clients that enable remote image viewing, processing and analysis. Processed images, calculated regions-of-interest, and quantitative measurements can be stored using OMERO's internal databases or in an HDF5-based tabular data store. OMERO is used in a number of commercial products, and runs the JCB DataViewer (http://jcb-dataviewer.rupress.org), the first publication system for original image data in the life sciences.
More information is available at http://openmicroscopy.org.

A synthetic molecular tool for post-transcriptional control of gene expression in E. coli.

F. Ceroni[1], S. Furini[2], E. Passini[1], E. Giordano[1]; [1]University of Bologna / Campus of Cesena - Italy, Cesena, Italy, [2]University of Siena - Italy

We here present a synthetic, modular, molecular device for the post-transcriptional control of the expression of any gene of interest in E. coli. To this aim, a CIS- and a TRANS-acting non-coding sequences were cloned into the same high copy number plasmid: the CIS element contains a non-coding region and a Ribosome Binding Site (RBS) upstream of a GFP reporter gene; the TRANS element (T4) is complementary to the CIS non-coding region and to the initial 4 nucleotides of the RBS, to be able to inhibit translation of the gene placed downstream of the CIS. T4 is regulated by the Lac repressor to tune, via IPTG, the number of available interfering molecules. To this aim a lac operator is placed upstream of the TRANS sequence. The Lac repressor is produced by a co-transformed low copy number plasmid, built up in two configurations, with either O1 or Os lac operator upstream of the lacI sequence. All parts used were in the BioBrick format. A mathematical model was also developed to describe/predict the behaviour of the entire molecular device upon characterization [see also Ceroni F., 2010] of its elementary parts (except of CIS/TRANS binding affinity).
Experimental measurements were performed in cells grown up to 14 hours in 5 ml M9 medium. 200 ul samples were taken every hour and fluorescence and OD measured with a Tecan® multiplate reader. Cells transformed only with the CIS-reporter yielded a GFP output of 10307±1561 arbitrary units (a.u.). When both CIS and TRANS sequences were present, fluorescent signal decreased down to 776±387 a.u., as the result of their interaction. Indeed, when the TRANS sequence was absent, fluorescence was restored to 9974±1154 au. The presence of O1- lacI or Os- lacI yielded respectively 11598±2768 a.u. and 11308±2152 au, in absence of IPTG inducer, proving that the LacI repressor can efficiently inhibit TRANS production. When up to 2 mM IPTG was added to the cells fluorescence did not change when O1- lacI was used. This suggests that the increase in the transcription of TRANS induced by IPTG, in this case was not sufficient to block GFP translation via CIS-TRANS annealing. On the

other hand, IPTG (0.1, 0.25, 0.5, 1 and 2 mM) added when Os- lac operator was upstream of the lacI sequence, produced respectively 8455±911, 8093±1524, 6814±1170, 5908±727 and 5679±1398 a.u. in fluorescence, showing that the device can tune gene expression. The behaviour of the genetic circuit was well described by the mathematical model, and model fitting allowed the identification of CIS-TRANS binding affinity (2.3*10-3 min-1*molecule-1). These results show that our synthetic, modular, molecular device allows post-transcriptional regulation of gene expression in E. coli, useful for multiple application in synthetic biology as well as a tool to study RNA interfering process in living cells.

1268

Characterization of a Fast Version of SNAP-tag for In Vitro and Live Cell Protein Labeling.

X. Sun[1], A. Zhang[1], L. Sun[1], B. Baker[1], C. Provost[1], N. Labarthe[1], J. Buswell[1], C. Noren[1], I. R. Correa Jr[1], M. Xu[1]; [1]New England Biolabs, Ipswich, MA

Protein synthesis, transport, localization, and degradation are highly dynamic and are modulated during a variety of cellular processes. However, the tools to study these events in living cells are limited. Site-specific labeling of cellular proteins with chemical probes allows for imaging and analyzing protein dynamics in live cells and small animals. One of the labeling systems is achieved through the reaction of O6-benzylguanine (BG) derivatives with SNAP-tag based on human O6-alkylguanine-DNA alkyltransferase (hAGT). The efficiency of the labeling depends mostly on the reactivity of SNAP-tag. In order to study fast dynamic cellular events, such as receptor endocytosis and protein turnover, we have recently reported a fast-labeling variant of SNAP-tag, termed SNAPf (Sun, X. et al., ChemBioChem, 2011, in press). SNAPf carries 19 amino acid substitutions and a C-terminal deletion compared to wild-type AGT, and 10 extra mutations compared to SNAP26m, a previously described hAGT variant. In this study, SNAPf has been further characterized and utilized in conjunction with a wide variety of SNAP-tag substrates, including fluorogenic probes and near-infrared dyes, to label proteins in vitro and in vivo. In vitro kinetics studies show that SNAPf has up to tenfold increased activity towards several fluorophore BG conjugates compared to SNAP26m. Live cell labeling assays using mammalian cell lines expressing different SNAP-tag fusion proteins confirm that SNAPf exhibits faster labeling kinetics than SNAP26m. Fluorescence microscopy and image analysis of labeled SNAP-tag fusion proteins in live mammalian cells demonstrates that SNAPf allows for shorter labeling times and improved signal-to-noise ratios. The increased reactivity of the SNAPf variant shows promise for analysis of proteins with rapid trafficking or fast turnover rates.

Yeast-based Biosensors for Environmental Monitoring.

J. T. Philip[1], A. Weaver[1], T. Barstis[2], M. Lieberman[1], H. Goodson[1]; [1]Chemistry and Biochemistry, Univ Notre Dame, Notre Dame, IN, [2]Chemistry, St. Mary's College

Water contamination is a major concern in both the developed and developing worlds, and current technologies to monitor water quality and detect contamination are inadequate. To address gaps in our water quality monitoring, we are developing yeast that respond to water contamination and testing sensor platforms to utilize these biosensors in diverse situations. Some of these yeast sensor strains are based on the genetic memory system developed by the lab of Dr. Pam Silver (Ajo-Franklin *et. al.* 2007). This system allows the yeast to respond to water contaminants at a threshold concentration and continue to signal exposure if contaminant levels drop. We will use these and other genetically engineered yeast as the core of devices that detect water contamination in various circumstances. For developed world applications, we are designing a device for continuous, long-term, in line water monitoring. This device will have two monitoring capabilities. Each strain will have a specific contaminant response, indicating

when that toxin is detected above an acceptable threshold, using a fluorescent signal. In addition, all strains will serve as monitors of catastrophic toxicity leading to death or halted growth through monitoring of yeast concentration. This can provide an early warning for changes in water quality that could lead to catastrophic disruption of water treatment plants. For developing world and field testing applications, we are developing paper analytical devices (PADs) incorporating yeast which will respond to water contamination by producing a color change. These devices will serve as an inexpensive, low technology method (from the use standpoint) to determine whether water sources are safe to drink.

1270

Computational Modeling of Cyclooxygenase in Drosophila.

Y. Qi[1], S. Singh[1]; [1]Biology, CUNY-Graduate center and CUNY- Brooklyn College, Brooklyn, NY

Eicosanoids are important mediators that are involved in reproduction, immune system, ion transport and etc. Eicosanoids are oxygenated from C20 polyunsaturated fatty acids. Mammalian eicosanoid biosynthesis consists of three pathways, COX (cyclooxygenase) pathway, LOX (lipoxygenase) pathway, and epoxygenase pathway. Cyclooxygenase (COX) catalyzes the committed step of biosynthesis of prostaglandins, thromboxanes and prostacyclins. There are two isoforms of COX: COX-1 and COX-2, both of which are membrane bound proteins. COX exists in many organisms including vertebrates and invertebrates, but has mostly been studied in mammalian systems. In this study, we used computational methods to identify several putative COX homologues in Drosophila. We have built three-dimensional models of all the putative COX enzymes in Drosophila using computational biology methods and compared them both at the sequence and structural levels. Our results are a preliminary attempt at uncovering the functional role of these putative COX proteins in the metabolic pathways of Drosophila with an emphasis on their role in immune regulation.

1271

Genome-wide Analysis for Enrichment of Seed Sequences Identifies Prominent Off-targeted Genes in RNAi Screens.

F. Sigoillot[1], S. Lyman[1], J. Huckins[1], E. Chung[1], B. Quattrochi[1], R. King[1]; [1]Dept. of Cell Biology, Harvard Medical School, Boston, MA

Off-target effects can hamper the ability to interpret the results of genome-wide RNAi screens, but there are no general methods available to rapidly identify potential off-targeted genes prior to performing validation studies. We developed a new method, Genome-wide Enrichment of Seed Sequences (GESS), which identifies candidate off-targeted genes from direct analysis of primary screening data. By comparing siRNAs with and without phenotype, GESS identifies genes that are enriched for miRNA-like binding sites among the group of siRNAs with phenotype. GESS identified MAD2 as frequently off-targeted in a screen for components of the spindle assembly checkpoint, which we confirmed experimentally. We applied GESS to several other published RNAi screens, and identified known and novel genes sensitive to seed-match based off-target effects. We provide GESS as standalone package and recommend it be implemented as a standard step in screen validation to identify genes sensitive to off-target effects.

1272

The proteome of a thermophilic Eukaryote.

N. Malik[1]; [1]Structural and Computational Biology, European Molecular Biology Laboratory, St. Louis, MO

Chateomium thermophilum, a thermophilic filamentous fungus, is on its way to becoming an established model organism. With an optimal growth temperature of 55°C, its proteins are extraordinarily stable and very amenable for structural studies [1]. We have used extensive peptide fractionation and tandem mass spectrometry to measure its proteome to saturation. We identified 3977 proteins and annotated almost 60% of the predicted ORFs using Gene Ontologies [1]. To investigate which functional protein categories in the cell adapt to thermophily, we systematically compared absolute protein abundances measured in *C. thermophilum* to *Saccaromyces cerevisiae* and *Chaetomium globosum*, the closest mesophilic relative. The preliminary results show that proteins responsible for cell wall and integral to plasma membrane, display a significantly higher abundance in *C. thermophilum.*

1273

Validation of automated subcellular tracking tool for kinetic image analysis.

S-J. J. Lee[1], C-C. Huang[2], H. Lai[1], S. Alworth[1], H. Watanabe[2], K. Saito[3], Y. Arai[3], T. Nagai[3]; [1]DRVision Technologies LLC, Bellevue, WA, [2]Nikon Instruments Company, [3]Hokkaido University

Background: Timelapse imaging of biological sample at microscopic level generates a wealth of novel, dynamic phenotypes that, if quantitatively analyzed, could provide new insights into biological processes and disease formation. Automated tracking of the subcellular objects is critical to the unbiased and complete quantification of the dynamic phenotypes. A large amount of work is being done in the scientific community to develop particle tracking and characterization tools for data sets composed of massive images. However, these tools are generally difficult to adopt in broad lab settings and are often application specific and limiting. We have reported in last meeting about development of a robust and flexible tracking method called "soft tracking" that can be taught to handle challenging tracking applications.
Objectives: Here we validate the automated subcellular tracking performance of our soft tracking tool by comparing with multiple conventional benchmark software including Image J (PTA Plugin), Matlab, Imaris and Metamorph.
Study Data: As a comprehensive set of benchmark movies, we used (A) 6 public movies: 3 synthetic movies containing different kinetic scenarios (exit and no enter; enter and exit; allowed to exit), a rotating golf ball (~180 points entering and exiting the scene), Birds (at different altitudes with frequent occlusions), Fishes (a flock of 150+ fishes in the sea); (B) 4 movies of COS7 cell expressing GFP in endosome with systematically reduced temporal sampling rates; (C) a movie containing microtubule (MT) tips transition through "growth", "pause" and "shrink" phases. It is challenging to track as the MT-tips lose contrast or even disappear during pause phase.
Results: In terms of tracking sensitivity and the error rate (sensitivity, error), our soft tracking tool had superior performance overall (0.718±0.033, 0.052±0.003), followed by Imaris (0.475±0.037, 0.154±0.006), and ImageJ PTA (0.398±0.037, 0.171±0.006).
Conclusion: the results indicate that our soft tracking could support subcellular tracking for comprehensive quantification of dynamic phenotypes.

Chaperones, Protein Folding, and Quality Control

1274

Adaptation to hydrogen sulfide protects against hypoxia in *C. elegans.*

E. M. Fawcett[1,2], J. Groulik[1], D. L. Miller[1]; [1]Department of Biochemistry, University of Washington, Seattle, WA, [2]Graduate Program in Molecular and Cellular Biology

Oxygen is an essential environmental nutrient for animals. Physiological responses to decreased oxygen availability (hypoxia) play important roles in development, metabolism and disease. We have found that, in *C. elegans*, exposure to specific hypoxic conditions cause disruptions in cellular protein homeostasis, as monitored by aggregation and toxicity of polyglutamine-containing proteins. This response to hypoxia is mediated by genetic factors, showing that it is an active response to changes in oxygen availability. Our data further indicate that the response to hypoxia has long-lasting effects on cellular physiology that persist even after return to room air. Recent evidence suggests that exogenous hydrogen sulfide can protect against the effects of ischemia-reperfusion injury in mammals. We have shown previously that adaptation to hydrogen sulfide increases lifespan and thermotolerance in *C. elegans*. Here we show that adaptation to hydrogen sulfide also protects against, and even reverse, the effects of hypoxia on protein homeostasis. Thus, as in mammals, hydrogen sulfide can protect against the damaging effects of decreased oxygen. We are currently exploring the molecular genetic mechanisms that mediate effects of adaptation to hydrogen sulfide on protein homeostasis. This work will provide unique insight into the mechanisms by which adaptation to hydrogen sulfide is integrated with the response to hypoxia at the cellular and organismal level.

1275

Peripheral neuropathy-linked mutations cause mislocalization and aggregation of ESCRT-I-interacting protein SIMPLE.

S. M. Lee[1], J. A. Olzmann[1], L-S. Chin[1], L. Li[1]; [1]Department of Pharmacology, Emory University, Atlanta, GA

Missense mutations in SIMPLE cause an autosomal dominant, demyelinating form of peripheral neuropathy known as Charcot-Marie-Tooth disease type 1C (CMT1C), but the pathogenic mechanisms of these mutations remain unknown. SIMPLE contains a PSAP motif that is known to bind the UEV domain of TSG101, a component of the ESCRT-I (endosomal sorting complex required for transport-I) complex involved in sorting ubiquitinated cargo proteins to the lysosomal pathway for degradation; however, the cellular function and subcellular localization of SIMPLE remain poorly characterized. Here, we report that SIMPLE is highly expressed in the peripheral nerves and Schwann cells. We found that SIMPLE is an early endosomal membrane protein that markedly co-localizes with TSG101 and have identified a transmembrane domain (TMD) for anchoring SIMPLE to the membrane. We find that CMT1C-associated mutations are clustered within or around the TMD of SIMPLE and that these mutations cause mislocalization of SIMPLE from the early endosome membrane to the cytosol. The CMT1C-associated SIMPLE mutant proteins are unstable and prone to aggregation, and they are selectively degraded by both the proteasome and aggresome-autophagy pathways. Our findings suggest that SIMPLE mutations cause CMT1C peripheral neuropathy via a combination of loss-of-function and toxic gain-of-function mechanisms and highlight the importance of both the proteasome and autophagy pathways in the clearance of CMT1C-associated SIMPLE mutant proteins.

1276

Global molecular mechanisms underlying hypoxia response and tolerance.

J. Hooda[1], A. Shah[1], D. Cadinu[1], R. Henke[1], X. Xin[1], R. Dastidar[1], L. Zhang[1]; [1]Molecular and Cell Biology, Center for Systems Biology, University of Texas at Dallas, Richardson, TX

Hypoxia is a widely occurring condition experienced by diverse organisms under numerous physiological and disease conditions. To probe the molecular mechanisms underlying hypoxia responses and tolerance, we previously performed a genome-wide screen to identify mutants with enhanced hypoxia tolerance in the model eukaryote, the yeast *Saccharomyces cerevisiae*. We identified five genes whose deletion significantly enhanced hypoxia tolerance. They are *RAI1, NSR1, BUD21, RPL20A, and RSM22*, all of which encode functions involved in ribosome biogenesis. Further analysis of the deletion mutants showed that they minimized hypoxia-induced changes in polyribosome profiles and protein synthesis. Strikingly, proteomic analysis using the iTRAQ profiling technology showed that hypoxia induced changes in a substantially fewer number of proteins in the deletion mutants. Computational analysis of the iTRAQ data indicated that the activities of a group of regulators were regulated by hypoxia in the wild type parent cells, but such regulation appeared to be diminished in deletion strains. Analysis of previous microarray gene expression profiling data also shows that a group of regulators, particularly certain components of Swi/Snf complexes, play important roles in oxygen regulation of gene expression. Experiments are currently underway to investigate the molecular mechanisms by which these regulators control gene expression in response to hypoxia or reoxygenation.

1277

Impairing PERK ameliorates neuropathy in Charcot Marie Tooth 1B mouse.

N. Musner[1,2], M. Sidoli[1,2], D. Zambroni[2], S. Saccucci[2], D. Ungaro[3], U. Del Carro[3], D. Ron[4], D. Cavener[5], M. L. Feltri[1,2], M. D'Antonio[2], L. Wrabetz[1,2]; [1]Hunter James Kelly Research Institute, University at Buffalo, School of Medicine and Biomedical Sciences, Buffalo, NY, [2]Division of Genetics and Cell Biology, San Raffaele Scientific Institute - DIBIT, Milan, Italy, [3]Neurology, San Raffaele Hospital, [4]Metabolic Research Laboratories, University of Cambridge, Cambridge, United Kingdom, [5]Biology, Penn State University, University Park, PA

Charcot-Marie-Tooth 1B (CMT1B) neuropathy is characterized by demyelination in peripheral nerves resulting in slowed nerve conduction velocity, muscular atrophy, and postural abnormalities. It is caused by mutations in Myelin Protein Zero (*MPZ*, P0), abundantly expressed by myelin-forming Schwann cells. When expressed in transgenic mice, P0S63del produces a demyelinating neuropathy that mimics the corresponding human CMT1B disease. P0S63del is retained in the endoplasmic reticulum of Schwann cells where it elicits an unfolded protein response (UPR) characterized by phosphorylation of eIF2alpha, ATF6 cleavage, IRE-1 induced Xbp-1 splicing and persistent CHOP synthesis. Genetic ablation of *Chop* restores motor capacity and ameliorates demyelination in S63del mice, suggesting that the UPR is maladaptive and pathogenic. Since CHOP is downstream of the PERK/eIF2alpha pathway, we studied the effect of *Perk* ablation in models of normal and S63del myelination. Myelinating DRG explant cultures prepared from S63del//*Perk -/-* mice show more and longer myelin internodes as compared to S63del. Ablation of *Perk* specifically in Schwann cells (S63del/P0Cre/*Perkf/f* mice) ameliorates myelination and nerve conduction velocities. Surprisingly, despite reduced levels of eIF2alpha phosphorylation in *Perk*-deficient S63del nerves, CHOP levels remain elevated. Interestingly, preliminary data suggest that IRE1 signaling could be more active in these nerves as compared to S63del. From these data we suggest that impairing PERK signaling ameliorates myelination in S63del/CMT1B neuropathy mice, perhaps by altering the balance between IRE-1 and PERK signaling in Schwann cells.

1278

Purinosome Formation is Altered in Cells from Patients with Defect in De Novo Purine Synthesis.

V. Baresova[1,2], V. Skopova[1,2], S. Kmoch[1,2], M. Zikanova[1,2]; [1]Institute for Metabolic Disorders, 1st Faculty of Medicine, Charles University of Prague, Prague, Czech Republic, Prague, Czech Republic, [2]Center for Applied Genomics, Charles University of Prague, Prague, Czech Republic

De novo purine synthesis (DNPS) requires ten enzymatic steps to generate IMP. This process is in eukaryotes catalyzed by six enzymes, which are organized into a multimeric protein structure: the purinosome. The purinosome is a transient structure which appears to be dynamically regulated by actual need and availability of purines. Dysfunction of DNPS is represented by two genetic diseases: AICA-ribosiduria and adenylosuccinate lyase deficiency (dADSL) both presenting mostly with devastating neurologic involvement. We hypothesized that some of the mutations may affect selectively formation or stability of the purinosome in vivo and lead thus to more severe phenotypes. In this work we therefore studied purinosome formation in skin fibroblasts from 10 patients with ADSL deficiency and from single case with AICA-ribosiduria.
We performed immunofluorescence labeling and subsequent analysis of confocal microscopy data of DNPS proteins produced by cells cultured in purine depleted conditions. We colocalized combinations of PPAT and ATIC, ADSL and ATIC, ADSL and PPAT enzymes in patient's skin fibroblasts.
PPAT protein formed clusters at reduced rate and ATIC remained diffuse in the patients` fibroblasts. When we focused on ADSL and ATIC proteins, we observed diffuse distribution of both proteins in patients cells, suggesting no purinosome formation. When compared to the control fibroblasts, the amount of the produced enzymes was reduced especially in AICA-ribosiduria and in more severe forms of dADSL. Colocalization of PPAT and ADSL proteins showed strong reduction of purinosome formation in patients with more severe dADSL, while reduction was only slight in AICA-ribosiduria and in moderate forms of dADSL. Control fibroblasts formed the complex very strongly in all tested enzyme combinations.
We observed correlation between purinosome formation and severity of the disease: no creation of the purinosome in neonatal and severe type of dADSL and strongly reduced formation in moderate type of dADSL and AICA-ribosiduria. These results indicate that genetic defects of DNPS affect not only activity and structure of the individual enzymes, but according to disease severity, also the functionality of the DNPS pathway by purinosome complex destabilization.
Study was granted by Ministry of Education of the Czech Republic MSM0021620806 and 1M6837805002 and LH11031

1279

Roles for nucleotide binding and multiple chaperones in *de novo* septin protein folding and higher-order assembly.

M. A. McMurray[1,2], J. Thorner[2]; [1]Department of Cell and Developmental Biology, University of Colorado, Denver School of Medicine, Aurora, CO, [2]Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Members of the septin family of GTP-binding proteins are found in nearly every eukaryote, typically as complexes composed of multiple septins. Filamentous septin arrays control cytokinesis in dividing cells, and morphogenesis in non-dividing cell types. As is true of other cytoskeletal polymers like actin and tubulin, binding and hydrolysis of nucleotide appear to regulate the structural integrity of septin filaments, presumably by stabilizing inter-subunit interfaces. However, unlike actin and tubulin, which traverse complex folding pathways and are substrates of multiple chaperone systems that prevent non-native interactions (e.g.,

aggregation), very little is known about nucleotide-dependent septin folding in vivo and roles for chaperones therein. In budding yeast, where septin filament formation is essential, mutations that abrogate septin nucleotide binding render cells temperature-sensitive, and destabilize oligomeric assemblies. At permissive temperatures such mutants display a striking defect in their ability to incorporate into higher-order structures when expressed *de novo* in a wild-type cell. Here, we show that this "competition" between wild-type and nucleotide-binding-mutant septins is mediated by two co-chaperones, prefoldin/GimC and Ydj1, a DnaJ-family Hsp40. As was known to be the case for multiple artificially-misfolded proteins, nascent Cdc10 polypeptides are apparently subject to Ydj1-dependent quality-control destruction. However, a large pool of each nucleotide-binding-defective septin that cannot "compete" with the wild-type is immune to degradation, and remains diffusely localized throughout the cell. Intriguingly, the CCT/TRiC chaperonin – which was known to bind septins and to help fold actin and tubulin – maintains the solubility of these misfolded septins, because they aggregate upon its inhibition. Our findings have important implications for the understanding of septin aggregation in human pathologies, including Parkinson's and Alzheimer's diseases.

1280

Chaperonin-Assisted Protein Folding at Low Temperature: Co-Evolution of Antarctic Fish CCT and Its Substrates.

J. Cuellar[1], H. Yebenes[1], S. K. Parker[2], G. Carranza[3], J. M. Valpuesta[1], J. C. Zabala[3], H. W. Detrich, III[2]; [1]Centro Nacional de Biotecnología (CNB-CSIC), Madrid, Spain, Madrid, Spain, [2]Department of Biology, Northeastern University, Boston, MA, USA, Boston, MA, [3]Departamento de Biología Molecular, Universidad de Cantabria, Santander, Spain, Santander, Spain

Marine ectotherms of the cold Southern Ocean (-2 to +1.5°C) surrounding Antarctica face energetic challenges to protein folding assisted by the chaperonin CCT. We hypothesize that CCT and its client proteins (CPs) from these organisms have co-evolved compensatory molecular alterations that facilitate CP-CCT binding and the ATP-driven folding cycle at low temperature. To evaluate this hypothesis, we compared CP/CCT systems purified from testis tissues of an Antarctic fish, *Gobionotothen gibberifrons*, and of the cow, *Bos taurus* (body T = 37°C). Purification of folding-competent *G. gibberifrons* CCT required substantial modifications to protocols used to isolate testis CCT from mammals. After establishing the fish CCT protocol, we tested the binding of denatured CPs (β-actin, β-tubulin) by the CCTs, both in homologous and in heterologous combinations and at temperatures of 4 and 20°C. Samples were processed for negative-stain EM at the incubation temperature, micrographs were recorded and digitized, and 1,000-2,000 particles from each reaction were scored as apo- or holo-CCT using maximum-likelihood classification procedures. In homologous combination, *G. gibberifrons* CCT possessed a higher affinity for β-actin or β-tubulin at 4 °C compared to 20 °C, whereas the converse was true for bovine CCT and its actin/tubulin CPs. When tested in heterologous combination, the binding affinities of the CCTs for the CPs were low at both Ts. The temperature dependence of the binding affinities of homologous CCT/CP pairs was analyzed in triplicate experiments at four Ts between -4 and +20°C. Irrespective of CP, the percentage of client bound by *G. gibberifrons* CCT declined linearly with increasing T, whereas the % of client bound by bovine CCT increased linearly with increasing T. The kinetics of the folding and release of native actin by *G. gibberifrons* CCT at 2°C were slow, reaching a plateau at 48 h. Together, our results suggest that CCT and CPs from Antarctic fishes have evolved interaction surfaces that place a greater reliance on polar and electrostatic bonds, which increase in strength as T decreases, at the expense of hydrophobic interactions, which weaken with decreasing T. Supported by NSF grants ANT-0635470 and ANT-0944517 (HWD) and by

MICINN grants BFU2010-15703 (JMV), CTM2009-08095-E/ANT (JMV, JCZ) and BFU2010-18948 (JCZ).

Chaperones in the Early-Diverged Eukaryote *Porphyra* (Rhodophyta): Revealing Hsp70 and Hsp40 Activities in the Cytoplasm of Thallus Cells under Control and Stress Conditions.

Y. Podlipaeva[1], S. Fulda[2], I. Telesh[3], A. Goodkov[1], H. Schubert[2], S. Skarlato[1]; [1]Institute of Cytology, Russian Academy of Sci., St. Petersburg, Russian Federation, [2]Institute of Biosciences, University of Rostock, Germany, Rostock, Germany, [3]Zoological Institute, Russian Academy of Sci., St. Petersburg, Russian Federation, Russia

Heat shock proteins are intensively studied in a number of organisms, but still very little is known about these stress proteins in early-diverged free-living photosynthetic eukaryotes, particularly in Rhodophyta. In algae, most attention is traditionally paid to sequencing genes that encode Hsp70 from different cell compartments, mainly chloroplast Hsp70, which is related to the cyanobacterial dnaK gene. Though cytoplasmic Hsp70 bears the main responsibility for heat shock response in the cell, there are no data on correlation between cytoplasmic hsp70 gene expression and the level of Hsp70 content in the cells of multicellular red algae. In this study, we investigated stress proteins of the thallus cells of *Porphyra* from the Kattegat area of the Baltic Sea (10 °C, salinity 28 psu) which were cultivated under control and stress conditions by Western blotting and ECL method using anti-Hsp70 antibodies. We revealed a faint band representing a 70 kDa protein and additionally a band with 40 kDa polypeptide. After heat shock at 28 °C during 1 hr we observed significant decrease of Hsp70 while Hsp40 was induced. The content of Hsp40 was 1.5 times higher in 4 hrs, and 10 times higher in 24 hrs after heat shock, if compare with control samples. To check the applicability of Remane's species-minimum concept to red algae, the experiments have been designed to study chaperone activities in *Porphyra* cells in the salinity gradient and compare the effects of different stresses (salinity and temperature) on Hsp expression in these early-diverged eukaryotes. Supported by IB/BMBF (RUS-09/038) and RFBR (10-04-00943).

S. cerevisiae genome-wide analysis identifies cellular processes affecting aggregation of Alzheimer's amyloid beta 42-EGFP fusion reporter.

S. Nair[1], M. Traini[1], A. Shevchenko[2], I. W. Dawes[1,3], G. Perrone[4]; [1]School of Biological Sciences, University of New South Wales, Sydney, Australia, [2]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, [3]Ramaciotti Centre for Gene Function Analysis, University of New South Wales, [4]School of Biomedical and Health Sciences, University of Western Sydney.

Alzheimer's disease (AD) is the leading cause of dementia in individuals over 65 years of age; and the risk of developing Alzheimer's disease increases steadily with age. Amyloid-beta (Aβ) plaques are a major neuropathological feature of AD. These plaques are primarily composed of aggregates of Aβ peptides generated via the amyloidogenic processing of the amyloid precursor protein. The two major isoforms of Aβ peptide are Aβ40 and Aβ42, of which the latter is highly prone to aggregation and shown to support a central role in AD disease progression. The increased presence and aggregation of intracellular Aβ42 peptides has been shown to be an early event in the disease progression of AD. Improved understanding of cellular processes involved in Aβ42 aggregation may have implications for our understanding of AD disease progression and possible development of therapeutic strategies.

In this study, Aβ42 fused to GFP (Aβ42GFP) was expressed in each mutant of the Saccharomyces cerevisiae genome-wide deletion library, to identify on a genome-wide scale the proteins and cellular processes that affect intracellular Aβ42 aggregation by assessing the fluorescence associated with the Aβ42GFP reporter. The genome-wide screening identified 98 mutants exhibiting intense Aβ42GFP-associated fluorescence. These deletion mutants were categorised according to broad biological functional groups/cellular processes based on the established or putative cellular roles of each of the respective 98 gene products. This approach identified four major cellular processes that were over-represented in the data set, of which mutants that were categorised into the lipid homeostasis functional group is discussed. In addition to the identification of cellular processes, distinct localisation of Aβ42GFP in the these lipid mutants were observed.
To identify the specific lipid macromolecule(s) that may potentially interact with amyloid-beta and hence abate its aggregation, a shotgun lipidomics approach was undertaken, to allow quantitative measurements of all cellular lipids. These data provide the first genome-wide evidence of cellular processes and macro-molecules that affect intracellular Aβ42GFP aggregation and may have important implications for our understanding of cellular mechanisms that affect intracellular Aβ42 aggregation and ultimately disease progression of AD.

1283

Expression of clusterin decreases with aging and oxidative stress in human normal epidermal keratinocytes and dermal fibroblasts and is stimulated by phospholipids.

M. Dumas[1], J. Cauchard[2], V. Jeronimo Monteiro[2], M. Moreau[2], F. Bonté[2], S. Schnebert[2], E. Perrier[2], C. Nizard[2]; [1]LVMH RECHERCHE, F-45804 Saint Jean de Braye, France, Saint Jean De Braye, France, Metropolitan, [2]LVMH RECHERCHE, F-45804 Saint Jean de Braye, France

Clusterin is a glycoprotein widely distributed in mammalian tissues and biological fluids and is implicated in a variety of physiological and pathological processes. Mature form of clusterine is secreted in extracellular spaces as an heterodimeric glycoprotein of 80 kDa. It acts as a molecular chaperone to stabilize proteins in a folding competent state and has a role in scavenging extracellular misfolded proteins produced following stress-induced injury. It has also a role in the clearance of cellular debris and phagocytosis promotion. Clusterin is associated with altered elastic fibers in aged human skin, and inhibits UV-induced aggregation of elastin. In epithelial cells, clusterin protects from exogenous H_2O_2 stress and over expression protects human skin fibroblasts against premature senescence
Objectives: to examine a possible alteration of clusterin expression on human skin cells in vitro during ageing and after oxidative stress.
Methods: Normal human dermal fibroblasts (NHDF) were obtained from donors from 25, 40 and 69 yo and epidermal keratinocytes (NHEK) from donors (n=18) from 49 to 66 years old. Expression of clusterin was followed by western blot and RT-QPCR with and without 20 min treatment of cells with H202 (100 to 500µM) or phospholipids vesicles are composed of a mixture of phosphatidylcholine and phosphatidylserine 70% and 30% respectively in weight
Results: NHDF and NHEK highly express clusterin at the mRNA and protein levels. This expression significantly decreases in NHDF from 25 year old (yo) to 40 yo (1.5 times less) and 69 yo (2,5 times less) donors. More over fibroblasts from the 69 yo donor are more sensitive to H_2O_2 particularly at the lowest 100µM dose. Expression of clusterin mRNA is also significantly decreased in NHEK from 49-66 yo donors (-54%) compared to cells from the younger group. Clusterin expression is also reduced after H202 exposure with a maximal effect observed at 200 µM. Vesicles of phospholipids are able to stimulate at 600µmol/L the expression of clusterin mRNA (2 times at 24h) and the extracellular protein secretion (1.8 times at 72h) in NHEK. More over a 24h preventive treatment of NHEK with these phospholipids, protects clusterin expression from H_2O_2 exposure.

Conclusion: These results demonstrate that aging and oxidative stress decrease clusterin expression in dermal and epidermal skin cells and that phospholipids could be used to stimulate its expression, and to protect it from oxidative stress.

Regulation of Aging

1284

Susceptibility of epidermal stem cells to 4-HNE stress: Oxidized protein measurement and aging studies.

C. Nizard[1], E. Noblesse[1], P. Schaeffer[1], M. Juan[1], S. Schnebert[1], E. Perrier[1]; [1]LVMH Recherche, Saint Jean de Braye, France

Accumulation of oxidized proteins is a hallmark of cellular ageing and is believed to be one of the main contributors to the aged phenotype. This process is dependent on an increased occurrence of oxidative damage to proteins and also on a decreased elimination of oxidative modified protein.
Stem cells have an extraordinary ability to multiply and consequently allow cell renewal and help maintain the quality of the skin. When no stress occurs, they remain dormant in the skin but multiply several times in case of damage. Subsequently, the cells differentiate, lose their ability to divide and migrate towards the surface of the skin, where they are eliminated via exfoliation.
Objective
The aim of the study is to set up a method of visualization and quantification of oxidized proteins. It has been done on young (mean 22 years old) and aged (mean 55 years old) Normal Human Keratinocytes (NHK) in culture. Furthermore, this technique has been performed on Colony Forming Unit in order to better characterized stem cells from skin epidermis. Oxidized proteins have been quantified with 4-HNE induction, a lipidic peroxidation product which can crosslink with proteins. We tried to counteract the effect of 4-HNE with a complex of anti-oxidants compounds.
Methods
The Oxidized proteins staining was performed with a monoclonal mouse anti-DNP antibody, and alexafluor 546 Goat anti-mouse secondary antibody. This staining has been performed on NHK and CFU cultivated on irradiated fibroblasts feeder-layer.
The OE complex is composed of 0,1% Phaeodactylum tricornutum extract + 0,1% Aframomum angustifolium extract and 0,002% dimethyl methoxychromanol. 4-HNE is used at 10 µM.
Results
In comparison with young donor keratinocytes, aged donors cells showed a very significant increase (+858 %) of oxidized proteins content. We can see a significant increase in the amount of oxidized proteins induced by HNE (+179 %) compared to the untreated control. The OE complex is able to significantly reduce the amount of oxidized proteins produced during HNE stress (-55.8 %). OE complex showed a significant decrease (-61,8 %) of oxidized proteins on CFU from epidermal stem cells.
We can see a 61% decrease of big colonies (from stem cells) with 4-HNE stress. A treatment with the complex counteracts the effect of HNE stress with 88 % increase of stem cells number. We observed that CFU from old keratinocytes donors are more sensitive to HNE stress compared to young donors cells (-69,1% for old cells and –35% for young cells). OE complex applied with HNE increased the number of big clones, and this particularly true for old cells: +302% compared to +84,7% for young cells.

Conclusions

We observed that epidermal stem cells from old donors are more sensitive to HNE stress compared to young cells maybe because old NHK (which contains fewer stem cells than young donor cells) have already a higher level of oxidized proteins. This damage can be significantly reduced by a unique anti-oxydant complex which protects old donor stem cells from HNE stress.

1285

SIRT2 is downregulated in insulin-resistant HepG2 cells: a possible role of oxidative stress.

V. Lemos[1], R. de Oliveira[2], T. Outeiro[2,3], P. Gomes[1]; [1]Department of Biochemistry, Faculty of Medicine, University of Porto, Porto, Portugal, [2]Cell and Molecular Neuroscience Unit, Institute of Molecular Medicine, Lisbon, Portugal, [3]Department of Neurodegeneration and Restaurative Research, University Medizin Gottingen, Gottingen, Germany

Sirtuin 2 (SIRT2), a member of class III histone deacetylases, has been reported to protect cells against oxidative and other types of stress. Moreover, increasing evidence suggests the existence of a link among increases in oxidative stress, activation of stress-sensitive pathways, and the development of insulin resistance. We therefore hypothesized that the antioxidant effect of SIRT2 could lead to improved insulin sensitivity. In this study, we established an in vitro model of insulin resistance by treatment of the human hepatocarcinoma cell line HepG2 with glucosamine (GlcN). We found that in GlcN-treated cells insulin-stimulated glycogen synthesis was impaired and this was associated with an elevation in H_2O_2 production. Moreover, insulin-resistant HepG2 cells showed an increase in basal ERK1/2 phosphorylation and failed to respond to acute insulin stimulation. We further demonstrated that GlcN induced SIRT2 downregulation in a time-dependent manner. The antioxidant N-acetylcysteine decreased H_2O_2 levels and partially improved insulin sensitivity, suggesting that insulin resistance was mediated to a significant extent via increased oxidative stress. Taken together, our results indicate that hepatic insulin resistance is associated with reduced expression of SIRT2. Further studies will address whether the modulation of SIRT2 levels and/or activity is able to improve insulin sensitivity through a ROS-mediated mechanism.

1286

Transcriptional profiling of hypoxia and/or UVB modulated genes in human epidermal keratinocytes reveals novel targets for reducing skin aging-induced effects.

A. *Primorac[1], R. Huggenberger[1], M. Dumas[2], C. Nizard[2], S. Schnebert[2], E. Perrier[2], M. Detmar[3]; [1]ETH Zurich, Switzerland, [2]LVMH Recherche, [3]Institute of Pharmaceutical Sciences, ETH Zurich, Zurich, Switzerland*

There is increasing evidence for hypoxic conditions (1.5 to 5% oxygen) in human epidermis. Because of the skin changes associated with skin aging, in particular with chronic photodamage, hypoxia appears to increase with aging of the skin. However, the effects of chronic hypoxia on skin growth and function, and on the UVB-mediated skin damage, are currently unknown.

The major goals of this project were to characterize the effects of chronic mild hypoxia, alone or in combination with UVB-induced skin damage, on the transcriptional profile and the functional behaviour of human epidermal keratinocytes in vitro.

HaCaT immortalized human epidermal keratinoctes were cultured under normal or hypoxic conditions (≈ 2% O2) for 24 hours or for 7 days and/or were irradiated with UVB light (≈ 20 mJ/cm2). Total RNA was extracted, and gene microarray profiling of the transcriptional profiles of the treated cells was performed in triplicates, using the Applied Biosystems gene array platform, followed by qRT-PCR confirmation of lead candidates.

We found that hypoxia and UVB irradiation induced distinct, partially overlapping gene expression patterns of human epidermal keratinocytes. Typical hypoxia-response pathways were activated by hypoxia, including glycolysis and HIF activation pathways, and typical hypoxia-response genes such as lysyl oxidase-like 2 and angiopoietin-like 4 were upregulated. After UVB irradiation, several genes including placental growth factor and filaggrin were induced or reduced. The modulation of candidate genes was confirmed by qRT-PCR. Current studies investigate the functional effects of these genes on the growth, differentiation and colony forming ability of normal human epidermal keratinocytes. Overall, we have identified a number of potential targets to modify the skin response to hypoxia and UVB damage.

1287

Slimming potential of a salicornia herbacea extract via its effect on adiponectin protection against oxidative stress.

J. Franchi[1], L. Pentecouteau[2], M. Dumas[1], S. Schnebert[1], R. Vallee[2], P. Morvan[2]; [1]LVMH RESEARCH, Saint Jean de Braye, France, [2]CODIF Internationa, Roz Sur Couesnon, France

OBJECTIVE: Ageing alters mitochondrial functions and biogenesis, increases the production of free radicals by mitochondria with dramatic consequences for epidermal and dermal cells but also for hypodermal cells (mainly adipocytes). The problem concerning ageing of adipocytes is how to protect them against oxidative stress in order to restore the lipolytic functions. Ageing alters the production of adipose-specific cytokines (adipokines) involved in the control of lipid synthesis, and in particular adiponectin. The aim of this work was to present a new potential ingredient to fight against adipocyte ageing and some of its effects, the decrease of adiponectin synthesis, and the decrease of lipolysis by human adipocytes.
METHODS: The cells used were adipocytes isolated from human adipose tissue or adipocytes obtained after differentiation of human adult mesenchymal stem cells. These cells were exposed to oxidative stress induced by UV rays (UV) or by glucose oxidase (GO). The effects of these treatment on lipolysis activity were evaluated by the measure of non esterified fatty acids (NEFA) released by adipocytes treated or not with the classical lipolytic agent caffeine (10mM). Adiponectin level was measured by ELISA method. An aqueous extract of the halophyte plant *Salicornia herbacea* was evaluated on fat cells.
RESULTS: Treatments with UVB (50 mJ/cm²) reduced the lipolytic response of isolated adipocytes to caffeine (increase of NEFA by +53% with UV versus +166% without UV) and reduced by 20% the adiponectin production by adipocytes. Treatment with GO (2 mU/ml) also limited caffeine –induced lipolysis and reduced by 50% the adiponectin production.
The extract of *Salicornia herbacea* has a high antioxidant activity evaluated by ORAC test (659 ± 14 mg ET/L ; ET = Equivalent Trolox). It protected adipocytes against reduction of the lipolytic response induced by UVB (50 mJ/cm²) or by GO (2 mU/ml). The adiponectin level was also protected against GO-induced stress: protection by 50% and 92% with *Salicornia herbacea* extract tested at 0.2% and 0.4%, respectively.
CONCLUSION: By protecting adiponectin against its degradation by free radicals, the anti-oxidant plant extract protects adipocyte metabolism.

1288

Role of Notch signaling in stem cell behavior in dystrophic muscle.

X. Mu[1], K. Weiss[1], J. Huard[1]; [1]Stem Cell Research Center, Department of Orthopaedic Surgery, University of Pittsburgh, Pittsburgh, PA

Duchenne muscular dystrophy (DMD) is a progressive disease that features chronic inflammation and continuous myofiber regeneration. The dystrophin gene was found to be defective in DMD patients; however, it has always been a puzzle why mdx mice, a model of

DMD being defective in the dystrophin gene, only develops very mild skeletal muscle defects and exhibits a very potent muscle regenerative capacity. It would therefore be of interest to find out the potential molecular mechanism that determines the differential behavior of muscle stem cells derived from the skeletal muscle of mdx mice and DMD patients. Notch signaling has been indicated to play an important role in the development and regeneration of skeletal muscle, and it can maintain muscle stem cells in a quiescent or undifferentiated state, which suggests a role for Notch signaling in reserving the stem cell pool in skeletal muscle. Moreover, Notch signaling was shown to potently repress myogenesis by affecting the function of the myogenic factor MyoD. However, the investigation of the role of Notch signaling in dystrophic muscle is lacking. Interestingly, it was recently reported that TNF-α can actually inhibit Notch1 activation in *in vitro* cultured muscle cells of mouse, and a potential similar mechanism in dystrophic muscle was suggested. Our current study was conducted to determine whether Notch signaling could be a critical contributor to the differential stem cell behavior and muscle regeneration potential of mdx and DMD muscle. Using semi-quantitative PCR, our results showed that, the expression of Notch signaling-related genes (*Notch1, 3, Stat3* and *Hes1*) were all greatly down-regulated in muscle cells from the dystrophic muscle of mdx mice, compared to those from wild type normal mice; however, Notch signaling in the muscle cells of DMD patients was found to be strongly activated. Meanwhile, the inactivation of Notch signaling in muscle cells isolated from DMD patients, using a Notch inhibitor, reduced the expression of inflammation marker genes and improved the myogenesis potential of the DMD cells. Our results indicate that the Notch signaling pathway could be the potential molecular switch which determines the differential behavior observed between muscle stem cells and the muscle phenotype of mdx verses DMD muscle. Therefore, a beneficial effect of muscle regeneration could be expected by the inactivation of Notch signaling in the dystrophic muscle of DMD patients, and the development of a potential new therapeutic regime for treatment of the disease.

1289

KLOTHO Regulates Retinal Pigment Epithelia functions through TRPV5 Ca2+ channels; Implication in Age-Related Macular Degeneration.

M. Kokkinaki[1], G. Ahern[2], N. Golestaneh[1,3]; [1]Ophthalmology, Georgetown University School of Medicine, Washington, DC, [2]Pharmacology and Physiology, Georgetown University School of Medicine, Washington, DC, [3]Neurology, Georgetown University School of Medicine, Washington, DC

Purpose: Age-related macular degeneration (AMD) is the leading cause of blindness in people over 55-years old in developed countries. AMD starts with the deposit of drusen between Retinal Pigment Epithelia (RPE) and Bruch's membrane and progresses with the death of RPE, photoreceptor degeneration, and eventually loss of central vision. RPE comprise a monolayer of pigmented cells and play many crucial roles in the retina. Recent discovery of KLOTHO (KL) gene that encodes for a transmembrane protein secreted primarily by the kidney, known for its senescence-suppression function in the mouse, has opened new avenues for studying of the age-related diseases. In this study we investigate the role of KL in the regulation of RPE functions that could be directly implicated in retinal degeneration and AMD.

Methods: Real-time PCR, Western blot, Ca2+ imaging, immunostaining, EIISA, knockdown assays.

Results: Here we show for the first time that human RPE express KL, and KL expression is significantly reduced in the eye during aging and due to oxidative stress. Using Ca2+ imaging we demonstrated that KL protein regulates the activity of Transient Receptor Potential cation channel subfamily V member 5 (TRPV5) in human RPE and increases the Ca2+ entry across

the apical membrane. We further demonstrate that reduction of KL expression by oxidative stress can increase the vascular endothelial growth factor (VEGF) expression in RPE, that is known to be implicated in neovascularization inducing visual loss in AMD.

Conclusion: Since Ca+2 is involved in many RPE functions (i.e., phagocytosis, VEGF secretion, light absorption, migration), its tight regulation is crucial for RPE functions and survival. Our results show for the first time that KL regulates RPE functions by increasing Ca+2 entry through TRPV5 channels, therefore, a decrease in KL expression during aging might be directly implicated in AMD. This study if completed can open new avenues for understanding the mechanisms of AMD and development of new treatments for the disease.

1290

Examining the Role of TPP-I in the Degradation of Fibrillar Aβ by Microglia.

D. Cruz[1], M. El-Banna[2], A. Majumdar[1], M. Muldowney[1], P. Lobel[2], F. R. Maxfield[1];
[1]Biochemistry, Weill Cornell Medical College, New York, NY, [2]Center for Advanced Biotechnology and Medicine, Robert Wood Johnson Medical School

The aggregated fibrils of β-amyloid (fAβ) associated with Alzheimer's disease are not completely degraded by microglia. These monocyte derived phagocytic cells of the CNS internalize fAβ and deliver it to the lysosomes, but the lysosomal pH of microglia is higher than that of macrophages and degradation of fAβ is incomplete. The lysosomal enzymes of microglia that we have examined are identical to those present in macrophages, but the activity of these enzymes is decreased by the higher pH. We hypothesize that the enzyme tripeptidyl-peptidase I (TPP1), which has a low optimal pH and has been shown to have an endopeptidase activity, is the key enzyme for initiating degradation of fAβ to allow further degradation by other lysosomal enzymes. This enzyme is present in all of the cell types that we have examined that degrade fAβ. We have previously shown that microglia treated with cytokines such as interleukin-6 (IL-6), lipopolysaccharide (LPS), or macrophage colony stimulating factor (MCSF) degrade more fAβ than untreated microglia and have a lower lysosomal pH. We have found that the level of TPP1 is increased in microglia treated with MCSF. We examined the role of TPP1 in the degradation of fAβ through enzyme addback experiments with microglia, chemical inhibitor additions to macrophages, and RNAi knockdown of the enzyme in osteosarcoma cells expressing Scavenger Receptor A (SRA), another cell line able to degrade fAβ. We are currently examining fAβ degradation by TPP1 knockout microglia treated with MCSF and wildtype and TPP1 knockout murine bone marrow macrophages. We have also begun to examine the levels of plaque deposition in an Alzheimer's disease mouse model that has limiting levels of the TPP1 enzyme. Our results to date show that although the lysosomal pH in microglia is more alkaline than that of macrophages, addition of either pooled lysosomal enzymes or purified TPP1 to microglia increases the degradation of fAβ by these cells. Without TPP1, MCSF-treated microglia do not degrade fAβ as well as wildtype MCSF treated cells. The addition of specific TPP1 inhibitors to macrophage and osteosarcoma cells, as well as RNAi knockdown of TPP1, blocks fAβ degradation. These results indicate that TPP1 plays an important initial role in the degradation of fAβ by microglia.

1291

Molecular Mechanisms distinguishing Reproductive Aging from Somatic Aging.

S. Luo[1], C. Murphy[1]; [1]Molecular Biology & Lewis Sigler Institute, Princeton University, Princeton, NJ

Female reproductive cessation is the earliest aging phenotype humans experience, occurring midway through life, and is governed by declining oocyte quality. We have shown previously

that C. elegans reproduction, which also persists for only half the worms' lifetime, is similarly limited by oocyte quality decline (Luo, et al. Cell 2010). Moreover, the transcriptional changes that worm oocytes undergo with age are similar to those in aging mammalian oocytes, and these changes are reversed in mutants with extended reproductive spans.
Both the TGF-b Sma/Mab and Insulin/IGF-1 signaling pathways regulate reproductive aging (Luo, et al. PLOS Genetics 2009), but IIS extends life span, as well (Kenyon, et al. 1999). We had previously identified the downstream DAF-16 targets of IIS that are responsible for long life span (Murphy, et al. Nature 2003). We wondered to what degree the mechanisms that extend reproductive span and life span are shared. In fact, very few of the terms overlap, suggesting that post-mitotic, non-proliferating tissues utilize one specific set of genes, while mitotically proliferating and cell-cycle-arrested cells utilize completely different mechanisms to keep cells youthful and functioning.

Establishment and Maintenance of Polarity II

1292

CPEB-mediated ZO-1 mRNA Localization Stimulates Mammary Epithelial Tight Junction Assembly and Cell Polarity.

K. Nagaoka[1,2], T. Udagawa[1], J. Richter[1]; [1]University of Massachusetts Medical School, Worcester, MA, [2]Tokyo Univ Agriculture/Technology, Tokyo, Japan

CPEB is a sequence-specific RNA binding protein that regulates cytoplasmic polyadenylation-induced translation; in so doing, it controls several biological processes including vertebrate germ cell development. CPEB knockout female mice do not produce mature oocytes and thus are sterile; their vestigial ovaries do not secrete sufficient levels of hormones to promote mammary gland development. CPEB heterozygous mice, however, are fertile but their mammary epithelial cells are disorganized and ZO-1 and claudin-3, apical tight junction proteins, are mis-localized. CPEB depletion from cultured mammary epithelial cells disrupts ZO-1 apical localization and tight junction distribution; conversely, ectopic expression of CPEB enhances apical ZO-1 localization. CPEB and ZO-1 mRNA are co-localized apically and ZO-1 3′UTR binding sites for CPEB promote the RNA localization. In a 3-dimensional culture system that models lumen-containing mammary ducts, depletion of CPEB or ZO-1 impairs central cavity formation, indicating a loss of tight junction formation and cell polarity. Cavity formation in ZO-1 depleted cells is substantially rescued when they are transduced with ZO-1 mRNA containing, but not lacking, the CPEB binding sites. These and other data indicate that CPEB promotes tight junction assembly and mammary epithelial cell polarity, and that one mRNA important for this process encodes ZO-1.

1293

Two B-type cyclins regulate anterior PAR protein localization in the early *C. elegans* embryo.

A. Rabilotta [1], J-C. Labbé[2]; [1]Molecular Biology, IRIC, University of Montreal, Montreal, QC, Canada, [2]Pathology and Cell Biology, IRIC, University of Montreal, Montreal, QC, Canada

We are using *C. elegans* as a model to study asymmetric cell division, an essential process to generate cell diversity during development. Establishment and maintenance of polarity are fundamental processes for a normal asymmetric division in all eukaryotes.
In the *C. elegans* embryo, the establishment of an anterior-posterior axis of polarity takes place after fertilization and depends on the asymmetric localization of the conserved PAR proteins in

two mutually exclusive groups: the anterior complex, with PAR-3, PAR-6, PKC-3 and the posterior group with PAR-2 and PAR-1. Depletion of any PAR protein causes a loss of polarity and embryonic lethality. A genome-wide RNAi screen identified two B-type cyclins, *cyb-2.1* and *cyb-2.2*, (together referred to as *cyb-2*) as suppressors of *par-2(it5ts)* lethality. The goal of this project is to determine the role of these cyclins in cell polarity.
Using double and triple mutants for *par-2* and each cyclin, we showed that the loss of *cyb-2.1* or *cyb-2.2* suppressed lethality and polarity defects in *par-2(it5ts)* mutants and that loss of both cyclins promoted the anterior displacement of the PAR-6 cortical domain. Suppression of *par-2(RNAi)* lethality was also observed in a thermosensitive mutant for the cyclin-dependant kinase *cdk-1*, suggesting that CYB-2 acts with its CDK-1 partner in this pathway. *cyb-2* mutants did not show defects in cell cycle progression, timing of polarity establishment or velocity of polarizing myosin flows, indicating that CYB-2 acts in polarity independently of these processes. Interestingly, western blot analyses revealed that PAR-6 levels are decreased in *cyb-2* mutants. Another suppressor of *par-2* lethality, *nos-3*, was previously shown to regulate PAR-6 levels through the activity of a CUL-2-based E3 ubiquitin ligase complex. Using epistatic analysis, we found that CYB-2 requires CUL-2 to suppress *par-2*(RNAi) lethality, suggesting that it also functions through this E3 ubiquitin ligase. Furthermore, mutations in *cyb-2* and *nos-3* were found to be additive, suggesting that these genes act independently on CUL-2 to regulate PAR-6 levels.
These results support a model in which a CYB-2/CDK-1 complex acts on CUL-2 to modulate PAR-6 levels independently of cell cycle progression during *C. elegans* embryonic polarization and suggest that the control of PAR-6 levels is a regulated step important for cell polarity. We are currently using biochemical and proteomic approaches to further define the molecular mechanism by which CYB-2/CDK-1 acts in this pathway.

1295

PAR-3 oligomerization gives rise to a bistable switch mechanism that may help maintain Par protein domains in the early *C. elegans* embryo.

A. T. Dawes[1], E. Munro[2]; [1]Mathematics/Molecular Genetics, Ohio State University, Columbus, OH, Canada, [2]Molecular Genetics and Cell Biology, University of Chicago

Shortly after fertilization, embryos of the nematode worm *Caenorhabditis elegans* polarize by segregating Par proteins to spatially distinct domains at the anterior and posterior poles. Recent experimental work demonstrated that during the maintenance phase, these domains are held with minimal drift in the position of the boundary between the domains, even in the absence of cortical actomyosin (Goehring et al, 2011). In this talk, we will discuss a mathematical model of Par protein interactions that incorporates mutual cross-inhibition of Par proteins and PAR-3 oligomerization. This model exhibits bistability and is able to maintain distinct Par protein domains independently of asymmetries or dynamics of cortical actomyosin. The model dynamics predict a sudden loss of polarization as the anterior Par protein PAR-6 is depleted, and we confirm the prediction experimentally using RNA interference.

1296

Crumbs prevents photoreceptor cell death by repressing Rac1/NADPH oxidase-dependent superoxide production.

F. Chartier[1], P. Laprise[1]; [1]Centre De Recherche De L`Hotel Dieu, Laval University, Quebec, QC, Canada

Drosophila Crumbs is crucial for establishment and maintenance of epithelial cell polarity. In addition to its role in apicobasal polarity, Crumbs is essential to prevent light-induced retinal degeneration. Similarly, mutations in CRB1, which encodes a human ortholog of Crumbs, cause

retinal dystrophies in humans. Recent findings have highlighted that Crumbs controls signaling pathways regulating growth and apoptosis in epithelial tissues. However, the molecular mechanisms by which Crumbs maintains photoreceptor cell viability remain largely unknown.

We have previously shown that Crumbs promotes epithelial tissue integrity by inhibiting Rac1 and PI3K in Drosophila embryos. Here we show that this function is conserved in photoreceptor cells, as loss of Crumbs increased active GTP-bound Rac1 levels and PI3K activity in retinas. This was associated with an increase in NADPH oxidase activity, which produces superoxide in a Rac1-dependent manner. Strikingly, inhibition of Rac1 and NADPH oxidase as well as antioxidant rescued the crumbs mutant phenotype. Similarly, knockdown of Rac1 and NOX (catalytic subunit of NADPH oxidase) prevented photoreceptor cell death.

Together, our data show that Crumbs represses Rac1/NADPH oxidase-dependent superoxide production, thereby preventing photoreceptor cell death. As Crumbs functions are evolutionarily conserved, it is likely that human CRB1 maintains retinal integrity through a similar mechanism.

1297

Identification of Par1b substrates required for regulating epithelial polarity.

D. Fernandez[1], A. Muesch[1]; [1]Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY

Simple epithelial cells share the same basic morphological structure. They have distinct luminal (apical) surfaces separated by tight junctions from the intercellular and blood barrier-interacting (baso-lateral) surface. The maintenance of these highly polarized cells is crucial for proper functioning of tissues such as kidney tubules, liver, and gastric epithelia. Par1b is a serine/threonine kinase which is well known for its role in maintaining polarity of epithelial cells. In MDCK cells, knockdown of Par1b causes cells to lose their apico-basal polarity. Conversely, overexpression promotes the establishment of a hepatic-type polarity, where the apical surface forms intercellularly. How Par1b acts as a molecular switch to regulate polarity is unknown. However, overexpression of a kinase-dead Par1b does not lead to the development of hepatic-type polarity, suggesting that the polarity regulation is controlled by Par1b's kinase activity. Par1b has few known substrates, none of which can single-handedly account for maintaining polarity. It is the goal of this project to 1) identify novel substrates of Par1b and 2) characterize those substrates for their role in the establishment and maintenance of epithelial cell polarity.

The identification strategy is based on a chemical genetics approach in which the ATP-binding pocket of a kinase is altered to accommodate bulky ATP-analogues that when offered as phosphate donor in complex mixtures can only be utilized by the engineered kinase to selectively phosphorylate its substrates. The ATP-analogues contain a chemical affinity tag that is transferred onto the substrates and allows their isolation along with the identification of the phosphorylation sites by LC-MS/MS analysis. We have generated an analogue-sensitive Par1b (Par1b-ATP*), and utilizing a radioactive ATP analogue, have successfully labeled substrates from Par1b immuno-precipitated complexes, Tx100 soluble cell lysates, and whole digitonin permeabilized cells. From the immuno-isolated Par1b complexes, we have identified 4 known substrates and 76 putative substrates. Thus far we have validated 10 of the candidates as *in vivo* substrates. We will expand our candidate list by identifying and validating novel substrates from MDCK cell lysates and digitonin permeabilized cells. Furthermore, we will examine how Par1b regulation of the substrate regulates epithelial polarity.

RAB25 regulates polarity in intestinal epithelial cells.

M. Krishnan[1], L. A. Lapierre[1,2], J. N. Higginbotham[3], J. R. Goldenring[1,2]; [1]Department of Surgery & Epithelial Biology Center, Vanderbilt University, Nashville, TN, [2]VA Medical Center, Nashville, [3]Department of Medicine & Epithelial Biology Center, Vanderbilt University, Nashville, TN

Objective: Epithelial cells establish apical and basolateral membrane domains during polarization. This conserved function of polarized epithelial cells requires efficient and organized vesicular trafficking to the correct apical or basolateral membrane domains. Rab25 is an epithelial-specific small GTPase. Rab25 regulates transcytosis in MDCK cells and recent studies indicate that it acts as a tumor suppressor in the intestine and colon. Here we have investigated Rab25's role during polarization of the intestinal epithelial cells using CaCo2–BBE cells. These cells form polarized monolayers in culture when grown on permeable supports. **Methods**: The CaCo2-BBE cells either stably expressing a scrambled shRNA or shRNA directed against Rab25 were plated on transwell filters for 3, 8 and 15 days, the cells were analyzed for apical and junctional proteins by western blotting, qPCR and immunofluorescence. The apical membrane was analyzed by scanning EM. **Results:** Rab25, but not Rab11a, expression increased from 1.5 to 2.5 fold at the both in protein and mRNA level as the cells polarized. Knockdown of Rab25 expression altered the expression both at the transcriptional and translational level of the microvillar proteins such as villin-1 and sucrase isomaltase (SI). Rab25 loss also caused improper assembly of microvilli/brush-border in the apical domain. Interestingly, knockdown of Rab25 caused a loss of β1, α1 and α5 integrins and altered expression of the tight junctional proteins like claudin-1,2,3,4 and 7. These tight junctional alterations decreased the transepithelial resistance in Rab25knockdown cells. The anchorage independent growth assay showed 2-fold increase in the number of colony formed and increased in diameter of the colony in the Rab25 knockdown cells when compared to control. All these changes were restored when knock-down cells were rescued with expression of rabbit Rab25. **Conclusions:** Taken together, our studies demonstrate that Rab25 is important for the proper assembly of microvilli/ brush-border in polarized intestinal epithelial cells.

1299

Phosphorylation of Rab11-FIP2 regulates polarity in MDCK cells.

L. A. Lapierre[1], K. M. Avant[1], C. M. Caldwell[1], A. Oztan[2], G. Apodaca[2], N. A. Ducharme[3,4], J. R. Goldenring[3,5]; [1]Surgery and Epithelial Biology, Vanderbilt Univ Med Ctr, Nashville, TN, [2]Cell Biology and Physiology, Univ. Pittsburgh School Medicine, Pittsburgh, PA, [3]Cell and Developmental Biology, Vanderbilt Univ Med Ctr, [4]Univ. Houston, Houston, TX, [5]Surgery and Epithelial Biology, Vanderbilt Univ Med Ctr

The Rab11 effector, Rab11-FIP2 regulates transcytosis through its interactions with Rab11a and Myosin Vb. Previous studies have implicated Rab11-FIP2 in the establishment of polarity in MDCK cells through phosphorylation of serine 227 by MARK2. Here we have examined the dynamic role of Rab11-FIP2 phosphorylation on MDCK cell polarity. Endogenous Rab11-FIP2 phosphorylated on serine 227 coalesced on vesicular plaques during the re-establishment of polarity following either monolayer wounding or calcium switch. While expression of the non-phosphorylatable Rab11-FIP2(S227A) elicited a loss in lumen formation in MDCK cell cysts grown in matrigel, the putative pseudophosphorylated Rab11-FIP2(S227E) mutant induced the formation of cysts with multiple lumens. On permeable filters, Rab11-FIP2(S227E)-expressing cells exhibited alterations in the compositions of both the adherens and tight junctions. At the

adherens junction, p120 catenin and K-cadherin were retained, while the majority of the E-cadherin was lost. While ZO-1 was retained at the tight junction, occludin was lost and the claudin composition was altered. Interestingly, the effects of Rab11-FIP2 on cellular polarity did not involve Myosin Vb or Rab11a. These results indicate that serine 227 phosphorylation of Rab11-FIP2 regulates the composition of both adherens and tight junctions and is intimately involved in the regulation of polarity in epithelial cells.

The Role of FIP5 and Kinesin-2 in the Regulation of Epithelial Morphogenesis.

D. Li[1], C. Willenborg[1], R. Prekeris[1]; [1]University of Colorado Denver, Aurora, CO

Epithelia outlining the organs possess multiple functions, including protection, secretion and selective absorption. To accomplish these functions, epithelia are structurally and functionally polarized. The plasma membrane (PM) of these polarized epithelial cells is divided into the apical and basolateral domains, each with distinct protein compositions. Appropriate protein transport via endocytic recycling is of great importance in establishing and maintaining epithelial polarity. The protein transport toward the apical membrane, apical recycling, has recently been shown to mediate lumen initiation and expansion during organogenesis. Recent work suggests that the formation, transport and docking (to PM) of the apical cargo-containing endocytic vesicles play a key role during the initiation of the apical lumen. However, the molecular mechanisms regulating apical lumen formation remain to be fully understood. In this study we demonstrated that the Rab11-binding protein, FIP5, mediates apical recycling via sequential binding of the Rab11/FIP5 complex to various endocytic transport proteins, including sorting nexin 18 (SNX18) and Kinesin-2. We further investigated the interactions between SNX18, Kinesin-2 and FIP5 by in vitro binding assays and have shown that SNX18 and Kinesin-2 forms mutually exclusive complexes with FIP5. We also used a combination of shRNA knockdown technique and 3D tissue culture assays to study how FIP5 and Kinesin-2 regulate lumen formation. We visualized the stepwise process of lumen initiation by live cell imaging. Thus, we propose that the Rab11/FIP5 complex acts as a scaffold for the sequential recruiting of the effector proteins to mediate the delivery of the apical proteins during the initiation of the apical lumen.

1301

Ankyrin-G Mediates a Conserved yet Versatile Pathway for Assembly of Specialized Membrane Domains in Epithelial Cells and Neurons.

P. M. Jenkins[1], K. R. Nilsson[1], C. Vasavda[1], J. Q. Davis[1], V. Bennett[1]; [1]Cell Biology, HHMI/Duke University Medical Center, Durham, NC

Epithelial lateral membranes and axon initial segments (AIS) represent physiologically important sites that host a number of structurally distinct proteins. It has long been hypothesized that a conserved core polarity pathway is shared between epithelial cells and neurons. While an epithelial-specific AP1B pathway has been identified, a common molecular mechanism remains elusive. Here we examine how ankyrin-G (AnkG) controls the polarized localization of E-cadherin and neurofascin to the epithelial lateral membrane and AIS, respectively. AnkG controls polarity in these very different cell types through binding to independently-evolved unstructured peptides in the cytoplasmic domains of its membrane partners. Interestingly, although the membrane-binding domain of AnkG is responsible for these interactions, there is a large range of binding affinities, with a direct high affinity binding to neurofascin and a tenfold lower binding affinity for E-cadherin. We show that the AnkG-binding-deficient mutants of E-cadherin and neurofascin are mislocalized to the apical membrane in epithelial cells, while mutant neurofascin is misdirected to both the axon and dendrite in hippocampal neurons. Stowe

and colleagues proposed that a dileucine motif within E-cadherin is responsible for interactions with the clathrin pathway. Interestingly, this dileucine motif is located in the putative AnkG binding site suggesting that epithelial cells have evolved a pathway by which these unstructured peptides sites can "moonlight" to further enhance polarity. Expression of the AnkG binding-deficient E-cadherin in clathrin shRNA MDCK cells demonstrates a worsened apical localization, showing that AnkG and clathrin cooperate in epithelial cells. In contrast, silencing of clathrin heavy chain in neurons has no effect on neurofascin localization to the AIS, demonstrating the epithelial specificity of the clathrin component of the polarity pathway. Finally, we show that the mechanism by which AnkG controls polarity is at least in part due to retention within the membrane and tethering to the spectrin-based membrane skeleton. This is based on increased E-cadherin mobility within the membrane upon expression of an inducible dominant-negative consisting of the AnkG binding site from beta 2 spectrin. These studies show that AnkG is the central component of a conserved yet versatile core pathway for the formation of specialized membrane domains in neurons and epithelial cells, and perhaps other polarized cells.

1302

Role of Uroplakins in Kidney Development.

S. Mitra[1], G. Ruiz[1], C. Cosentino[2], S. Sanker[3], L. Traub[3], N. Hukriede[2], G. Apodaca[1];
[1]Department of Medicine, University of Pittsburgh, Pittsburgh, PA, [2]Department of Developmental Biology, University of pittsburgh, [3]Department of Cell Biology and Physiology, University of Pittsburgh

Mammalian Uroplakin3a (UPK3a) is a transmembrane protein expressed on the apical plasma membrane of umbrella cells lining the uroepithelium of kidney and bladder. Genetic defects in UPK3a cause altered kidney development and function, but the mechanism(s) involved remain elusive. To understand the role of UPK3a in these events, we analyzed its expression and function in the zebrafish kidney (pronephros), whose organogenesis mimics that of the early mammalian kidney. Earlier studies showed that the zebrafish genome encodes UPK3l, an ortholog of the mammalian UPK3a. We confirmed the expression of UPK3l mRNA by RT-PCR and western blotting. Further, *in situ* hybridization (ISH) showed its expression in pronephric tubules (PT) and ducts and Immunocytochemical analysis revealed its localization at the apical surface of PT epithelial cells. UPK3l-knockdown using an UPK3l-morpholino (MO) led to the development of pericardial edema in zebrafish embryos 2.5-day post fertilization (dpf), which was rescued upon expression of a MO-resistant variant. The morphants expressed Pax2.1, an early developmental marker, and formed tubules positive for the adherens junction-associated protein Cdh-17, indicating that early pronephros development is not obviously altered. Also, ISH analysis of relevant markers showed that glomerular development and PT segmentation is not altered significantly. However, morphants were unable to effectively clear injected dextran, indicating a defect in pronephric clearance. Moreover, morphants showed apical mislocalization of Na^+/K^+-ATPase suggestive of an altered polarity of the PT epithelial cells. Immunofluorecence and electron microscopic analysis also revealed an alteration in the structure of cilia and microvilli lining the PT epithelial cells in morphants. Our studies indicate that UPK3l is a key regulator of PT structural and functional integrity. Further, we identified that the cytosolic domain of UPK3l harbors the key functional residues suggesting that it may regulate signaling events crucial for its function.

1303

Mitochondrial fusion regulates hepatocyte polarization.

D. Fu[1], K. Mitra[2], P. Sengupta[1], J. Lippincott-Schwartz[1], I. Arias[2]; [1]NICHD, National Institutes of Health, Bethesda, MD, [2]NHLBI, National Institutes of Health, Bethesda, MD

We previously demonstrated that activation of AMPK, the cells' metabolic sensor which increases ATP production, is required for polarization of rat hepatocytes in collagen sandwich cultures (Fu D. et al, J Cell Sci 2010, PNAS 2011). Mitra et al, (PNAS, 2009) proposed that mitochondrial fusion enhances ATP production and metabolic efficiency. Therefore, we used similar cell biologic and immunologic methods to investigate the relation between mitochondrial fusion and function, and hepatocyte polarization.

Sequential live cells imaging of mitochondria (mitotracker green) and immunofluorescent staining of mitochondrial Tom20 revealed that day 1 hepatocytes were not polarized, and almost all mitochondria were small and not fused. Polarization and mitochondrial fusion progressively developed in parallel (days 2-6). By day 4-5, most mitochondria were fused and formed tubular structures. In Western blots sequentially performed during polarization, mitochondrial fusion proteins, Mfn1 and 2, selectively increased; fission-facilitating protein Drp-1 was not specifically activated, and structural proteins, Tom20, Hsp60 and Cox IV, were unchanged. Mitochondrial potential and ATP levels progressively increased (2 and 3 fold, respectively) during polarization. FCCP inhibited polarization, and decreased ATP production and mitochondrial potential by ~50%. Mitochondrial fission inhibitor, MDIVI1, did not affect mitochondrial morphology or hepatocyte polarization.

This study reveals that mitochondrial fusion is associated with AMPK activation, increased mitochondrial ATP production and membrane potential during hepatocyte polarization as manifested by bile canalicular network formation. Our results suggest that mitochondrial fusion may be an important determinant of energy production and polarization. Mitochondria may thus be a potential therapeutic target in inheritable and acquired diseases affecting hepatocyte polarization.

1304

Nematode Sperm Secrete Serpin to Coordinate both Sperm Motility and Sperm Competition.

Y. Zhao[1], W. Sun[1], X. Ma[1], Y. Shang[1], Y. Hu[1], F. Meng[1], L. Miao[1]; [1]Institute of Biophysics, Chinese Academy Sciences, Beijing, China

Sperm competition has been widely recognized as one of most potent driving forces in the evolution, studies on sperm competition mechanisms have been focused on some physical traits of sperm and on seminal fluid produced by several accessory glands in the male body. Completion of secretory events in sperm and subsequent release of sperm components are required for reproductive success in most animal species, however, whether these released components are involved in sperm competition remains unknown. Here we identified a Serpin family protein (As_SRP-1) that is secreted from spermatids during nematode Ascaris suum spermiogenesis (or sperm activation) and showed that As_SRP-1 coordinates both spermatozoon motility and sperm competition. First, As_SRP-1 functions in cis to support Major Sperm Protein (MSP)-based cytoskeletal assembly in the spermatid that releases it, thereby facilitating sperm motility and enhancing the competitiveness of the resulting spermatozoon. Second, As_SRP-1 released from an activated sperm inhibits, in trans, the activation of surrounding spermatids by blocking vas deferens secreted As_TRY-5, a trypsin-like serine protease necessary for sperm activation. These findings suggest that sperm play an active role

in sperm competition and that sperm activation and sperm competition are mechanistically connected in nematodes. Given the fact that the exocytosis of essential components in sperm vesicle(s) is necessary to create fertilization-competent sperm in many animals, sperm-secreted components might mediate sperm competition more widely among animals than was previously appreciated.

Functional Genomics of Cell Regeneration in the Giant Ciliate *Stentor coeruleus*.

M. Slabodnick[1], W. Marshall[1]; [1]Univ California-San Francisco, San Francisco, CA

The mechanisms that specify cell shape and organization are not currently understood. Ciliates provide ideal model systems to tackle problems of cell morphology due to their complex cell organization and unique patterning. With current advances in technology along with work done in *Paramecium tetraurelia* and *Tetrahymena thermophila*, it is now possible to apply these tools to studying other organisms. *Stentor coeruleus* is a large, ~1mm long, single cell with a highly patterned cell cortex and the ability to regenerate and reorganize after surgical or chemical manipulations. The ease of surgical manipulations gives *Stentor* significant advantages over other ciliate models. Using the surgical techniques unique to *Stentor* as well as modern RNA interference (RNAi) methods, visualization techniques, and genomic sequencing I will revive *Stentor* as a model for studying cell polarity and organization. With the current state of Next Generation Sequencing it has become feasible for a lab to sequence the genome of a Eukaryotic organism. We have begun our own sequencing effort for *Stentor*'s macronuclear genome in order to facilitate the development of a better experimental toolbox. We have been able to repeat many of the surgical experiments performed by Vance Tartar, Noël de Terra and others. Using data obtained from preliminary sequences I constructed RNAi vectors that target endogenous *Stentor* genes and here I provide evidence that methodology developed for other ciliates can function in *Stentor* as well. Results for RNAi of Alpha-Tubulin and Mob1 result in dramatic changes in cell polarity and organization of the cortex and provide strong evidence that studies in *Stentor* can yield exciting and useful results. Knocking down Alpha-Tubulin, a key structural component in the cortex, results in clear cortical defects and problems with cell regeneration. This is very different from the Mob1 knockdown, which results in the drastic elongation of cells and other cortical aberrations. Using RNAi in conjunction with the unique microsurgical methods available in *Stentor*, it should be possible to restore this classical system to its previous status as a central model for addressing many important questions, including centriole structure, cell polarity, biological pattern formation, and cellular regeneration.

1306

Dynamic compartmentalization of SCAR/WAVE signaling scaffolds and active pools of ARP2/3 during polarized growth.

C. Zhang[1], R. Stahelin[2], E. Mallery[1], L. Samuels[3], D. Szymanski[1]; [1]Department of Agronomy, Purdue University, West Lafayette, IN, [2]Department of Chemistry and Biochemistry, University of Notre Dame, South Bend, IN, [3]Department of Botany, University of British Columbia, Vancouver, BC, Canada

In plants, the epidermis is a biomechanical shell, the growth of which can affect the behavior of underlying cell layers and the overall architectural properties of the leaf. Understanding the genetic and molecular basis of its morphogenesis is an important problem in basic research and applied plant science. Arabidopsis pavement cell and trichome morphology mutants continue to identify new genes and biochemical pathways that affect the growth process; however, it is unclear how these complicated networks of proteins interact with the endomembrane and cytoskeletal systems to initiate and maintain polarized growth. The Rac/ROP small GTPase

exchange factor SPIKE1 and an actin based growth control system defined by the "distorted" mutants is a perfect example. Genetic and biochemical analyses provide a logic model for information flow from the formation of a Rac/ROP activation scaffold through a series of heteromeric protein complexes (WAVE/SCAR and ARP2/3) that generate an actin filament nucleation response. The cellular deployment of the pathway is unknown, but commonly believed to occur at specialized cortical domains. Contrary to this notion, our most recent results suggest that abundant subdomains of the ER termed ER exit sites (ERES) serve as a distributed network of SPK1-ROP activation sites. We describe recent live cell imaging, genetic, and biochemical analyses indicating that SPIKE1 signals diverge from ERES to control distinct trafficking and cytoskeletal activities. We will discuss how signal generation and cytoskeletal responses are compartmentalized and how this unexpected cellular deployment might regulate the cytoskeleton and morphogenesis at the spatial scale of a cell.

1307

Polarization and traffic of cell wall building enzymes in the filamentous fungus Neurospora crassa.

M. Riquelme[1], E. Sanchez-Leon[1], R. Fajardo-Somera[1], J. Verdin[1]; [1]Microbiology, Center for Scientific Research and Higher Education of Ensenada CICESE, Ensenada, Mexico

Apical growth in filamentous fungi is supported by the constitutive exocytosis of secretory vesicles, which maintain the normal complement of plasma membrane proteins and lipids through "full fusion" and provide the necessary enzymes and building-blocks for cell wall synthesis. Our main interest is to identify the cargo of the different populations of vesicles presumably reaching the cell tip and to analyze their traffic during polarized growth in the filamentous fungus Neurospora crassa. Using chromosomal fluorescent tagging of candidate proteins, we found that vesicles containing cell-wall building enzymes accumulate temporarily in an apical body, the Spitzenkorper (Spk), in a stratified manner. Four out of the seven chitin synthases present in N. crassa, localized at the core of the Spk, in microvesicles. In contrast, a glucan synthase related protein localized in macrovesicles in the Spk periphery. These vesicles are distributed from the Spk outwards until reaching the plasma membrane, where they are tethered presumably by an exocyst-mediated process. The exocyst components SEC-8, Exo-70 and EXO-84 accumulated in N. crassa surrounding the frontal part of the Spk, whereas SEC-3, -5, -6, and -15 were found in a delimited region of the apical plasma membrane, which correlates with the zone of maximum exocytosis predicted earlier by the Vesicle Supply Center model for hyphal morphogenesis.

1308

Quantitative analysis of organelle distribution and dynamics in Physcomitrella patens protonemal cells: new insights in tip growth.

F. Furt[1], K. Lemoi[2], E. Tüzel[2], L. Vidali[1]; [1]Biology and Biotechnology, WPI, Worcester, MA, [2]Physics, WPI, Worcester, MA

In the last decade, the moss Physcomitrella patens has emerged as a powerful plant model system, amenable for genetic manipulations not possible in any other plant. This moss is particularly well suited for plant polarized cell growth studies, as in its protonemal phase, expansion is restricted to the tip of its cells. Based on pollen tube and root hair studies, it is well known that tip growth requires active secretion and high polarization of the cellular components. However such information is still missing in Physcomitrella patens. To gain insight into the mechanisms underlying the participation of organelle organization in tip growth, it is essential to determine the distribution and the dynamics of the organelles in moss cells. Here, we used fluorescent protein fusions to visualize and track Golgi stacks, mitochondria, and peroxisomes in

live protonemal cells. We also visualized and tracked chloroplasts based on chlorophyll auto-fluorescence. We showed that all four organelles are gradually distributed in protonemata from the tip of the apical cell to the base of the sub-apical cell. For example, the number of Golgi dictyosomes is 4.7 and 3.4 times higher at the tip than at the base in caulonemata and chloronemata respectively. While Golgi stacks are concentrated at the extreme tip of the caulonemal cells, chloroplasts and peroxisomes are totally excluded. However, such compartmentalization was not observed in chloronemata. Interestingly, caulonemal cells, which grow faster than chloronemal cells, also contain significantly more Golgi stacks and less chloroplasts than chloronemal cells. Moreover, the motility analysis revealed that organelles in protonemata move with low persistency and instantaneous velocities ranging from 29 to 75 nm/sec, which are at least three orders of magnitude slower than those of pollen tube or root hair organelles. This study reports the first quantitative analysis of organelles in Physcomitrella patens and by comparing the distribution and dynamics of organelles from different tip growing plant cells, may help better understand the mechanisms of plant polarized cell growth.

1309

Structurally and Functionally Mimicked Three-dimensional Hepatic Structure in vitro.

K. Kim[1], K. Ohashi[1], R. Utoh[1], T. Okano[1]; [1]Institute of Advanced Biomedical Engineering and Science, Tokyo Women's Medical University (TWIns), Tokyo, Japan

Introduction

Hepatocyte-based tissue engineering has been considered as an attractive possibility for treatmenting metabolic disorder and liver injury. However, hepatocytes are known to lose their functions within several days under monolayer culture conditions. Effective hepatocytes culture systems, which allow hepatocytes to preserve their morphologies and functions for a long-term, need to be established. The present study created a triple-layered structure mimicking hepatic cord in vivo structurally by stratifying monolayer hepatocyte sheets and other types cell sheets (3T3 cell and endothelial cell) using a cell-sheet technology for preserving hepatic functions and morphologies for a long-term. Functional and morphological analyses of the triple-layered co-culture were performed, and the results were compared with those of mono- and double-layered homotypic hepatocyte sheets.

Materials and Methods

Hepatocytes were isolated from the livers of six-week-old rats. Isolated hepatocytes were cultured on 35-mm temperature responsive culture dishes (TRCDs) for forming monolayer hepatocyte cell sheets. After 4 days culturing, a monolithic hepatocyte sheet (Hep) was harvested from TRCD at 20? and sandwiched with two endothelial cell sheets (EC, bovine endothelial cell) or 3T3 cell sheets (3T3, mouse embryonic fibroblast cell line) on a culture insert by a fibrin gel-coated manipulator.

Results

Triple-layered hepatic structures (EC-Hep-EC and 3T3-Hep-3T3) were successfully created, and their albumin secreting functions and cytochrome P450 (CYP) activities related with drug metabolism were investigated. Albumin secretion levels of homotypic co-cultured mono- and double-layered hepatocyte sheets showed a steep decline. In contrast, triple-layered heterotypic hepatic structures (EC-Hep-EC and 3T3-Hep-3T3) were found to preserve albumin secretion levels until 20 days. Especially, the albumin secretion level of 3T3-Hep-3T3 was higher than those of EC-Hep-EC and monolayer hepatocytes (Hep). Furthermore, CYP3A induction assay by pregnenolone-16a-carbonitrile known as CYP3A inducer showed that CYP activities of 3T3-Hep-3T3 and EC-Hep-EC were 3.3- and 2-fold increases compared with that of monolayer hepatocyte, respectively.

Conclusions

This study succeeded in creating a triple-layered structure that structurally resembles the microstructure of the liver by stratifying hepatocyte and other type cell sheets (ECs and 3T3 cells). Hepatic functions such as albumin secretion and CYP activities were highly preserved for a long-term in the present triple-layered co-culture system. These results demonstrate the cell sheet-based 3-D culture system was a potentially valuable method to create useful assessment tools for drug screening and a valuable tissue source for liver tissue engineering.

Embryogenesis

1310

Formation of early axon tracts in the embryonic vertebrate brain.

M. Ware[1], F. Schubert[2]; [1]Developmental Neurobiology, St Jude Children's Res Hosp, Memphis, TN, [2]Biological Sciences, University of Portsmouth, Portsmouth, United Kingdom

Initial nerve connections in the vertebrate brain form an array of longitudinal tracts, transversal tracts and commissures, from clusters of neurones. These tracts will act as a scaffold for later, follower axons that allow more complex connections to be set up in the brain. The early axon scaffold has been identified in a number of species, and many of the tracts appear remarkably conserved between all vertebrates analysed. However, a direct comparison of early tracts between different species is lacking, and many of the tracts are poorly characterised. By using a range of pan-neural antibodies the early axon scaffold was mapped in cat shark, *Xenopus*, chick and mouse embryos. The aim was to provide a comparative description of early neurones and their tracts in the embryonic vertebrate brain. This has provided insight into the evolution of the embryonic brain architecture and is critical for the interpretation of early neuronal phenotypes in gain- and loss-of-function studies. The longitudinal tracts, the MLF and TPOC and transversal tract TPC are highly conserved in all these vertebrates. The MLF forms first in the cat shark, *Xenopus* and chick brains, however the DTmesV forms first in mouse brain. The genes involved in specification of neurones to an MLF fate are unknown; microarray analysis was used to identify candidate genes with a possible role in MLF neurone specification in the embryonic chick brain. Once the neurones have differentiated, the axons then need to project along the correct path. The role of Netrin1 and Netrin2 in the guidance of axon tracts within the early axon scaffold have been investigated using expression constructs in gain-of-function experiments. This led to a reduction or loss of the TPC in the embryonic chick brain.

1311

TULP3 is an effector of the IFT-A complex in regulating neural tube morphogenesis.

S. Mukhopadhyay[1], X. Wen[2], W. Lane[3], S. Scales[2], P. Jackson[1]; [1]Cell Regulation, Genentech Inc., So San Francisco, CA, [2]Molecular Biology, Genentech Inc., [3]Harvard Microchemistry Facility, Harvard University

Tissues are built through an orchestrated process of morphogenesis coordinated by morphogen gradients, which prime distinct zones of cellular differentiation; for example, sonic hedgehog (Hh) gradients regulate patterning of the neural tube. Primary cilia and intraflagellar transport (IFT), an ancient conserved trafficking mechanism within the cilia, are fundamentally important in vertebrate Hh-mediated signaling. The tubby-like proteins (Tulps) comprise of a family of poorly understood proteins with roles in neural development and function. Mutants in tubby-like protein 3 (Tulp3) and IFT-A complex (implicated in retrograde IFT within the cilia) show over-activation of the Hh pathway in the neural tube. However, mice carrying mutations in the retrograde IFT motor dynein 2 show reduced Hh signaling in the neural tube. This suggests that IFT-A may be modulating other processes in addition to retrograde IFT during neural tube

differentiation. While generating the tubby family interactome using tandem affinity purification and high-confidence mass spectrometry-based proteomics, we were surprised to discover that specific tubby family proteins, notably TULP3, bind to the IFT-A complex. Furthermore, systematic depletion of the IFT-A subunits using RNA interference suggested that a "core" IFT-A sub-complex comprising of WDR19, IFT140, and IFT122, associates with TULP3. Surprisingly, in addition to its known role in retrograde IFT, the "core" IFT-A sub-complex also functions in providing ciliary access to TULP3. What does TULP3 and IFT-A do in this second role? We find that TULP3 and IFT-A promote ciliary trafficking of a subset of rhodopsin-family G protein-coupled receptors (GPCRs) in a wide variety of cells. Both IFT-A and membrane phosphoinositide binding properties of TULP3 are required for ciliary GPCR localization. Notably, Tulp3 does not affect the ciliary trafficking of the frizzled-family GPCR Smoothened (Smo) raising the possibility that an additional GPCR regulates neural tube patterning. We are characterizing knockouts of candidate GPCRs, and have generated a detailed IFT-A-Tulp3 proteomic network in order to discover key players in neural tube differentiation. To conclude, the Tulp3-IFT-A protein interaction network is a major regulator of neural tube patterning, and provides us with important insights into its morphogenesis.

1312

The expression and characterization of cysteine sulfinic acid decarboxylase during zebrafish embryogenesis.

Y-C. Chang[1], M-F. Huang[2], H-T. Chang[2], S-T. Ding[1,3], I-H. Liu[1,4];[1]Department of Animal Science and Technology, National Taiwan University, Taipei, Taiwan, [2]Department of Chemistry, National Taiwan University, Taipei, Taiwan, [3]Institute of Biotechnology, National Taiwan University, Taipei, Taiwan, [4]Research Center for Developmental Biology and Regenerative Medicine, National Taiwan University, Taipei, Taiwan

Cysteine sulfinic acid decarboxylase (CSAD) is the rate-limiting enzyme in the biosynthesis of taurine. There are numbers of physiological roles of taurine such as bile salt synthesis, osmoregulation, lipid metabolism and oxidative stress inhibition. To investigate the roles of de novo synthesis of taurine during embryonic development, zebrafish CSAD was cloned and the cDNA encodes for a protein of 482 amino acids with its sequence highly homologous to mammalian CSAD and conserved throughout evolution. Semi-quantitative RT-PCR detected CSAD mRNA as early as 0 hours post fertilization (hpf) indicating the existence of maternal CSAD message. Whole-mount in situ hybridization demonstrated that CSAD was expressed in yolk syncytial layer and various mesoderm tissues such as pronephric duct, notochord and cardiogenic field during early embryogenesis. Knockdown of CSAD by morpholino oligos (MOs) reduced taurine level in embryos dramatically. The CSAD morphants showed increased early mortality, elevated cell death in cardiogenic region and tail, pericardial edema and malformation of tail. mRNA coinjection and taurine supplementation rescued the mortality and cardiac phenotypes in CSAD morphants suggesting that the heart malformation in CSAD morphants was due to taurine deficiency via de novo synthesis pathway. Our findings indicated that de novo synthesis pathway via CSAD plays critical role in taurine acquisition in zebrafish early embryos and taurine plays a role in zebrafish cardiac development.

Akt1 regulates Hox gene expression in mouse embryonic fibroblast.

K-A. Kong[1], H. Yoon[1], J-Y. Lee[1], M. Kim[1]; [1]Anatomy, Embryology Lab., Yonsei Univ Coll Med, Seoul, Korea

In mammals, precise spatiotemporal expressions of Hox genes control body pattern and provide positional information along the body axis during embryogenesis. However, the mechanism by

which Hox genes are regulated is poorly understood. To search for novel regulators of Hox genes, we analyzed the archived gene expression profiles from the Gene Expression Omnibus (GEO) database. In a particular dataset, clustered Hox gene expressions were largely altered in Akt1-/- mouse embryonic fibroblasts (MEFs) compared to the wild type, suggesting a hypothesis that Akt1 is required for proper expression of the Hox genes during mouse embryonic development. We therefore examined all 39 Hox gene expressions using quantitative RT-PCR and found that the transcripts of 5¡Ç Hoxc genes, Hoxc10, 11, 12 and 13 including a noncoding RNA, were upregulated in Akt1 null MEFs. Particularly, the upregulation of Hoxc11 was further confirmed in the Akt1 null embryonic limbs using quantitative RT-PCR and in situ hybridization. Finally, epigenetic modifications correlated with active transcription, such as DNA hypomethylation at promoter regions and increased acetylation of histone H3K9, underlied the upregulation of Hoxc11 and 12 in Akt1 null MEFs. These results suggest that Akt1 is necessary for epigenetic regulation of a group of Hox genes during embryogenesis.

Robo-Slit Pathway: Molecular Gatekeeper for Corneal Nerves during Embryonic Eye Development.

T. Schwend[1], P. Y. Lwigale[2], G. W. Conrad[1]; [1]Kansas State University, Manhattan, KS, [2]Rice University

PURPOSE: During avian cornea development, trigeminal nerves reach the cornea margin at embryonic day (E)5 where they are initially repelled for days, instead encircling the cornea's periphery in a nerve ring. The molecular events coordinating nerve guidance during cornea development are poorly understood. Here we evaluated a potential role for the Robo-Slit nerve guidance family.

METHODS: mRNA expression for *Slit 1-3* and their cognate *Robo1* receptor was examined in E5-10 corneas, lens and trigeminal ganglions (TG) by RT-PCR or *in situ* hybridization. TG explants (a source of neurons) were co-cultured adjacent to lens vesicles or corneas which secrete nerve guidance molecules, in the presence or absence of inhibitory Robo1-Fc proteins, and neurite guidance assessed.

RESULTS: *Slit 1-3* expression in the cornea and lens persisted during all stages of cornea innervation examined. *Robo1* expression was developmentally regulated in TG cell bodies, expressed robustly during nerve ring formation then later declining concurrent with projection of growth cones into the cornea. In organotypic co-cultures, lens and cornea tissues strongly repelled E7 TG neurites, except in the presence of inhibitory Robo1-Fc protein. Nerve guidance of older, E10, neurons was not impacted by Robo1-Fc protein and repulsion by cornea diminished.

CONCLUSIONS: This study suggests that nerve repulsion from the cornea during nerve ring formation is mediated by lens- and cornea-derived Slit molecules and Robo receptors on trigeminal nerves. Later, a shift in nerve guidance behavior occurs, in part due to molecular changes in trigeminal neurons including *Robo1* downregulation, allowing nerves to find the *Slit*-expressing cornea permissive of growth cones.

Telescoping: characterizing a new cellular movement in gastrulation.

M. L. Martik[1], D. R. McClay[2]; [1]Genetics, Duke University, Durham, NC, [2]Biology, Duke University

Gastrulation is a complex orchestration of movements by cells that are specified early in development. Live imaging and experimental techniques allow examination of morphogenesis at the cellular level in the optically clear sea urchin embryo. Using time-lapse microscopy, our lab

has discovered a new phenomenon that we have termed “telescoping” which contributes significantly to gut elongation. During gastrulation, the cells of the endoderm lineage slide anteriorly alongside one another away from the vegetal pole. These cells move in a fashion similar to opening a telescope to elongate the gut. Until now, it was thought that lateral rearrangement of endoderm cells by convergent extension was the main contributor to gut elongation. This project characterizes the telescoping phenomenon and attempt to distinguish it from possible convergent extension movements that are coincident, or follow the initial invagination.

The objective of this project is to analyze the movements of telescoping cells and their molecular control. The sea urchin is a strong model system because of its well-studied endomesoderm gene regulatory network (GRN) that describes the cell fate specification of the future larval gut. However, the GRN does not describe specific cell biological events driving morphogenesis. Still, several molecules known to be involved in aspects of morphogenesis such as adhesion, signaling, polarity, and cytoskeletal remodeling rely on the circuitry described in the GRN for their contribution to morphogenesis. Rac1, a small RhoGTPase, is localized to the adherens junctions prior to gastrulation where it co-localizes with the adhesion molecule β-catenin. Both cytoskeletal regulators are removed from adherens junctions of the forming gut. This suggests that the absence of these molecules at cellular membranes destabilizes adherens junctions of endoderm cells not only enabling the sliding mechanism of telescoping, but also allowing the intercalation events of convergent extension while maintaining stability of the forming larval gut. Connecting the endomesoderm GRN to the morphogenetic and adhesion events of telescoping will provide a framework for characterizing this remarkable sequence of cell movements in the simplest of deuterostome models.

A Sub-circuit of the Ectoderm GRN Integrates Positional Information and Patterns the Sea Urchin Embryonic Skeleton.

D. C. McIntyre[1], D. R. McClay[2]; [1]Genetics and Genomics, Duke University, Durham, NC, [2]Biology, Duke University

The Gene Regulatory Network (GRN) driving the first 30 hours of development in the sea urchin is at an advanced state of understanding. It effectively explains how most tissues in the embryo are specified, and it has been used to identify a variety of evolutionarily conserved regulatory modules. Yet the current GRN is not sufficient to explain how the complex morphological patterns present in the developing embryo arise. In particular, the pattering of the embryonic skeleton is not explained, even though the specification of the mesenchyme cells which produce it is one of the best understood GRNs to date. We know that signals including VEGF, coming from a few ectodermal cells bordering the endoderm, communicate this patterning information to the mesenchymal cells that will produce the calcium based skeleton. Yet these signals are a final messenger, the end result of a process which identifies the site of skeleton formation from a thin band of ectodermal cells neighboring the endoderm. We call this region the border ectoderm. To understand this process we identified a group of transcription factors expressed in the border ectoderm. These include IrxA, Nk1, FoxJ1, Msx, and Lim1. Perturbations showed however that while the D-V axis is needed to restrict the expression of these border ectoderm genes, the activation of these genes must originate elsewhere. This led us to hypothesize that the border ectoderm is activated by a signal from neighboring cells, most likely in the endoderm. Several lines of evidence support this hypothesis. Finally, perturbations of genes in the border ectoderm cause defects in skeleton formation, consistent with our hypothesis that these genes partition the border ectoderm and are necessary to establish the signaling centers for skeletogenesis. We conclude that cells in the border ectoderm execute a GRN capable of

integrating positional information from the two major embryonic axes in order to establish the pattern of the embryonic skeleton.

Gap junctional transport through endoderm cells is required for LR asymmetry in mouse embryos.

R. S. Saund[1], M. Kanai-Azuma[2], Y. Kanai[3], I. Kim[4], M. Lucero[1], Y. Saijoh[1]; [1]University of Utah, Salt Lake City, UT, [2]Department of Veterinary Medicine, University of Tokyo, Japan, [3]University of Tokyo, Japan, [4]Korea Advanced Institute of Science and Technology

The development of left-right (LR) asymmetry is an integral part of the organization of the body plan. In developing mouse embryos at day 8 post fertilization, the initial asymmetric signal is generated by the leftward flow of extracellular fluid called Nodal flow, over the midline located node cells. This LR signal is transferred to the left lateral plate mesoderm (LPM) which then expresses Nodal and downstream targets Lefty2 and Pitx2, conferring left side characteristics to the LPM. An important unresolved question is the mechanism of this asymmetric signal transfer from the node at the cellular as well as molecular level. In this study, we have focused on the role of endoderm cells in the signal transfer process, which form a single epithelial layer tightly apposed to the node along the outer surface of the embryo and show elevated levels of free intracellular calcium ions after the onset of Nodal flow in the node. To specifically target the endoderm cells for study, we studied the Sox17 mouse mutants, which show defects specifically in the definitive endoderm population arising from the primitive streak. We found that the asymmetric gene expression of Nodal, Lefty2 and Pitx2 in the left LPM was absent in a majority of mutant embryos, moreover the mutants also showed randomized heart looping orientation. Functional analysis of the mutant nodes revealed that the initial asymmetric is determined and the LR signal is generated in the left side, suggesting that the LR defect of the Sox17 mutants is most likely due to absent or reduced signal transfer from the node. To uncover the mechanisms by which endoderm cells may relay the asymmetric signal from the node, we analysed the properties in endoderm differentiation in the Sox17 mutants. Most significantly, we found that the mutant endoderm cells failed to localize Connexin43 to the cell membrane and showed highly reduced gap-junction permeability assayed by dye iontophoresis. Although the endoderm cells labelled by a Sox17-GFP knock-in construct formed a surface epithelial sheet as evidenced by ZO1 immunohistochemistry, they were also found interspersed in the underlying mesoderm cells, suggesting delamination due to loss of epithelial polarity. Disorganized adherens junctions, abnormal microtubule assembly and actin polarization suggest possible causes for defective gap-junction assembly in the mutants. These studies have led to novel insights into the LR development process and will be useful to identify the molecules that pass through gap–junctions to relay the asymmetric LR signal to the left LPM.

Cell Fate Determination

Wnt signaling through Lef1 regulates mechanosensory organ progenitor cell identity in the zebrafish.

H. McGraw[1], C. Drerup[1], M. Culbertson[1], T. Linbo[2], D. Raible[2], A. Nechiporuk[1]; [1]Cell and Developmental Biology, Oregon Health & Science University, Portland, OR, [2]Biological Structure, University of Washington

The formation of the zebrafish posterior lateral line (pLL) provides an excellent model in which to study the role of progenitor cell behavior during organogesis. The pLL is a mechanosensory system comprised of discrete sensory organs called neuromasts (NMs) that are stereotypically arrayed along the trunk of the fish. The pLL NMs are derived from a pLL primordium (pLLp), a group of ~100 migratory cells that are organized into 2-3 polarized rosettes called proto-NMs. During migration, NMs are formed in a cyclical fashion: after a proto-NM is deposited from the trailing region of the primordium and a new proto-NM forms from proliferating progenitor cells in the leading region. Wnt signaling is active in the leading zone of the pLLp and global Wnt inactivation leads to a failure of the pLLp patterning, migration and NM deposition. However, the exact cellular events that are regulated by the Wnt pathway are not known. We identified a mutant strain, *lef1^{nl2}*, which contains a lesion in the canonical Wnt effector gene *lef1*. *lef1^{nl2}*mutants invariably lack terminal NMs and live imaging revealed that proto-NM renewal fails during later stages of pLLp migration. The overall pLLp patterning, as assayed by the expression of various markers, was not altered in *lef1^{nl2}* mutants. Lineage tracing and mosaic analyses revealed that the presumptive progenitors move out of the pLLp and are incorporated into NMs; this results in a decrease in the number of proliferating progenitor cells and an eventual pLLp disorganization. We concluded that Lef1 function is not required for the initial pLLp organization or migration, but is necessary for regulating the behavior of progenitor cells that contribute to proto-NM renewal during later stages of pLL formation. These findings revealed novel a role for canonical Wnt signaling during the formation of the pLL in the zebrafish and may shed light on mechanism for progenitor cell regulation in other organ systems.

Transcriptome Transfer Generates tCardiomyocyte a Model for Understanding the Phenotype of Cardiomyocytes.

T. K. Kim[1], J-Y. Sul[1], N. Peternko[2], M. Lee[3], J. H. Lee[1], V. Patel[2], J. Kim[3,4], J. Eberwine[1,4]; [1]Pharmacology, University of Pennsylvania, Philadelphia, PA, [2]Penn Cardiovascular Institute and Division of Cardiovascular Medicine, University of Pennsylvania, [3]Biology, University of Pennsylvania, [4]Penn Genome Frontiers Institute, University of Pennsylvania

Cardiomyocytes are among the most sought after cells in regenerative medicine because they may help to repair an injured heart by replacing lost tissue. Functional cardiomyocyte-like cells have been induced from embryonic stem cells (ESCs), induced from pluripotent stem cells (iPSCs) and generated from direct conversion of fibroblast using defined transcription factor transduction but the induced cardiomyocytes often develop undesired phenotypes such as carcinogenesis or early senescence. In order to generate a model for understanding the phenotype of cardiomyocytes, we used TIPeR (Transcriptome Transfer Induced Phenotype Remodeling) methodology that we have developed in this lab. Our methodological approache was to transfect primary mouse embryonic fibroblast with poly-A+ RNA isolated from wild type adult mouse ventricular myocytes, assess the expression of cardiac antigenic markers, analyze expression profiles of single cells and perform patch-clamp recordings on putative

tCardiomyocytes using whole-cell patch recordings. We also transfected primary mouse cortical astrocyte with poly-A+ RNA from ventricular myocytes to test the dependency of transdifferentiation on initial cell type. Transcriptome-effected cardiomyocytes (tCardiomyocytes) from fibroblasts and astrocytes display morphologies, immunocytochemical properties and expression profiles of postnatal cardiomyocytes. Those global phenotypic changes occur in a time-dependent manner and confer electro-excitability to the tCardiomyocytes. These data highlight the dominant role of the gene expression profile in developing and maintaining cellular phenotype. The Transcriptome Induced Phenotype Remodeling (TIPeR) generated tCardiomyocyte has significant implications for understanding and modulating cardiac disease development.

Investigating the role of CACN-1 in the Canonical Wnt Signaling Pathway.

M. LaBonty[1], L. Byrnes[1], E. Cram[1]; [1]Northeastern University, Boston, MA

Development of the *C. elegans* gonad is an excellent eukaryotic system in which to study cell specification, differentiation, and migration *in vivo.* CACN-1, the novel and highly conserved *C. elegans* homolog of Cactin, is expressed in a number of tissues, including the somatic gonad. Our project aims to characterize the role of CACN-1 in the canonical Wnt signaling pathway, one of the signaling cascades responsible for setting up proper cell identities in the somatic gonad. Using an integrated strain of *C. elegans* containing POPTOP, a TOPFLASH-like reporter, we can measure changes in the activity of the downstream Wnt signaling component, TCF/LEF, *in vivo*. Knockdown of *cacn-1* by RNA interference in POPTOP-containing worms causes a dramatic increase in POPTOP expression levels, and this increase is dependent on POP-1, the single worm TCF/LEF homolog. Other TCF/LEF-related processes including determination of embryonic cell polarity, endoderm specification and seam cell specification also require CACN-1 for proper execution. Our data provides support for the hypothesis that CACN-1 acts in the canonical Wnt/beta catenin pathway as a TCF/LEF repressor. Further experiments will explore the effect of CACN-1 on other components of the canonical Wnt signaling pathway and may help reveal its role in eukaryotic development.

1321

Regulation of endothelial cell differentiation by Prx1 during embryonic development.

K. Ihida-Stansbury[1,2], T. Ito[3], N. Aiad[2], T. Yamazaki[3], Y. Yoshimatsu[3], K. Miyazono[3], T. Watabe[3]; [1]Pathology & Laboratory Medicine, University of Pennsylvania, Philadelphia, PA, [2]Institute for Medicine & Engineering, University of Pennsylvania, Philadelphia, PA, [3]Molecular Pathology, University of Tokyo, Japan

Homeobox genes encode highly conserved transcription factors that control tissue patterning and morphogenesis throughout development, yet relatively little is known about their roles in lung vascular development. Previously, we have shown that paired related homeobox gene transcription factor Prx1 is expressed in and around the developing lung vessels and plays a key role in vessel maturation. However, whether Prx1 plays a role on endothelial cell specification (i.e. arterial, venous and lymphatic endothelial cell) during lung vessel functional maturation is unknown. In this study, we examined blood vessel, undifferentiated and lymphatic vessel endothelial cell marker expression (CD31, Lyve1 and Prox1 respectively) in embryo lungs from Prx1-null and wild type mice. At E14.5d, lung immunostainings showed that the number of Lyve1 positive endothelial cells was higher in Prx1-null lungs while the number of CD31 positive endothelial cells was lower as well as highly co-localized with Lyve1 positive undifferentiated endothelial cells. In contrast, wild type lungs expressed higher CD31 positive endothelial cells than Lyve1 positive cells. In parallel to immunostaining results, real time PCR

showed that mRNA expression of Prox1, which is essential for lymphatic vessel differentiation, was two-fold higher in Prx1-null lungs than wild type. Downstream of Prox1, VEGFR3 and Lyve1 mRNA expressions were also up-regulated in Prx1-null lungs compare to wild type. These results indicate that Prx1-null lungs have more uncommitted endothelial cells in developing vessels compare to wild type. Furthermore, gain-of-function studies at the cellular level demonstrated that overexpression of Prx1 gene down-regulated the mRNA expression of Prox1 and VEGFR3 in human umbilical vein endothelial cells and lymphatic endothelial cells. We suggest that Prx1 may interact with Prox1 and regulate blood vessel endothelial cell specification and functional vessel development in the embryonic lung.

1322

AuroraA regulates the endocytic activity of Numb.

M. Cotton[1], Y. Rannou[1], G. LeDez[1], C. Prigent[1], R. LeBorgne[1]; [1]CNRS UMR6061 Univ Rennes1, Rennes, France

During asymmetric cell division of Drosophila Sensory Organ Precursor (SOP), the cell fate determinant Numb localizes at the anterior cortex and is unequally inherited by the anterior daughter cell. In this cell, Numb negatively regulates Notch signalling at least in part by promoting the internalisation of the four pass transmembrane protein Sanpodo (Spdo), a Notch-binding partner essential for Notch activation in asymmetrically dividing cell. The anterior cell adopts the pIIb cell identity. Notch is activated in the posterior cell that adopts the pIIa identity. The Ser/Thr kinase AurA was shown to phosphorylate PAR complex to regulate Numb asymmetric localization (Wirtz-Peitz F et al., 2008). We here report the identification of Numb in a 2-Hybrid screen using AurA as a bait. AurA phosphorylates Numb on the evolutionarily conserved Ser304 residue that falls into the AurA consensus phosphorylation site, suggesting a direct regulation of Numb localization and/or activity by AurA. Using three distinct mutant alleles of AurA that exhibits strong to complete loss of kinase activity in vitro, we confirmed that AurA is a negative regulator of Notch signaling. Using time-lapse confocal microscopy of aurA MARCM clones, we observed that mitosis lasts four-time longer than in wild-type cells and that the asymmetric localization of Numb is delayed compared to control cells. In contrast to previous reports (Berdnik and Knoblich, 2002), live imaging revealed that in prometaphase, Numb is asymmetrically localized and unequally inherited. Despite the unequal segregation of Numb, the anterior SOP daughter cell systematically adopts the pIIa fate. Thus, in the absence of AurA kinase activity, asymmetrically localized and inherited Numb fails to negatively regulate Notch activation in the anterior cell. These observations raised the possibility that AurA could control Numb endocytic activity and prompted us to analyse the localisation of Spdo. In control cells, Spdo localized in intracellular dotted compartments in cells expressing or inheriting Numb, namely during interphase and mitosis of SOP and in the anterior SOP daughter cell. In contrast, loss of AurA activity causes Spdo to localize at the plasma membrane during SOP division and in the anterior daughter cell, strongly suggesting that Numb does not longer promote Spdo endocytosis in aurA mutant cells. Numb was previously shown to bind to the clathrin endocytic adaptor AP-2 and Spdo. Coimmunoprecipitation experiments indicate that the ability of Numb to interact with Spdo and AP-2 relies on the phosphorylation of Ser304. We thus favour a model in which AurA regulates asymmetric cell division at two distinct steps. First, AurA phosphorylates PAR to control the kinetics of Numb asymmetric localization at mitosis. Second, AurA phosphorylates Numb and directly regulates Numb endocytic activity of Spdo, that ultimately regulate Notch signalling.

1323

Latent Process Genes for Cell Differentiation are Common Decoders of Neurite Extension Length.

K. Watanabe[1], Y. Akimoto[1], K. Yugi[1], S. Uda[1], J. Chung[1], S. Kuroda[1,2]; [1]Department of Biophysics and Biochemistry, Graduate School of Science, University of Tokyo, Toshima-ku, Japan, [2]Department of Computational Biology, Graduate School of Frontier Science, University of Tokyo

A latent process involving signal transduction and gene expression is needed as a preparation step for differentiation. We previously found that nerve growth factor (NGF)-induced cell differentiation has a latent process, which is dependent on ERK and gene expression and required for subsequent neurite extension. A latent process can be considered as a preparation step by decoding extracelluar stimulus information into cellular functions. However, molecular mechanisms of the latent process remain unknown. We examined the time course change of gene expression and neurite extension in response to NGF. Using the siRNA-mediated knockdown experiments, we identified *Metrnl*, *Dclk1*, and *Serpinb1a* as the latent process (LP) genes, which were induced during the latent process and required for subsequent neurite extension in PC12 cells. The LP genes showed distinct ERK dependency and were also induced during the latent process of pituitary adenylate cyclase-activating polypeptide (PACAP)- and forskolin-induced cell differentiation. Regardless of neurotrophic factors, expression levels of the LP genes during the latent process always correlated with subsequent neurite extension length. Although ERK activity was required for the expression of the LP genes and neurite extension, phosphorylation level of ERK was not correlated with neurite extension length. Considering the fact that expression of the LP genes occurred during the latent period (0-12 h) and neurite extension was induced during the extension period (12-24 h), information of neurite extension length contained in ERK is likely to be decoded into the expression levels of the LP genes before the extension process starts. Co-overexpression of all LP genes, but not that of each LP gene alone, enhanced NGF-induced neurite extension. This result suggests that all LP genes can cooperatively enhance neurite extension. Our findings provide a molecular insight and physiological meaning of the latent process as the preparation step by decoding information of future phenotypic change.

PCL Nanopillars Vs Nanofibers: A Stark Contrast in Progenitor Cell Morphology, Proliferation, and Fate Determination.

D. Berger[1], K. Popat[1,2], A. Prasad[1,3]; [1]Biomedical Engineering, Colorado State University, Fort Collins, CO, [2]Mechanical Engineering, Colorado State University, [3]Chemical and Biological Engineering, Colorado State University

Background and Objective: Plastic-adherent, fibroblast-like populations of bone marrow cells, termed multipotent mesenchymal stromal cells (MSCs), have garnered increasing attention in the tissue engineering community resulting from their ease of acquisition, ex vivo expandability, and exciting potential for tissue regeneration. Previous work with human MSC populations have shown that they are capable of differentiation in response to a variety of stimuli, including soluble cues, surface chemistry, matrix elasticity, seeding density, and cell geometry. Recently, MSCs have been demonstrated to differentiate into osteoblast-like cells without the use of bone differentiation media, by modifying the substrate nanotopography to contain nonordered nanopits or nanotubes. In this work, the role of nanotopography on the long-term response of progenitor cells is explored using polycaprolactone (PCL) nanopillar and nanofiber surfaces seeded with plastic-adherent rat MSCs.

Study Design/Materials and Methods: Electrospun PCL nanofibers and gravimetrically extruded PCL nanopillars serve as experimental surfaces to investigate progenitor cell response to nanotopography. Smooth PCL surfaces act as negative topographical controls, while the combination of standard tissue culture polystyrene with bone differentiation media serves as positive controls for osteogenesis. MSCs extracted from the bone marrow of Wistar and Sprague-Dawley rats were seeded on all four surface types at equal densities. Following two, three, and four weeks in culture, MSC morphology was assessed via immunofluorescence imaging of the actin cytoskeleton. On the fourth week, surface induced osteogenesis was investigated by staining for bone marker proteins.
Results: After four weeks in culture under normal expansion media conditions, MSCs cultured on nanofibers exhibit better adherence, increased proliferation, and maintain increasingly dense fibroblast-like morphologies. In contrast, MSCs seeded on nanopillar surfaces display lowered adherence, reduced proliferation, and adopt highly elongated cellular morphologies. Immunofluorescent staining of MSCs on PCL nanopillars reveals the presence of two bone marker proteins, osteopontin and osteocalcin, providing evidence for surface induced stretching and subsequent differentiation into osteoblast-like cells. Unlike the nanopillar topography, MSCs cultured on nanofiber and smooth PCL surfaces did not appear to undergo osteogenesis.
Conclusions: Observed differences in cellular response to the PCL nanotopographies offer strategies to direct progenitor cell populations solely based upon submicron surface modifications. This study provides a foundation for additional work exploring variations in PCL nanopillar topography with the goal of optimizing adherence and osteogenic response of MSCs.

Differentiation potential of a line of human hematopoietic stem cells.

T. A. Lonergan[1], C. Barksdale[2], H. Walking Woman[2]; [1]Biological Science, Western Connecticut State University, Danbury, CT, [2]Western Connecticut State University

A line of commercially available human hematopoietic stem cells was characterized for its potential to differentiate into osteocytes and transdifferentiate into neuron-like cells. This cell line expresses the cell surface marker CD 34, and was found to have a perinuclear arrangement of mitochondria, a marker that is becoming more apparent as representing the undifferentiated state of mesenchymal adult stem cells. Upon stimulation of this cell line to osteocytes, mitochondria dispersed throughout the cytoplasm, an apparent marker for the initial differentiation, followed by the synthesis of a calcium-based extracellular matrix. This cell line was also able to undergo transdifferentiaiton into neuron-like cells with a concomitant dispersion of mitochondria away from the nuclear region, loss of CD34 expression, and the formation of polymerized neurofilments. Expression of unpolymerized neurofilament protein is not a marker of neurons since the undifferentiated stem cells also express this protein. The transdifferentiation is rapid, starting within 12 hours after exposure to neural induction medium, with approximately 30% of the cells assuming a neuron-like morphology after 48 hr. The number of neuron-like cells does not increase with subsequent exposure to induction medium. The transdifferentiation process is not stable in the absence of the neural-induction medium with cells either reverting back to the undifferentiated state or becoming necrotic.

Multispectral cell tracking and dynamic analysis in intact tissues using confocal and multiphoton microscopy of five fluorescent proteins.

D. Malide[1], J-Y. Metais[2], C. E. Dunbar[2]; [1]NHLBI Light Microscopy core facility, NIH-NHLBI, Bethesda, MD, [2]Hematology Branch, NIH-NHLBI

The use of multicolor fluorescent proteins (FPs) to label cells has emerged as a powerful tool for cell tracking and lineage tracing during morphogenesis or regenerative processes. However many FP variants have similar excitation and emission properties, making unambiguous separation of signals from each reporter difficult. When multiple FPs are combined in the same experiment, high resolution multidimensional imaging could provide new insights into complex biological processes. We approached this challenge using lentiviral vectors encoding five FPs: Cerulean, eGFP, Venus, tdTomato, and mCherry, respectively to stably mark cells. Co-transduction with these vectors generates a large palette of combinatorial colors and gives the ability to track individual cells and their progeny. We optimized conditions of transduction and detection of different FPs using NIH3T3 cells. Confocal spectral imaging was used to record the five individual FP fingerprints, and software-aided linear un-mixing was performed to separate them. Although spectral imaging can be performed in 3D, the lengthy time for data collection prohibits imaging of large volumes or dynamic tracing of cells. We overcame these obstacles using the individual FP spectra and intensities to set sequential imaging channels for accurate separation of the 5FPs. We subsequently used these vectors to mark murine hematopoietic stem and progenitor cells (HPSCs) and followed engraftment and regeneration of hematopoiesis in the bone marrow (BM). In these studies we found that spectrally-coded HPSC-derived cells can be detected non-invasively in various intact tissues, including the BM, for extensive periods of time following transplantation. Moreover, we demonstrate that confocal imaging can be combined with multiphoton microscopy, revealing complementary information from autofluorescent and second-harmonic-generating structures. The unprecedented high resolution images from optical sections were used to computationally reconstruct 3D-patterns of great complexity to depths of 150-300μm. These revealed multiple expanding clones derived from individual transduced HPSCs in the BM, clearly demarcated by color-marking, in the bone proximity. HPSC-derived individual cells could be resolved in the thymus, lymph nodes, spleen, liver, lung, heart, skin, skeletal muscle, adipose tissue, and kidney as well. The 3D-images can be assessed qualitatively and quantitatively to appreciate the distribution of cells with minimal perturbations of the tissues. Finally, we illustrated the feasibility of live dynamic studies in 4D by combining resonant scanning multiphoton and confocal time-lapse imaging. This methodology enables non-invasive high resolution, multidimensional cell-fate tracing of spectrally marked cells populations in their intact 3D architecture, providing a powerful tool in the study of tissue regeneration and pathology.

1327

The Mouse Mammary Microenvironment Redirects Cells from Mesoderm-derived Bone Marrow Cells to a Mammary Epithelial Progenitor Cell Fate.

C. A. Boulanger[1], R. D. Bruno[1], M. Rosu-Myles[2], G. H. Smith[1]; [1]NCI, NIH, Bethesda, MD, [2]Biologlcs and Genetic Therapies Directorate, Ottowa, Canada

Mammary stem cells reside in protected tissue locales (niches), where their reproductive potency remains essentially unchanged through life. Disruption of the tissue leads to a reduced capacity of dispersed epithelial cells to recapitulate complete functional mammary structures. Previous studies demonstrate that during the reformation of mammary stem cell niches by dispersed epithelial cells in the mammary stroma, non-mammary cells of ectodermal germ origin may be sequestered and reprogrammed to perform mammary epithelial cell functions including

those ascribed to mammary stem/progenitor cells. To test whether tissue cells from organs derived from different germ layers could respond to mammary epithelial-specific signals, we utilized FACS-purified Lin- and Lin-/cKit+ adult male bone marrow cells to mix with mammary epithelial cells. We mixed wild type mammary epithelial cells with bona fide bone marrow cells isolated from the femurs of WAP-Cre/R26R males at a 1:1 ratio and inoculated them into the cleared inguinal fat pads of immune-compromised Nu/Nu female hosts The host mice were bred 6-8 weeks later and examined 20-30 days post involution. This approach allowed for growth of mammary tissue, transient activation of the WAP-Cre gene, recombination and constitutive expression of LacZ from the Rosa 26 promoter. PCR analysis of the DNA isolated from the chimeric outgrowths demonstrated the presence of both transgenes and sequences specific to the Y chromosome, verifying the presence of mesodermal-derived male cell DNA. Similar results were obtained when secondary outgrowths from BMC/MEC outgrowths were sectioned and analyzed by in situ fluorescent hybridization for male Y-chromosome associated DNA Our evidence shows that the signals provided by the mammary microenvironment are capable of redirecting mesoderm-derived adult progenitor cells to produce functional mammary epithelial cell progeny.

1328

Reprogramming of the osteoclast lineage using murine macrophages.

S. Jeganathan[1]; [1]Univ Toronto-Scarborough, Scarborough, ON, Canada

Macrophages are cells produced by the differentiation of monocytes in tissues. They function in innate, as well as adaptive, immunity. In addition to their roles as phagocytes, macrophages can be differentiated, by the addition of RANKL and M-CSF, into osteoclasts (large, multinucleated cells that are responsible for bone resorption). In this work, we set out to characterize whether the addition of various stimuli to RANKL pre-treated murine macrophages (RAW264.7), can alter the type of multinucleated cell obtained. Following a four-day differentiation protocol, along with LPS/IFNgamma as one stimulus, and IL-4 as the other, three types of multinucleated cells were generated. The cells were then characterized using various microscopy techniques (light, epifluorescent and scanning electron) and western blotting for osteoclast markers. We found that, as expected, RANKL treatment alone resulted in osteoclasts whereas the addition of LPS/IFNgamma to RANKL pre-treated macrophages generated Langhan's Giant Cells-type cells while IL-4 led to giant cells resembling those found in Giant Cell Tumors of the Bone. While osteoclasts had irregular morphologies, with nuclei located throughout the cell, LPS/IFN-treated cells were epitheliod in shape with peripherally located nuclei. In contrast, IL-4-treated cells were "fried-egg" shaped in appearance with centrally located nuclei. Western blotting for two osteoclast markers, tartarate-resistant acid phosphatase (TRAP) and cathepsin K, showed all three cell types being positive for TRAP and varying degrees of cathepsin K expression. Current research is focused on how the nuclei within these cell types are organized and what protein motors are involved in their movement.

Genetic mapping and characterization of a mutation that affects male-specific neural development in *C. elegans*.

M. Rowneki[1], D. J. Killian[2]; [1]Biology, The College of New Jersey, Ewing, NJ, [2]Biology, Colorado College, Colorado Springs, CO

Objective: The *C. elegans* male and hermaphrodite nervous systems display sexually dimorphic development characterized, in part, by the presence of 8 hermaphrodite-specific neurons and 89 male-specific neurons. We are interested in identifying the genes and molecular mechanisms that govern sex-specific neural development in *C. elegans*. **Methods:** Through a

mutagenesis screen using a *pkd-2::GFP* reporter to label male-specific neurons, we recovered several mutants that display defects in sex-specific neural development. **Results:** Males carrying the *sm129* mutation lack *pkd-2::GFP* expression in the male-specific CEM neurons that are involved in mate finding. Since CEMs undergo programmed cell death in hermaphrodite embryos, we investigated whether CEMs inappropriately undergo cell death in *sm129* males or whether these cells adopt an alternative cell fate. Blocking programmed cell death in *sm129* mutants, using a mutation in the caspase gene *ced-3*, does not result in the appearance of *pkd-2::GFP*-marked CEMs. This suggests that CEMs in *sm129* mutant males have adopted an alternative cell fate or are improperly specified. *sm129* mutant males also have reduced *pkd-2::GFP* expression in neurons in the male tail and have a very poor mating efficiency suggesting that male-specific neurons associated with the male tail are not formed or are not properly specified. The *sm129* mutant phenotype appears to be male-specific; hermaphrodites homozygous for the *sm129* mutation are not affected. The recessive *sm129* mutation is not a null allele; the phenotype of *sm129/Deficiency* trans-heterozygotes is more severe than *sm129/sm129* homozygotes. Three-factor mapping and deficiency mapping place *sm129* within a small region on linkage group II between 1.84cM and 2.83cM that spans roughly 100 genes. *mab-3* is a gene located in this region that affects sexually dimorphic development, but *sm129* complements a null allele of *mab-3* suggesting that *sm129* affects a different locus. There are no other genes in this region that are known to affect sex-specific development. **Conclusions:** We present evidence for a previously uncharacterized gene that regulates male-specific neural development in *C. elegans*.

Derivation of skeletal muscle progenitor cells from human embryonic stem cells.

K. J. Wilschut[1], H. S. Bernstein[1]; [1]Cardiovascular Research Insitute, University of California, San Francisco, San Francisco, CA

Muscular dystrophy comprises a group of genetic diseases that cause progressive weakness and degeneration of skeletal muscle resulting from defective proteins critical to muscle integrity. This leads to premature exhaustion of the muscle stem cell pool that maintains muscle integrity during normal use and exercise. Stem cell therapy holds promise as a treatment for muscular dystrophies, since clinical trials with human skeletal myoblasts demonstrated that these fuse with diseased fibers, providing a source of normal muscle proteins. Embryonic stem cells (ESCs) harbor infinite proliferation capacity, and can differentiate into cell types comprising most body tissues. To date, consistent approaches to the directed differentiation of ESCs into skeletal muscle precursors have been elusive and laborious. The development of efficient methods for directing skeletal muscle differentiation of ESCs would provide a model system for elucidating the control and regulation of skeletal myogenesis, and lead to the derivation of muscle progenitor cells for therapy. To address this, we tested several conditions to direct the differentiation of H9 human ESCs into skeletal muscle. Embryoid bodies (EBs) were formed in the presence or absence of the transforming growth factor-beta inhibitor, SB431542, in defined medium containing 10% fetal bovine serum (FBS) or a cocktail of insulin, transferrin and selenium. By quantitative RT-PCR we observed dramatically increased expression of muscle transcription factors, *Pax3* and *Pax7*, and increased expression of *hepatocyte growth factor receptor* (*cMET)*, a marker of satellite cells, in the presence of 10% FBS and the inhibitor after 3 days of differentiation. We also detected an increase in the percentage of cells expressing neural cell adhesion molecule, a marker of myogenic precursors, by flow cytometry. When plated on Matrigel in 2% horse serum, adherent EBs showed outgrowth of desmin-expressing myoblasts, as detected by immunocytochemistry, after 2 weeks. These studies demonstrate a validated approach to derive skeletal muscle progenitor cells from human ESCs for the study of

human myogenesis, and the development of cell therapy for the treatment of muscular dystrophies.

1331

Potential Role for Liver X Receptor in Osteoblast Function.

L. C. Shum[1], A. R. Berry[1], R. M. Ackerson[1], A. Orellana[2], A. L. Bucknell[1,3], K. B. King[1,3]; [1]Orthopaedics, University of Colorado, Aurora, CO, [2]Chemistry, York University, [3]Veterans Affairs Eastern Colorado Health Care System

The liver X receptors (LXRα and LXRβ) are nuclear receptors that function in cholesterol metabolism. Despite their name, the oxysterol-activated LXRs may also have an active role in bone and joint health. While LXRα is expressed mostly in the liver, kidney and intestines, LXRβ is expressed ubiquitously. Based on microarray and other data, a potential role for oxysterols in osteoblast (OB) differentiation has been proposed. This study investigates whether activation of LXR with a synthetic ligand would enhance OB differentiation. A human fetal pre-osteoblastic cell line (hFOB) was treated with and without 10μM synthetic LXR-agonist (N,N-dimethyl-3beta-hydroxy-cholenamide, DMHCA) in culture for 3, 7 and 14 days. At these time points, gene expression by each culture was measured using quantitative real-time PCR (RT-qPCR). Two known downstream targets of LXR, ATP-binding cassette A1 (ABCA1) and ABCG1; a marker of OB differentiation and function, osteocalcin (OCN); and β-actin for a housekeeping gene were measured. ABCA1 and ABCG1 were significantly increased with DMHCA treatment at days 7 and 14 ($P<0.05$). OCN significantly increased with treatment on day 7 ($P<0.05$). These data indicate that OBs have functional LXR receptors that can be activated with DMHCA and further that LXR activation may promote OB differentiation and/or function.

Canonical Wnt signaling regulates the renewal of differentiated taste cells of adult mice.

D. Gaillard[1], S. E. Millar[2], F. Liu[3], L. A. Barlow[1]; [1]Department of Cell & Developmental Biology, and Rocky Mountain Taste & Smell Center, University of Colorado Anschutz Medical Campus, School of Medicine, Aurora, CO, [2]Departments of Dermatology and Cell & Developmental Biology, University of Pennsylvania, School of Medicine, Philadelphia, PA, [3]Institute for Regenerative Medicine at Scott & White Hospital, Texas A&M University System Health Science Center, Temple, TX

In adult mice, cells within taste buds are continually renewed. Signaling pathways including Sonic Hedgehog, BMP, and Notch are thought to control this turnover, but specific molecular mechanisms have not been elucidated. Moreover, while Wnt/β-catenin signaling controls embryonic taste bud development (Liu et al., 2007, Nat Genet 39(1):106-12), its involvement in adult taste cell turnover is unexplored. We used conditional doxycycline-inducible Cre recombination of either exons 2-6 or exon 3 of the β-catenin gene to induce β-catenin loss- (LOF) or gain- (GOF) of function, respectively, in the taste epithelium of adult mice. After two weeks of doxycycline, β-catenin LOF resulted in a significant reduction in PLCβ2-IR (type II) cells in taste buds in the circumvallate papilla (CVP). Moreover, we found that proliferation of perigemmal basal cells in the CVP was reduced after 4 days of drug treatment, as determined by the proliferation marker Ki67. In the β-catenin GOF mice, we found that PLCβ2-IR cells appear taller and more numerous after 4 days on doxycycline, yet paradoxically, these cells were greatly reduced after 2 weeks of doxycycline. Interestingly, proliferation was virtually abolished at day 4 of β-catenin GOF, and then only somewhat recovered by day 7. Although both GOF and LOF of β-catenin both result in reduced proliferation and type II taste receptor cells, we suspect that the underlying mechanisms are quite different. Reduced proliferation following β-catenin LOF is likely because β-catenin is required for proliferation of perigemmal

basal cells, which are the progenitor population for taste buds; thus in the absence of β-catenin, new taste cells are not generated. Beta-catenin GOF also results in an early reduction in proliferation, but we hypothesize that this is because elevated β-catenin forces progenitor cells to exit the cell cycle and/or differentiate into mature taste bud cells, depleting the proliferative progenitor population.

Supported by NIH/NIDCD DC008373 and ARRA DC008373-03S1 to LAB, and an American Heart Association fellowship to DG.

Distinct protein domains regulate stability and patterning of MEX-3 in the *C. elegans* embryo.

N. N. Huang[1], C. P. Hunter[2]; [1]Biology Department, The Colorado College, Colorado Springs, CO, [2]Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA

PAL-1, the *C. elegans* caudal homolog, is a homeodomain protein required to specify posterior cell fates. While *pal-1* mRNA is present throughout the embryo, translation is restricted to the posterior in a process that requires the 3' untranslated region (3'UTR) of the *pal-1* mRNA, and the RNA-binding protein MEX-3. MEX-3 protein is present uniformly throughout the newly fertilized embryo, but becomes depleted in the posterior by the four-cell stage. Normal MEX-3 patterning requires the CCCH Zn-finger protein MEX-5, the RNA Recognition Motif protein SPN-4, and the serine/threonine kinase PAR-4. Genetic and biochemical evidence suggests the following model: MEX-5 binds to MEX-3 in the anterior and protects it from degradation, allowing MEX-3 to bind the *pal-1* 3'UTR and repress translation. MEX-3 that is not bound to MEX-5 becomes inactivated in a *par-4* dependent fashion, possibly through phosphorylation, then targeted for degradation through binding to SPN-4.

To determine which regions of the MEX-3 protein are required for stability and which for degradation, different regions of the protein were fused to GFP and introduced into the C. elegans embryo. Full-length MEX-3 expressed in this manner can functionally replace endogenous MEX-3. Results indicate that the N-terminus of MEX-3, which contains two KH domain RNA binding motifs, confers unusual stability to GFP. In contrast, the C-terminus of MEX-3, which contains potential phosphorylation sites, causes GFP to be degraded over the same timeframe as endogenous MEX-3. Furthermore, a region in the C-terminus containing a glutamine-rich region and just a few potential phosphorylation sites is required for timely degradation. Research on neurodegenerative diseases resulting from expansion of polyglutamine tracts, including Huntington's Disease, indicates that polyglutamine regions can serve as sites for protein cleavage and that polyglutamine proteins can be ubiquitinated and targeted to the proteosome. This raises the possibility that MEX-3 is inactivated by phosphorylation, then ubiquitinated and targeted to the proteosome for degradation. Intriguingly, the four human Mex-3 homologs and the apparent ascidian homolog all contain a RING finger motif, which can serve as an E3 ubiquitin-protein ligase. By creating additional fusion proteins that are missing potential ubiquitination and/or phosphorylation sites, we are determining which residues are required for inactivation and degradation.

Differentiation Analysis of Alveolar Bone Derived Mesenchymal Stromal Cells (Al-MSCs) and Bone Marrow Mesenchymal Stem Cells (BMSCs): A comparison.

K. Pekovits[1], A. Wildburger[2], M. Payer[2], N. Jakse[2], G. Dohr[1], H. Hutter[1]; [1]Institute of Cell Biology, Histology and Embryology, Medical University of Graz, Austria, Graz, Austria, [2]Department of Dentistry and Maxillofacial Surgery, Medical University of Graz, Austria, Graz, Austria

Tissue engineering is a promising approach for regenerative procedures in oral and maxillofacial surgery. Here we investigated the suitability of oral skeletal tissue as an applicable source of human mesenchymal stromal cells and an alternative to the iliac crest bone marrow. The aim was to compare the multilineage differentiation potential of alveolar bone derived mesenchymal stromal cells (Al-MSCs) and bone marrow mesenchymal stromal cells (BMSCs). Al-MSCs were isolated using explant cultures of intra-orally harvested bone chips during routine oral surgery. BMSCs were obtained from iliac crest bone marrow aspirates and used as positive control for multilineage differentiation analysis. Cells were immunocytochemically characterized. Differentiation capacities into the osteogenic, adipogenic and chondrogenic lineages were investigated using cytochemical tests (alkaline phosphatase activity, Oil Red O and Alcian blue staining) and RT-PCR analysis. Al-MSCs showed characteristics of BMSCs like plastic adherence and fibroblast like shape. Immunocytochemical analysis revealed a specific surface antigen expression pattern considered typical for multipotent mesenchymal stromal cells. Al-MSCs showed consistently high expression of CD73, CD90, CD105 and lack of expression of CD14, CD34, CD45, CD79α, HLA-DR surface molecules. Their differentiation capacity into the osteogenic, adipogenic and chondrogenic lineages was comparable to that of BMSCs. These findings suggest that Al-MSCs have a similar differentiation potential to BMSCs' in vitro. Oral skeletal tissue may be considered as a suitable source of cells for tissue engineering therapies in regenerative dentistry.

Characterization of Stem Cell Differentiation and Dedifferentiation using Gene Expression Signatures.

J. C. Poole[1], A. J. Poole[2], C. T. Fredrickson[2], T. L. Gaige[1], G. Nistor[2], R. Kovelman[1], A. Vilalta[1]; [1]EMD Millipore Bioscience Inc., San Diego, CA, [2]California Stem Cell Inc., Irvine, CA

Stem cell-based therapies are promising for the treatment of currently intractable medical conditions. These therapies rely on transplantation of differentiated stem cells that are functionally analogous to the differentiated tissues they replace. A major bottleneck in efforts to efficiently differentiate stem cells is derived from the inability to quickly and accurately monitor the effectiveness of a protocol and thereby determine if a functional cell type has been obtained. Ultimately the final product may require functional testing to satisfy this requirement, but this is impractical when differentiation protocols are under development and evolving quickly. Therefore, a fast and accurate method to monitor the efficacy of differentiation protocols is needed.

Here we describe the use of a series of qPCR panels specifically designed to identify molecular profiles that accurately monitor functional hepatocyte differentiation. We demonstrate the use of a small set of lineage-specific markers to effectively track the differentiation of human embryonic stem cells into mature hepatocytes. We show that these cells express the appropriate immunocytochemical markers and possess functional activities of mature hepatocytes, such as glycogen storage, albumin production and indocyanine green dye uptake. In addition, key genes in the cytochrome P450 superfamily are highly upregulated. These CYPs include CYP3A4, CYP2C9 and CYP2E1 which are all critical for proper hepatocyte function in drug metabolism.

Levels of other markers associated with mature hepatocytes such as Albumin and Alpha-1 antitrypsin are also found to closely follow that of their respective proteins. By validating our qPCR panels with functional testing, we show that gene expression signatures can be a useful method for monitoring differentiation protocols for functional relevance.

1337

Highly-reproducible transfer of cyclic mechanical stretch to stem cells: a novel bioreactor.

M. Govoni[1], F. Lotti[2], L. Biagiotti[2], M. Lannocca[2], G. Pasquinelli[2], S. Valente[2], C. Muscari[2], F. Bonafè[2], C. M. Caldarera[3], C. Guarnieri[2], S. Cavalcanti[1], E. Giordano[1]; [1]University of Bologna / Campus of Cesena - Italy, Cesena, Italy, [2]University of Bologna - Italy, Bologna, Italy, [3]National Institute for Cardiovascular Research - Italy, Bologna

Dynamic culture of cells seeded on biocompatible 3D-poymeric matrix is a suitable condition to create a engineered pseudo-tissue useful for the regenerative medicine. Several studies has demonstrated that mechanical forces influence the growth and the shape of virtually every tissue. The aim of this work was the development of a novel bioreactor (WIPO WO2011013067 entitled “Bio reactor for stem cell stimulation”) able to transfer controlled and standardized mechanical stimuli to Mesenchymal Stem Cells (MSCs) for their commitment towards the muscle phenotype.
Bone marrow MSCs were isolated from wild type adult male Wistar rats and were seeded onto selected scaffold (3x2 cm hyaluronan-based woven mesh) at the concentration of 10^6 cells per cm^2. Control cells were cultured on scaffold in conventional static condition during 2 weeks, whereas dynamic experimental test was carried out maintained the cells in standard condition during 1 week and transferring them in the bioreactor during the following week. Dynamic cultured conditions were: frequency = 600 ms (1.66 Hz; 100 bpm), mean load over the cycle = 10 g (0.1 N) obtained with 2.5 mm amplitude of stretching (< 10% of scaffold length available for cell growth = 2.5 cm). At the end of experiment the cells were examined in light microscopy (LM), scanning electron microscopy (SEM), transmission electron microscopy (TEM), and protein extracts were submitted by SDS-PAGE and Western blot.
After 7 days of “training” in dynamic condition, we observed a significant difference between MSCs cultured in dynamic condition compared with the cells in static control culture. Two main differential features were scored by LM: the large number and the multilayer organization of cells in the dynamic setting. SEM and TEM showed structural differences and cellular alignment along with stretching direction. In addition, the mechanical stretching stimulation increased the expression of typical muscle markers (smooth muscle actin and α-sarcomeric actin) witness of an ongoing differentiation process.
The dynamic bioreactor presented in this work aims to support maintenance of constant parameters during mechanical stimulations, in order to obtain a suitable, standard method for dynamic cell culture where strain is required. Therefore, this bioreactor may represent a new basic research tool in the field of tissue engineering and in the study of stem cells differentiation towards specialized phenotypes.

Inhibition of Myosin Light Chain Kinase by Aurora B Kinase Leads to Cytokinesis Failure and Tetraploidization in Cancer Cells.

R. M. Sahasrabudhe[1], W. S. Saunders[1]; [1]Biological Sciences, University of Pittsburgh, Pittsburgh, PA

Cancer cells can fail in cytokinesis leading to tetraploidy and chromosomal instability, a common phenotype of malignant cells. A key regulator of the process of cytokinesis is the enzyme Aurora B kinase. Dys-regulation of Aurora B is known to cause cytokinesis failure and tetraploidization. However, the mechanism of Aurora B mediated tetraploidization is not yet known. An essential step in cytokinesis is phosphorylation of myosin regulatory light chain (MLC), required for actin–myosin interaction and formation of the cleavage furrow. Previous studies have shown that MLC phosphorylation is deficient in cancer cells and that MLC phosphorylation deficiency is the cause of cytokinesis failure in the tested cancer cell lines. Myosin light chain kinase (MLCK) is a key enzyme that phosphorylates MLC during cytokinesis and is inhibited in cancer cells. As Aurora B kinase is known to phosphorylate MLCK, we hypothesize that Aurora B is an inhibitor of MLCK and the source of MLCK deficiency in cancer cells. Consistent with our hypothesis, we show that Aurora B is an inhibitor of MLCK *in vitro* and also in cultured mammalian cells. Our data also suggests that chromosome segregation errors can be a cause of Aurora B over-expression and MLCK inhibition in cancer cells. Thus, we have identified what we believe is the molecular explanation for Aurora B-induced cytokinesis failure in tumor cells. These results contribute to understanding of the consequences of Aurora B over-expression and the causes of cytokinesis failure in malignant cells.

1339

Hepatitis B Virus X (HBx) induces chromosomal instability through reduction of aurora B kinase activity.

S. Chae[1], J. Seong[2], H. Cho[1,3]; [1]Department of Biochemistry, Ajou University School of Medicine, Suwon, Korea, [2]Collage of Veterinary Medicine, Seoul National University, Seoul, Korea, [3]Department of Molecular Science and Technology, Ajou University, Suwon, Korea

Correction of mal-attached microtubules is required to prevent chromosome mis-segregation and subsequent chromosomal instability and tumorigenesis. Although Hepatitis B virus X (HBx), an onco-protein encoded by HBV genome, is involved in the development of HBV-mediated liver cancer, its precise mechanism of action remains unclear. Here we show that HBx reduces Aurora B activity, which induces chromosomal segregation defects. Expression of HBx induces severe anaphase lagging and micronuclei formation after monastrol release, indicating insufficient correction of mal-attachment leading to segregation defects. In addition, HBx causes chromosome congression defects at metaphase. Interestingly, HBx interacts with Aurora B in the presence of HBxAP, an associating protein with HBx, which leads to a significant decrease of the kinase activity of Aurora B, but not the expression of Aurora B based on western blot analysis using phospho-specific antibodies. Likewise, HBx colocalizes with Aurora B at the centromere. Together, our data strongly suggest that the decrease of Aurora B kinase activity through binding with HBx protein is involved in HBx-induced chromosomal instability. This provides a novel mechanism for mitotic aberrations by a viral pathogen, which contributes to the accumulation of genomic instability during hepatocarcinogenesis.

1340

Depletion of cellular poly (A) binding protein prevents protein synthesis and results in p53 mediated apoptosis in HeLa cells.

M. T. Zannat[1], J. Bag[1]; [1]MCB, University of Guelph, Guelph, ON, Canada

The cytoplasmic poly (A) binding protein (PABP) is an important activator of mRNA translation and also regulates mRNA stability. It interacts with eIF4G at the 5'cap which leads to the circularization of translating mRNA and enhances mRNA translation. In yeast, PABP gene is essential and its conditional mutation leads to inhibition of mRNA translation. However, it is uncertain, whether mammalian PABP is essential for mRNA translation. PABP depletion from a cell free extract prevents mRNA translation whereas according to a recent report ablation of PABP expression by siRNA did not prevent mRNA translation in HeLa cells in culture. We re-examined the effect of PABP depletion on mRNA metabolism in both HeLa and HEK 293 cells by using small interfering RNA. We found that depletion of PABP reduced protein synthesis by approximately 50-75%, and consequently leads to cell death in both cell lines. Significant reduction of cellular PABP level resulted in the nuclear translocation of the glycolytic enzyme GAPDH. Presumably the nuclear GAPDH activated an apoptotic pathway by enhancing acetylation and serine 46 phosphorylation of p53.We have shown that p53 translocates to the mitochondria to initiate Bax mediated apoptosis in PPABP depleted cells. It is likely that p53 induce apoptosis by a transcription independent mechanism in PABP depleted cells We have shown that p53 binds to the pro survival protein Bcl2. Bcl2 normally binds to pro apoptotic protein Bax and prevents apoptosis by inhibiting its oligomerization and mitochondrial translocation. Therefore, perhaps in PABP depleted cells binding of p53 to Bcl2 released Bax from Bcl2 inhibition and allowed Bax to oligomerize and triggered apoptosis.

1341

Cytoplastic sequestration of p53 by the heat shock protein 70 family member, mortalin, in human colorectal carcinoma cell lines.

E. E. Gestl[1], R. Giovenella[1], N. G. Taraska[1], S. M. Terkowski[1], S. A. Boettger[1]; [1]Biology, West Chester University, West Chester, PA

Colorectal carcinomas are among the leading cancer deaths in Western countries and typically arise due to mutations in tumor suppressors and oncogenes, as well as functional inactivation of tumor suppressor proteins. The examination of 16 colorectal adenocarcinoma cell lines to determine expression levels for p53 and a heat shock protein family member mortalin was conducted. Inactivation of p53 through cytoplasmic sequestration has been suggested to promote carcinogenesis by tethering of the p53 protein by mortalin thereby rendering it non-functional. All cell lines displayed punctate p53 and mortalin localization in the cell cytoplasm with the exception of cytoplasmic p53 protein in HCT-8 which was never detected, possibly because p53 levels are below detectable limits. Nuclear and therefore actively functioning p53 was only observed in HCT-116 40-16, LS123, and HT-29 cell lines. Co-immunoprecipitation revealed that p53 and mortalin were bound and co-localized in five of eight cell lines examined thus far. HCT-116 40-16 and 386, HT-29, LS123 and LoVo, were preventing p53 from being shuttled into the nucleus and therefore causing its inactivation. Elevated mortalin gene expression levels were observed in all p53-containing cell lines and most cell lines showing cytoplasmic p53 sequestration resulting in elevated p53 gene levels. Current experiments include the disruption of p53-mortalin interaction using either MKT-077, a cationic rhodacyanine dye analogue or siRNA targeted to mortalin. Initial results for the HCT-116 cell lines show a return of p53 to its functional site, the nucleus. Our data reveal the first evidence of cytoplasmic sequestration of p53 by the heat shock protein mortalin in colorectal adenocarcinoma cell lines,

which had previously been suggested but not yet proven as it has been the case for other unrelated cancers.

1342

Annexin A2 facilitates cell cycle by sustaining c-Jun N-terminal kinase-inhibited p53 expression in lung adenocarcinoma.

C-Y. Wang[1], C-F. Lin[2,3]; [1]Institute of Basic Medical Science, Tainan, Taiwan, [2]Institute of Clinical Medicine, Tainan, Taiwan, [3]Department of Microbiology and Immunology, Tainan, Taiwan

Overexpression of annexin A2 is required for cancer cell proliferation and invasion; however, the molecular mechanism underlying cell cycle is still unknown. Annexin A2 richly expressed in lung adenocarcinoma and positively correlated to poor prognosis. Non-small cell lung cancer cell A549 lacking annexin A2 exhibited defects on tumor growth *in vivo* and cell proliferation *in vitro* without cytotoxicity. Knockdown of annexin A2 induced cell cycle arrest in G_2 phase of interphase. Unexpectedly, silencing annexin A2 increased expression of p53 and its downstream genes followed by p53-mediated G_2 arrest, at least in part. Aberrant c-Jun N-terminal kinase (JNK) inactivation in annexin A2 deficient cells caused cell proliferation inhibition following G_2 arrest. Lack of annexin A2 caused loss of JNK-regulated c-Jun expression followed by p53 increase transcriptionally. Treatment of cisplatin caused annexin A2 cleavage accompanied by p53 increase, whereas annexin A2 knockdown increased cisplatin-induced p53 expression as well as apoptosis while annexin A2 overexpression reduced such effects. These results demonstrate a novel role of annexin A2 in lung cancer cell proliferation by facilitating cell cycle through maintenance of JNK/c-Jun-inhibited p53.

1343

PA28γ is required for effective initiation of apoptosis signaling by p53.

S. S. Simpson[1], L. Ellington[1], P. Shah[1], L. F. Barton[1]; [1]Biology, Austin College, Sherman, TX

The tumor suppressor p53 regulates a wide array of biological processes including cell cycle arrest, DNA repair, and apoptosis to maintain genomic integrity. Due to p53's role in these critical cellular processes, persistent regulation is important. Cell stress typically results in increased concentration of p53, subsequently promoting cell cycle arrest, apoptosis, or senescence. In order to maintain low levels of p53 in normal cells, negative regulation of p53 is accomplished by MDM2-mediated proteasomal degradation. The proteasome activator, PA28γ, has been shown to play a critical role as a cofactor by facilitating MDM2-dependent degradation of p53 by proteasomes. Additionally PA28γ has been identified as an important component in regulating the cellular distribution of p53. Murine embryonic fibroblasts (MEF) that lack PA28γ, exhibit high levels of p53 expression but lack the expected increased sensitivity to apoptotic stimuli, measured by caspase 3/7 activity. This led us to hypothesize that our PA28γ-deficient MEFs express a dysfunctional p53 in order to compensate for lack of PA28γ expression and to maintain viability. Upon sequence analysis of cloned cDNA, it was determined that PA28$\gamma^{-/-}$ MEFs have a Met to Thr mutation at the 120th amino acid residue. The location of this mutation is in the DNA binding domain of p53, and is flanked by Ser residues that represent possible phosphorylation regulation sites. To examine the possible effects of the M120T mutation, we investigated p53's ability to transcribe the gene Noxa. Our data suggest that the M120T mutation does not affect the transcriptional transactivation of p53 on Noxa, under basal conditions or when cells are treated with UVR where a 9-fold increase in Noxa concentration is observed in both control and PA28 $\gamma^{-/-}$ MEFs. There are several post-translational modifications including phosphorylation and acetylation that affect p53 stability, localization, and function that could explain the phenotype we observe. Currently, no significant differences in p53 modifications have been detected in PA28 $\gamma^{-/-}$ cells. We confirm that elevated p53 levels in PA28

γ$^{-/-}$ MEFs are related to proteasome degradation rates; however, we conclude that PA28γ has additional roles in regulating the initiation of the caspase cascade and promoting apoptosis unrelated to its regulation of p53 concentration.

1344

Inhibitor of Growth 1 (ING1) Stabilizes Tumor Suppressor p53 by Blocking Polyubiquitination.

S. Thalappilly[1], X. Feng[1], K. Suzuki[1], K. Riabowol[1]; [1]Biochemistry and Molecular Biology, University of Calgary, Calgary, AB, Canada

Introduction: The INhibitor of Growth tumor suppressors (ING1-ING5) affect aging, apoptosis, DNA repair and tumorigenesis. Plant homeodomains (PHD) of ING proteins bind histones in a methylation-sensitive manner to regulate chromatin structure. ING1 and ING2 contain a polybasic region (PBR) adjacent to their PHDs that binds stress-inducible phosphatidylinositol monophosphate (PtIn-MP) signaling. ING1 induces apoptosis independently of p53, but several studies suggest proapoptotic interdependence of ING1 and p53 leaving their functional relationship unclear. Here we identify a novel ubiquitin-binding domain (UBD) that overlaps with the PBR of ING1 and shows similarity to previously described UBDs involved in DNA damage responses. **Results:** The ING1 UBD binds ubiquitin with high affinity (Kd~100 nM) and ubiquitin competes with PtIn-MPs for ING1 binding. ING1 expression stabilized wild-type, but not mutant p53 in an MDM2-independent manner and knockdown of endogenous ING1 depressed p53 levels in a transcription-independent manner. ING1 stabilized unmodified and six multimonoubiquitinated forms of wild-type p53 that were also seen upon DNA damage, but not p53 mutants lacking the six known sites of ubiquitination. We also find that ING1 physically interacts with herpesvirus-associated ubiquitin-specific protease (HAUSP), a p53 and MDM2 deubiquitinase (DUB), and knockdown of HAUSP blocks the ability of ING1 to stabilize p53. **Conclusion:** These data link ING1 to ubiquitin-mediated proteasomal degradation through the PBR/UBD of ING1 and further indicate that ING1 stabilizes p53 by inhibiting polyubiquitination of multimonoubiquitinated forms via interaction with and colocalization of the HAUSP-deubiquitinase with p53.

1345

EGFR-Stimulation in Breast Cancer Cells Causes Membrane Capacitance Changes Similar to a Neurosecretory Cell.

F. Azizi[1], E. J. Tisdale[1], C. R. Artalejo[1]; [1]Pharmacology, Wayne State University, Detroit, MI

Over-expression of the epidermal growth factor receptor (EGFR) is responsible for many cancers including breast, which is the most common cancer diagnosed among women in the United States. Although EGFR endocytosis has been extensively studied, the molecular machinery and regulatory determinants required for EGFR internalization and recycling remains uncertain. The objective of this study was to directly measure in “real-time” EGFR membrane trafficking in breast cancer cell lines and noncancer cell lines by using state-of-the-art electrophysiological membrane capacitance (Cm) measurements. Membrane capacitance allows detection of small changes in membrane surface area that are the result of incorporation and or retrieval of transport vesicles containing EGFR. We have discovered using this ‘high-resolution technique’ never before applied to cancer cells that EGFR stimulation with EGF and related ligands causes extremely fast, kinetically and mechanistically distinct pathways of EGFR membrane incorporation, endocytosis, and receptor recycling. Importantly, these pathways do not exist in noncancer breast cells. Based on our preliminary data, we propose that breast cancer cells possess cancer-specific EGFR pathways to efficiently maintain the cells high

functional demands and self-sufficiency characteristic of malignant breast cancer. (This work was supported by NIH grant GM068813)

Phosphatase SHP-1 supports mammary epithelial cell acinus formation by limiting EGFR activity, phosphorylation and recycling.

F. Martin[1], O. Bergin[1], S. McNally[1], S. Madden[1], W. Gallagher[1]; [1]Conway Institute, University College Dublin, Dublin, Ireland

Primary epithelial cells harvested from mid-pregnant mouse mammary glands form acini when supported on a laminin-rich EHS extracellular matrix. We have previously shown that such acinus formation is dependent on JNK MAP kinase activity. Here we have used a small molecular weight JNK inhibitor to disrupt acinus formation (it blocks cell polarisation and lumen clearance) and so define the contribution of epidermal growth factor receptor (EGFR) signalling to acinus formation. In EGF is not added to the culture medium perfect acini form from dispersed primary mammary epithelial cells supported on the EHS matrix but they are significantly smaller than normal. If acinus formation is disrupted by inhibiting JNK activity, acinus formation can be rescued by inhibiting EGFR activity. Thus limited EGFR activity is required to support acinus formation. We have addressed a possible mechanism of how EGFR activity is curtailed in this context. As normal acini form we show that EGFR levels remain constant, the EGFR is retained on the plasma membrane and is under auto-phosphorylated on tyrosine. If acinus formation is disrupted by JNK inhibition total EGRF levels fall, EGFR levels on the plasma membrane fall (suggestive of receptor recycling) and the remaining EGFR is hyper-autophosphoylated. During normal acinus formation a small isoform of the EGFR phosphatase, SHP-1, was detectable; SHP-1 was phosphorylated on its Src-dependent activational site and SHP-1 activity was high. If acinus formation was disrupted with the JNK inhibitor, a bigger SHP-1 isoform was detected, low levels of SHP-1 phosphorylation on the activational site was detected and SHP-1 activity was low. Over-expression of two dominant negative SHP-1 mutants both impaired acinus formation by MCF10A human mammary epithelial cells and reduced total EGFR levels. Over-expression of a dominant negative JNK mutant, which impairs MCF10A acinus formation, reduced SHP-1 phosphorylation on the activational site. Thus, SHP-1 shows the properties necessary for a regulator of EGFR activity during acinus formation. Interestingly, we could show, in a large cohort of human breast cancer patients, that high SHP-1 expression was significantly associated with a good outcome in lymph node negative patients.

Aberrant DNMT3B proteins alter E-cadherin expression and cell proliferation in breast cancer cells.

P. R. Brambert[1], D. J. Kelpsch[1], M. F. Lahey[1], K. R. Ostler[2], L. A. Godley[2], S. L. Raimondi[1]; [1]Biology, Elmhurst College, Elmhurst, IL, [2]University of Chicago

With breast cancer responsible for more than 39,000 female deaths in 2010, it is the second most common cause of cancer death in American women. Tumor progression is regulated by changes in gene expression and one mechanism to regulate gene expression is DNA methylation. DNA methylation occurs when one of three DNA methyltransferases (DNMT1, DNMT3A, or DNMT3B) adds a methyl group to a CpG dinucleotide causing DNA to become tightly coiled. As a result, transcription of methylated DNA is prevented and affected genes become silenced. Previous studies have shown abnormal methylation in cancer cells. Furthermore, aberrantly spliced versions of DNMT3B have been indentified in several cancer cell lines, including breast cancer. Therefore, we hypothesize that aberrant DNMT3B isoforms alter protein expression leading to changes in cell proliferation in breast cancer cells. Our

studies indicate that the breast cancer cell lines MCF-7 and MDA-MB-231 have been shown to express many aberrant DNMT3B isoforms including DNMT3B7 and ∆DNMT3B6. Interestingly, the invasive MDA-MB-231 cells express increased levels of DNMT3B7 and ∆DNMT3B6 compared to the poorly invasive MCF-7 cells. To further our studies, MCF-7 and MDA-MB-231 cells were stably transfected with aberrant DNMT3B expression constructs. Western blots were performed on cytoplasmic and nuclear lysates collected from the transfected cells and observed bands revealed a difference in E-cadherin expression between transfected and non-transfected cells. Additionally, cell proliferation was measured and indicates a correlation with E-cadherin expression. The novel results presented in this study suggest the need for additional studies to determine the role of aberrant DNMT3B transcripts in cancer. Ultimately, this work may lead to a better understanding of breast cancer progression and the development of novel therapeutics.

1348

Role of HSP90 in stability of PTK6 which is an oncoprotein overexpressed in breast cancer cells.

S-A. Kang[1], S-T. Lee[1]; [1]Department of Biochemistry, College of Life Science and Biotechnology, Yonsei University, Seoul, Republic of Korea, Seoul, Korea

PTK6 (also known as Brk) is a non-receptor tyrosine kinase containing the SH3, SH2, and catalytic domains. PTK6 is overexpressed in breast carcinomas, but not in normal mammary tissues. PTK6 induces proliferation, anti-apoptosis, migration, and anchorage-independent growth. To understand roles of an oncoprotein PTK6, proteins interacting with PTK6 were analyzed. Heat shock protein 90 (Hsp90) was identified as an interacting protein of PTK6. Hsp90 interacted with the kinase domain of PTK6 but its catalytic activity was not required for the interaction. A Hsp90 inhibitor, geldanamycin, decreased the protein level of PTK6 through proteasome-dependent degradation of PTK6. Treatment of geldanamycin also reduced phosphorylation of PTK6 substrates due to the decreased amount of PTK6. Moreover, overexpression of CHIP, which is a chaperone-dependent E3 ligase, enhanced the proteosomal degradation of PTK6. Silencing of endogenous CHIP expression in breast carcinoma cells abolished the geldanamycin-induced degradation of PTK6. Geldanamycin increased the interaction of PTK6 with CHIP while it decreased the interaction of PTK6 with Hsp90. These results demonstrate that Hsp90 plays an important role in stability of PTK6 by assisting the correct folding of PTK6 and suggest that Hsp90 inhibitor should be useful as a therapeutic drug for the PTK6-positive cancers including breast cancer.

1349

The HER2 amplicon includes several genes required for the growth and survival of HER2 positive breast cancer cells.

K. Kleivi Sahlberg[1,2], V. J. Hongisto[2], H. Edgren[3], R. Mäkelä[2], K. Hellström[2], E. U. Due[1], H. Moen Vollan[1,4], N. Sahlberg[2], M. Wolf[3], A-L. Börresen-Dale[1,4], M. Perälä[2], O. Kallioniemi[2,3]; [1]Institute for Cancer Research, Oslo University Hospital Radiumhospitalet, Oslo, Norway, [2]VTT Technical Research Centre of Finland, Turku, Finland, [3]Institute for Molecular Medicine Finland, [4]Institute for Clinical Medicine, University of Oslo

Over 20 % of breast cancers are characterized by amplification and overexpression of the *HER2* oncogene. Although significant progress has been achieved for treating such patients with HER2 inhibitor Trastuzumab, more than half of the patients respond poorly or become resistant to such treatment. Since the HER2 amplicon at 17q12 is large and contains multiple genes, we wanted to systematically explore the role of the *HER2* co-amplified genes in breast cancer development and Trastuzumab resistance. Here, we integrated mapping data of the

HER2 amplicon size in 71 HER2 positive breast tumors and 10 cell lines with systematic functional RNA interference analysis of the 23 of the core amplicon genes with several phenotypic endpoints in a panel of Trastuzumab responding, non-responding and HER2 negative breast cancer cells. Silencing of *HER2* caused a greater growth arrest and apoptosis in the responding compared to the non-responding cell lines. Several other genes in the amplicon also showed effects when silenced, indicating that expression of several *HER2* co-amplified genes may be needed to sustain the growth of breast cancer cells. Importantly, co-silencing of the *PPP1R1B (DARPP-32), STARD3* and *PERLD1* together with *HER2* led to a synergistic inhibition of cell viability as well as AKT and S6K phosphorylation. Taken together, these studies indicate that breast cancer cells may become addicted to the amplification of several genes that reside in the HER2 amplicon and that simultaneous targeting of these genes may increase the efficacy of the anti-HER2 therapies and possibly also counteract Trastuzumab resistance. Taken together with literature evidence, our data also suggest that many gene products in the HER2 amplicon also signal through the PI3K-AKT complex, supporting the ongoing efforts to develop inhibitors for these pathways for combinatorial treatment of HER2+ breast cancers.

WNT5A Overexpression Promotes Breast Cancer Progression in the Presence of VANGL1.

C. D. MacMillan[1,2], H. S. Leong[1], L. H. Souter[1,2], A. F. Chambers[1,3], A. B. Tuck[1,2]; [1]London Regional Cancer Program, London Health Sciences Centre, London, ON, Canada, [2]Department of Pathology, Schulich School of Medicine and Dentistry, The University of Western Ontario, Lodnon, ON, Canada, [3]Department of Oncology, Schulich School of Medicine and Dentistry, The University of Western Ontario

The 21T cell lines have previously been shown to mimic specific stages of breast cancer progression (21PT, Atypical Ductal Hyperplasia; 21NT, Ductal Carcinoma *in situ*; 21MT-1, Invasive Mammary Carcinoma). Expression profiling has revealed differences in WNT5A and VANGL1 expression among these three cell lines. WNT5A expression levels are moderate in 21PT, low in 21NT, and high in 21MT-1 cells, whereas VANGL1 levels are low in 21PT and high in 21NT and 21MT-1 cells. WNT5A and VANGL1 both play roles in the non-canonical Wnt/planar cell polarity (PCP) signalling pathway. The precise role of this pathway in breast cancer progression has yet to be determined, as activation of the pathway via Wnt5a has been shown to promote either differentiation or progression. This dual effect may be due to the presence or absence of other PCP components such as VANGL1. Based on this and the expression patterns of WNT5A and VANGL1 in the 21T cell lines, we hypothesized that WNT5A will promote breast cancer progression only in the presence of elevated levels of VANGL1. Here, we have characterized an *in vitro* model of breast cancer progression using the 21T cell lines to measure 3D colony morphology when grown in reconstituted basement membrane. Using this model and transwell migration and invasion assays we show that overexpression of transfected WNT5A in the 21NT cells (high endogenous VANGL1 expression), but not the 21PT cells (low endogenous VANGL1 expression) promotes cancer progression. Specifically, WNT5A overexpression had a profound effect to increase invasion and migration of the 21NT cells, but only had a modest effect on cell migration of the 21PT cells, and had no effect on invasion. WNT5A overexpression also increased the percentage of non-spherical colonies in 21NT cells but had no effect on 21PT cells. In addition, VANGL1 overexpression promoted progression of the 21PT cells (which have moderate levels of endogenous WNT5A expression). Specifically, VANGL1 overexpression increased cell migration and invasion and also decreased the percentage of extracellular lumen formation, polarized structures, and increased the number of non-spherical colonies. Taken together, these findings implicate a role for the PCP pathway in promoting breast cancer progression and this role may be dependent on VANGL1 expression.

1351

Tumor Suppressor Gene p16/INK4A Dependent Regulation of Cell Cycle Exit in a Spontaneous Canine Model of Breast Cancer.

P. Agarwal[1], P. DeInnocentes[1], M. Sandey[2], R. C. Bird[1]; [1]Dept Pathobiology, Auburn University, Auburn University, AL, [2]Scott-Ritchey Research Center, Auburn University, Auburn University, AL

p16/INK4A is an important tumor suppressor gene which arrests cell cycle in early G1 phase inhibiting binding of CDK4/6 with cyclin D1 leaving the Rb tumor suppressor protein unphosphorylated and E2F bound and inactive. We have previously shown that p16 is frequently mutated in canine mammary cancer comparable to human breast cancer. Because p16 expression persists following cell cycle exit, we hypothesize that p16 has a role in exit from cell cycle that becomes defective in cancer cells and that p16 has alternate binding partners other than CDK4/CDK6 in quiescent or differentiated cells. Well characterized p16-defective canine mammary cancer cell lines (CMT28, CMT27, and CMT12), normal canine fibroblasts (NCF), and p16-transfected CMT cell clones (CMT27A, CMT27H, CMT28A, and CMT28F) exhibiting a rescued phenotype, have been used to investigate expression of p16 after serum starvation into quiescence followed by re-feeding to induce cell cycle re-entry. CMT cells lack p16 expression either at mRNA or protein expression levels, while p27, CDK4, CDK6, cyclin D1, and Rb, appear to be expressed at normal levels. We have successfully demonstrated cell cycle arrest and synchronous cell cycle re-entry in parental CMT12, CMT28 and NCF cells as well as p16 transfected CMT27A, CMT27H, CMT28A, and CMT28F cells and confirmed this by 3H-thymidine incorporation and flow cytometric analysis of cell cycle phase distribution. p16 transfected CMT27A and CMT27H exited cell cycle post serum-starvation in contrast to parental CMT27 cells. NCF, CMT27A, and CMT28F cells expressed up-regulated levels of p27 mRNA coincidently with elevated expression of p16 mRNA as cells exited cell cycle and entered quiescence. To find alternating binding partners of p16, co-immunoprecipitation was performed in quiescent CMT27A cells which resulted in unique co-immunoprecipitation of the p53-associated and putative tumor suppressor 14-3-3σ protein only in quiescent CMT27A cells in comparison to exponential cells. Levels of 14-3-3σ mRNA expression also rose along with p16 in quiescent NCF cells. Because quiescence and differentiation are associated with decreased levels of cyclin D1 and/or CDK6 our data demonstrating that p16 is up-regulated during quiescence suggests the presence of alternative binding partners for p16, such as 14-3-3σ, in promoting and maintaining the quiescent and/or differentiated phenotype (funded by NCI/NIH).

The Sphingosine 1-Phosphate Receptor S1P2 Maintains Homeostasis of Epithelium.

Y. Gu[1], T. Forostyan[1], J. Rosenblatt[1]; [1]Huntsman Cancer Institute, Salt Lake City, UT

The cells comprising epithelia turn over via cell death and division at the highest rates in the body. Because most solid tumors, or carcinomas, originate from epithelia, misregulation of this balance of epithelial cell death and division, or homeostasis, is likely at the heart of tumor formation. Surprisingly little is known, however, about what regulates the balance between cell division and death in epithelia in vivo. We have found that epithelia use a process termed “apoptotic cell extrusion” to remove apoptotic cells from a layer while maintaining an intact barrier. Specifically, an early apoptotic epithelial cell triggers its neighboring cells within the epithelium to form and contract an actin and myosin ring, which squeezes the dying cell out. We recently found that the signal that induces extrusion is sphingosine-1-phosphate (S1P) and it signals through S1P2 in neighboring cells to bring about actin assembly and extrusion. One surprising finding is that when extrusion is blocked by S1P2 antagonist or anti-S1P mAb, there is a marked decrease of induced cell death. Interestingly, reduced cell death mediated by

blocking S1P2 is not observed in cells that cannot extrude, such as NIH3T3 cells, suggesting that extrusion is a necessary process for epithelial cell death. Overgrown human bronchial epithelial (HBE) cells with S1P2 knockdown not only display reduced naturally-occurring cell death but also accumulate up to three layers. Mixed culture of normal and S1P2 knockdown HBE cells shows that only S1P2 knockdown cells accumulate up to multiple layers and continue to proliferate (by BrdU incorporation assay) after a long period of culture. In addition, zebrafish that carry a loss-function mutation in S1P2 are defective in epidermal cell extrusion and develop epidermal cell clumps. Taken together, these data support a conclusion that S1P2 maintains epidermal homeostasis, likely through mediating cell extrusion.

1353

Molecular and Signalling Functions of Tumor Protein D52 in Cancer Cells.

H. Shahheydari[1,2], S. Frost[2], Y. Chen[2], J. Byrne[1,2]; [1]Discipline of Paediatrics and Child Health, University of Sydney, Sydney, Australia, [2]Children's Cancer Research Unit, Kids Research Institute, The Children Hospital at Westmead, Westmead, Australia

A large number of studies have shown that the *tumor protein D52 (TPD52)* gene is amplified and/or overexpressed in different types of cancer. Independent studies have demonstrated increase Akt phosphorylation in response to TPD52 overexpression in prostate cancer cells, suggesting that TPD52 represents a signalling intermediate in the PI3-Kinase pathway. Despite the increasing recognition of the significance of TPD52 overexpression in cancer, the basis of TPD52's oncogenicity is poorly understood, in part due to a lack of binding partners which might explain TPD52's oncogenic properties. The present study aimed to identify novel TPD52 partners with relevance to cancer through a large-scale yeast two-hybrid screening approach. A full-length human TPD52 bait was screened against a human breast carcinoma cDNA expression library in Hf7c cells. This screening identified 4 candidate partners for TPD52, which are all integral membrane or membrane-associated proteins. Our further study focused on two of these candidates, proteolipid protein 2 (PLP2) and Rab5c, as both proteins have been linked with PI3-Kinase and/or Akt functions. GST pull-down assay confirmed interactions between PLP2 or Rab5c and TPD52. Moreover, we also examined the binding activity of a panel of deleted TPD52 proteins with PLP2 and Rab5c in both the yeast two hybrid system and pull-down assays. Interaction domain mapping showed that these partners bind within TPD52 amino acids 111-131, outside the coiled-coil motif. Confocal-based immunofluorescence analyses in breast carcinoma cell lines showed that TPD52 and flag-tagged PLP2 co-localised towards the plasma membrane. Currently, we are examining the subcellular localisation of TPD52 and CFP-tagged Rab5c. In summary, we identified 2 novel binding partners for TPD52, PLP2 and Rab5c. These two partners have different structures and functions; however they bind similar regions of TPD52. Further functional studies of these two partners could provide a better understanding of TPD52 functions in cancer cells.

1354

Ha-Ras^{V12} induced cancer cell softening facilitate tumor formation.

H-H. Lin[1], Y-W. Chiou[2], J-Y. Liu[3], M-J. Tang[1]; [1]Department of Physiology, College of Medicine, National Cheng Kung University, Tainan, Taiwan, Tainan, Taiwan, [2]Institute of Bimedical Engineering, National Cheng Kung University, Tainan, Taiwan, Tainan, Taiwan, [3]Institute of Basic Medical Sciences, College of Medicine, National Cheng Kung University, Tainan, Taiwan, Tainan, Taiwan

Large amount of evidence about cancer cell biology has been accumulated in the past with the advancement of genetic and biochemical approach. However, less was known about the mechanical or physical property of a cancer cell. We previously demonstrated that collagen gel

induced apoptosis in epithelial cells, but not transformed or cancer cells, due to low stiffness (lower than 100Pa) nature of the gel (1). We hypothesized that normal epithelial and cancer cells might exhibit different physical property which provided the advantage for cancer cell to evade low-substratum rigidity induced apoptosis. In order to explore the physical properties of cancer cells, we established the technology to explore the stiffness of a single cell with Bio-Atomic Force Microscope. We found that cancer cells were softer than normal epithelial cells in general. To further elucidate the underlying mechanisms that cancer cells are softer than normal cells, we established the IPTG inducible Ha-Ras^{V12} expression system in NIH3T3 and MDCK because oncogenic Ras has been implicated in carcinogenesis of various types of cancer. Ha-Ras^{V12} overexpression conferred the resistance to anoikis and facilitated foci formation, anchorage independence growth, cell proliferation on low rigidity as well as invasiveness ability in both NIH3T3 fibroblast and MDCK epithelial. Interestingly, those Ha-Ras^{V12} overexpressing cells exhibited lower cell stiffness earlier than obtaining the transformation phenotypes. MEK-1/2 inhibitor U0126 inhibited Ha-Ras^{V12} induced-cell softening and anchorage independence growth. Dominant negative Ras and mutant Raf reversed both cell stiffness and Ras-transformed phenotypes. Antitumor drugs such as Ras inhibitor trans-farnesylthiosalicylic acid (FTS) and Tricostatin A abolished Ha-Ras^{V12} overexpressing induced-cell softening. Taken these data together, Ha-Ras^{V12} induced-cell softening might confer the advantage of cell proliferation or survival on soft substratum as well as malignant phenotypes. Further investigation on the cell biological roles of lowered cell stiffness in cancer cells should facilitate our understanding of the development of cancer.

Adenomatous Polyposis Coli Mutation Leads to Increased Incidence of Head Tumors in Zebrafish.

N. Museles[1,2], Q. Weinberg[1,2], E. Glasgow[1]; [1]Georgetown University Medical Center, Washington, DC, [2]Sidwell Friends School, Washington, DC

The most common mutation in colon cancer in humans is inactivation of adenomatous polyposis coli (APC), a key inhibitor of the Wnt/β catenin pathway. In human carriers of an APC inactivating mutation, the risk of colorectal cancer by age 40 is almost 100%. Truncation of the tumor suppressor APC constitutes the primary contributor to sporadic colon cancer in humans. In the zebrafish system, the same truncated mutation causes digestive tract neoplasia. However, the incidence of tumors outside the intestinal system in the APC mutant has not been reported. In order to determine if other tumors arise at high frequency in the APC mutant, we monitored our population of heterozygous APC fish on a weekly basis over a one-year period. Specimens displaying evidence of tumors or general signs of declining health were euthanized, photographed, tail clipped for genotypic analysis, and then fixed and embedded in Paraplast for histological examination. Analysis of the data showed that 1.2% of the APC mutant zebrafish within our facility had abnormally enlarged and distended abdomens (possibly from intestinal neoplasia), and 1.8% of the mutants developed head tumors. We have yet to detect a single head tumor in the non-APC carriers in our facility. Overall, the information collected reveals that APC mutant zebrafish exhibit remarkably increased incidence of externally visible head tumors when compared to incidence in wild type fish. Pathological investigation of tumor-stricken fish uncovered the highly invasive nature of these head tumors. Furthermore, relative to other zebrafish mutants, APC zebrafish begin developing tumors early in the life cycle. The APC mutant zebrafish is particularly susceptible to aggressive head tumors, providing new opportunities for cancer research in the zebrafish system.

1356

Role of 14-3-3 gamma in centrosome duplication and neoplastic progression.

A. Mukhopadhyay[1], S. Dalal[1]; [1]Sorab's Lab, Tata Memorial Centre, ACTREC, Navi Mumbai, India

Cells, to achieve neoplastic transformation, need to proceed through a phase of genomic instability towards the genomic stability. Down-regulation of a pSer/Thr-binding protein 14-3-3gamma, increases aneuploidy and causes early tumor formation in SCID mice. These observations raise general questions that how the depletion of 14-3-3gamma causes genomic instability and how the unstable cells gradually achieve stability afterwards. One of the major reasons for genomic instability is unequal segregation of chromosomes during cell division. Unequal chromosome segregation is caused by asymmetric spindle organization. Spindle is generated in mammalian cells from a spindle organization centre known as centrosome. Depletion of 14-3-3gamma by short hair-pins causes multiple centrosome formation, a state that disrupts the bipolar chromosome segregation system during mitosis. Multiple centrosome foci correspond to the multiple spindle foci which in turn cause asymmetric segregation of chromosomes. To understand the fate of asymmetrically divided cells, the knockdown cell line was studied from an early passage to a very high passage. Cell death was found to be high at lower passage but the death rate gradually decreased with the increase of passage. Moreover, cells in higher passage showed an effective bi-polar spindle orientation in spite of having multiple centrosomes. This leads towards the stability and transformation.

Mechanistically, depletion of 14-3-3gamma activates Cdc25 phosphatases which in turn activate CycB1/CDK1 and CycE/CDK2 complexes. Active CDK1 and CDK2 phosphorylates NPM1 at T199 residue. Upon phosphorylation, NPM1 gets separated from the mother centriole and the licensing of daughter centriole formation begins at the G1/S checkpoint. Therefore, knockdown of 14-3-3gamma disrupts the centrosome duplication cycle causing centrosome amplification which leads to genomic instability and neoplastic progression.

1357

SFRP1 and IGFBP3 are secreted mediators of senescence.

D. J. Elzi[1], M. Song[1], K. Hakala[2], S. T. Weintraub[2], Y. Shiio[1]; [1]Greehey Children's Cancer Research Institute, Univ Texas Hlth Sci Ctr-San Antonio, San Antonio, TX, [2]Department of Biochemistry, Univ Texas Hlth Sci Ctr-San Antonio, San Antonio, TX

Cellular senescence is widely believed to play key roles in tumor suppression, but signaling pathways mediating senescence are incompletely understood. By analyzing the proteins secreted from senescent cells, we identified two novel mediators of senescence.

1) Employing the quantitative proteomic analysis of secreted proteins, we determined that the Wnt signaling inhibitor SFRP1 (Secreted Frizzled-related Protein 1) is over-secreted from IMR-90 human primary fibroblasts induced to senesce by DNA damage (etoposide treatment). Downregulation of SFRP1 by shRNA or by neutralizing antibody inhibited etoposide-induced senescence while recombinant SFRP1 by itself was able to induce senescence, indicating that SFRP1 is necessary and sufficient for senescence induction. SFRP1 induced senescence through inhibition of Wnt signaling and activation of the Rb pathway. Interestingly, cancer-associated SFRP1 mutants were defective for senescence induction.

2) In addition to normal cells, cancer cells also undergo senescence upon chemotherapeutic drug treatment. We observed that non-senescent MCF-7 breast cancer cells become senescent upon addition of the conditioned medium from senescent MCF-7 cells induced to senesce by

doxorubicin treatment, which suggested the presence of secreted mediator(s) of senescence. Proteomic comparison of protein secretion from senescent and non-senescent MCF-7 cells revealed that IGFBP3 (insulin-like growth factor binding protein 3) is over-secreted from doxorubicin-treated senescent MCF-7 cells. We found that IGFBP3 can be cleaved and inactivated by t-PA (tissue-type plasminogen activator). t-PA is negatively regulated by another known secreted mediator of senescence, PAI-1 (plasminogen activator inhibitor 1). We have discovered a cascade whereby PAI-1 induces senescence through the elevation of IGFBP3 levels. IGFBP3 is known to modulate the activities of insulin-like growth factors and display anti-proliferative effects on some cancer cells. RNAi suppression of PAI-1 or IGFBP3 inhibited senescence induction upon doxorubicin treatment of MCF-7, indicating that PAI-1 and IGFBP3 mediate doxorubicin-induced senescence in these cells.

These studies identified extracellular components of senescence signaling. Senescence mediators secreted from senescent cells may amplify the senescence response and provide a non-cell autonomous tumor suppression mechanism in precancerous cells as well as in chemotherapy-treated tumor cells.

1358

Effect of Androgen Receptor (AR) Expression Levels and Proteasome Inhibitors on AR Activity in Prostate Cancer Cell lines.

D. Macaulay[1], T. Taylor[1], E. Williams[1], J. Stone[2], D. Peterson[1], C. Kelly-Brown[2], L. Carson[2], G. C. Regisford[1], M. Nakka[3], W. E. Bingman III[3], N. L. Weigel[3]; [1]Biology, Prairie View A&M University, Prairie View, TX, [2]CARC, Prairie View A&M University, [3]Molecular and Cellular Biology, Baylor College of Medicine

Prostate cancer is a cancer of the male reproductive system and is one of the most common types of cancer occurring in older men. Androgen ablation therapy is the most common form of treatment for metastatic prostate cancer. Typically, prostate cancer grows back in an AR dependent but castration resistant form, hence it is important to develop means to block this activity. The aim of our project therefore was to examine the effects of proteasome inhibitors and AR antagonists on AR activity and cell growth and to characterize the transcriptional activity and overall cell growth in AR overexpressing cell lines. We also tried to determine the dose dependence of AR expression and activity in stable LNCaP cell line variants by various doses of doxycycline treatment.

The cell lines used were LNCap, VCaP, LNCaP-ARFL, LNCaP-ARV7. Casodex and MDV3100 were the AR antagonists used while Bortezomib and MLN2238 were used as proteasome inhibitors. Techniques used were qRT-PCR, Luciferase assay, ß-gal assay.

Results indicate that AR activity is reduced by proteasome inhibitors in all cell lines used. AR antagonists (Casodex and MDV3100) inhibit AR activity at lower expression levels but Casodex begins to behave as an agonist at higher levels. Dose dependence studies showed that AR activity peaks at a certain dose of doxycycline. However more testing needs to be done to further refine these results.

Cancer Therapy I

Cytotoxicity of novel ruthenium-ketoconazole complexes on a panel of human cancer cells lines.

E. Robles-Escajeda[1], A. Varela-Ramirez[1], R. Sánchez-Delgado[2], R. J. Aguilera[1]; [1]Department of Biological Sciences, Border Biomedical Research Center, The University of Texas at El Paso, El Paso, TX, [2]Chemistry Department and The Graduate Center, The City University of New York, Brooklyn, NY

Emerging novel chemical compounds with selective anti-cancer cytotoxic properties may have important consequences in the general undergoing of anticancer therapeutics. Novel ruthenium-ketoconazole compounds were characterized for their cytotoxicity activity on a panel of cancer and non-cancer cells, measured by Differential Nuclear Staining (DNS), a highly reliable imaging assay that used to determine the percentage of cytotoxicity after compound treatment. The DNS assay utilizes Hoechst to label all the cell nuclei and Propidium iodide, which only stains nuclear content of dead cells. The fluorescence signal emitted by stained cells was captured by a high-throughput bioimager in two separate channels according to the dye emission requirements. Ketoconazole is a member of the azole family that has been widely used as antifungal drug, but is also being used as a treatment for hormone-refractory cancer. The main goal of this project was to determine if the ruthenium-ketoconazole complexes had selective cytotoxicity as compared with ketoconazole alone, on cancer cell lines, with lower toxicity on untransformed human cells. Cytotoxicity assays were performed using 96-well format on three prostate cell lines (DU-145, LNCap, and 22Rv1), one of cervical origin (HeLa), one leukemia (YT NK-like) and non-tumorigenic human keratinocyte cell line (HaCaT). Our results indicate that several of the complexes induced cytotoxicity in some but not all cancer cell types, as compared with non-cancerous cell lines. Our results demonstrate that ruthenium-ketoconazole complexes are more effective than ketoconazole alone in inducing cell death in prostate cancer cell lines when compared with the non-cancerous cell line at low concentrations. These results confirm that the novel ruthenium-ketoconazole compounds have significant anticancer activity and that they may selectively induce cell death on specific cancer targets.

1360

Efficient Elimination of Cancer Cells by Deoxyglucose-ABT-263/737 Combination Therapy.

R. Yamaguchi[1], E. Janssen[2], G. Perkins[3], M. Ellisman[3], S. Kitada[4], J. Reed[4]; [1]Kyushu Univ Med Sch, Fukuoka, Japan, [2]Division of Molecular Immunology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, [3]Neuroscience, UCSD, La Jolla, CA, [4]Sanford-Burnham Medical Research Institute, La Jolla, CA

Genotoxin-based chemotherapies are most effective in treating tumors at early stages of development, while recently developed targeted therapies can be very effective on certain types of cancer at later stages. For most of the common cancer types, however, these targeted therapies are not available because potential targets are not even identified in most of cancer types, let alone have targeting drugs in development. Furthermore, the recent data from the Cancer Genome Atlas Project also suggested that targeting and inactivating just one protein would not be enough to kill cells in most cancer types, implying that multiple targeted drugs may be required to kill most cancer cells. Here we described a new therapy that is safe and effective

in eliminating many cancer cells, including checkpoint defective, genotoxin-resistant, PTEN-deleted, late stage cancer cells.

The new therapy is based on combining 2-deoxyglucose (2DG), a glycolysis inhibitor, with ABT-263/737 (ABT), molecules targeting the anti-apoptotic Bcl-2 family of proteins. As single agents, ABT-263 and ABT-737 (ABT), molecular antagonists of the Bcl-2 family, bind tightly to Bcl-2, Bcl-xL and Bcl-w, but not to Mcl-1, and induce apoptosis only in limited cell types. The compound 2-deoxyglucose (2DG), in contrast, partially blocks glycolysis, slowing cell growth but rarely causing cell death. Injected into an animal, 2DG accumulates predominantly in tumors but does not harm other tissues. However, when cells that were highly resistant to ABT were pre-treated with 2DG for 3 hours, ABT became a potent inducer of apoptosis, rapidly releasing cytochrome c from the mitochondria and activating caspases at submicromolar concentrations in a Bak/Bax-dependent manner. Bak is normally sequestered in complexes with Mcl-1 and Bcl-xL. 2DG primes cells by interfering with Bak-Mcl-1 association, making it easier for ABT to dissociate Bak from Bcl-xL, freeing Bak to induce apoptosis. A highly active glucose transporter and Bid, as an agent of the mitochondrial apoptotic signal amplification loop, are necessary for efficient apoptosis induction in this system. This combination treatment of cancer-bearing mice was very effective against tumor xenograft from hormone-independent highly metastasized chemo-resistant human prostate cancer cells, suggesting that the combination treatment may provide a safe and effective alternative to genotoxin-based cancer therapies.

Development of DNA aptamers to CD44 that inhibit migration of breast cancer cells.

J. Iida[1], R. L. Clancy[1], J. R. Lehman[1], S. Somiari[2], R. Somiari[3], R. J. Mural[4], C. D. Shriver[5];
[1]Cancer Biology, Windber Research Inst, Windber, PA, [2]Tissue Bank, Windber Research Institute, Windber, PA, [3]ITSI-BioScience, Johnstown, PA, [4]Windber Research Institute, Windber, PA, [5]Surgery, Walter Reed Army Medical Center, Washington DC, Washington DC

Aptamers have several advantages over antibodies. One of such advantages is that they can be reproduced by automated chemical synthesis thus offering a wide variety of targeted modifications to introduce the resistance to biodegradation process and visualize the target molecules. Although antibodies could be generated against immunologic target molecules, aptamers are isolated by in vitro selections that are independent of the antigenicity of target molecules but dependent on specific affinity for the targets. Thus, DNA aptamers that recognize cancer cells will be easier to develop and have a great impact for the next generation of strategies for cancer detection, diagnosis, and therapy.
In this study we established a model system to develop DNA aptamers targeting cell adhesion receptors in triple negative (TN) breast cancer cells. Recent studies identified CD44 as a metastasis-related molecule with multiple functions such as promoting cell-cell and cell-ECM interactions and as cooperating with growth factor receptors (i.e. c-met), which lead to an enhancement of migration, invasion and growth of tumor cells. Although previous studies demonstrated that exon v10 of CD44 plays a key role in promoting breast tumor develop and progression, the biological functions of this exon was not entirely clear. In this study, we demonstrated that antibody against exon v10 of CD44 significantly inhibited triple negative (TN) breast cancer migration toward type I collagen. Previous studies using peripheral blood stem cells suggest that exon v10 plays a key role in promoting leukocytes adhesion to bone marrow cells and migration to disease sites in mice. Thus, it is possible that exon v10 of CD44 expressed on TN breast cancer cells would play a key role in facilitating tumor invasion and metastasis.
We, therefore, established screening systems to isolate DNA aptamers that specifically bind to exon v10 of CD44 using SELEX (systematic evolution of ligands by exponential enrichment). Using recombinant exon v10 expressed in E. coliBL21(DE3)PLysS as a substrate, we isolated 7

DNA aptamers that appear to bind to CD44+ breast cancer cells (HCC38) but not to CD44- breast cancer cells (SK-Br-3) by FACS analysis. We also identified 4 DNA aptamers that significantly inhibited alpha2beta1/alpha3/beta1-mediated TN breast cancer migration to type I collagen. Thus, developing of small molecules (i.e. DNA aptamer) that specifically recognize and antagonize the biological functions of cell adhesion receptors such as CD44 would be a promising approach for treatment of TN breast cancer patients.

1362

Novel Stilbene-based compound(s) demonstrate an anti-migratory effect against glioblastoma cells.

A. McPherson[1], P. Cagle[1], M. Franks[2], P. Martin[1]; [1]Biology, North Carolina A&T State University, Greensboro, NC, [2]Chemistry, North Carolina A&T State University, Greensboro, NC

Even with modern treatment options, glioblastoma multiforme (GBM), the most common type of brain tumor, is highly aggressive. Treatments include chemotherapy and surgery, but prognosis is usually low, with patients only surviving one to two years. Due to the fact that the brain is a sensitive organ with its own protective barrier, designing new chemical compounds to target GBMs is difficult. Therefore, we designed a study to investigate the antitumor capacity of a series of newly synthesized aromatic stilbene-based compounds (JKS001 – JKS014). We hypothesized that these compounds would be able to prevent both GBM cell proliferation and/or migration based on results from compounds synthesized with similar chemical properties and structures. To investigate the effect of these compounds on the proliferative capacity and migration rate of these compounds we utilized MTT and wound healing assays respectively. None of the JKS, stilbene-based compounds (4 µM – 400 µM) were able to significantly decrease GBM cell proliferation. However, one of the tested compounds (JKS014) demonstrated a stable decrease of GBM cell migration. Specifically, the addition of 4 µM of JKS014 resulted in significant changes in cellular morphology, represented by shortened cell extensions and less cell protrusions. These cell shape changes were accompanied by changes in actin, tubulin and cofilin. These data suggest that the novel, newly-synthesized stilbene-base compound JKS014 has the ability to alter GBM cell architecture and migration capacity as well as reduce the metastatic potential of GBM cells.

Enantiomer specific inhibition of Rac1 and Cdc42 in Ovarian Cancer.

S. R. Kenney[1], J. Roxby[1], E. Romero[2], O. Ursu[3,4], T. Oprea[3,4], L. Sklar[2,4], A. Wandinger-Ness[2], L. G. Hudson[1]; [1]Department of Pharmaceutical Sciences, University of New Mexico, Albuquerque, NM, [2]Department of Pathology, University of New Mexico, [3]Division of Biocomputing, Department of Biochemistry and Molecular Biology, University of New Mexico, [4]University of New Mexico Center for Molecular Discovery

Ovarian cancer is the 5th leading cause of cancer death for women in the United States and is frequently diagnosed at late stage with multiple secondary metastases. Ras-homologous (Rho) family GTPases contribute to metastatic dissemination through regulation of actin reorganization, cell motility, cell-cell and cell-extracellular matrix adhesion. Rho GTPases are altered in a number of human cancers and our work provides the first evidence for dysregulation of Rac1 and Cdc42 in ovarian cancer. These findings suggest that Rac1 and Cdc42 inhibitors represent potential therapeutics for ovarian cancer. Using high throughput screening we identified the R-enantiomers of ketorolac and naproxen as novel inhibitors of Rac1 and Cdc42. Although it has been noted that R-enantiomers of nonsteroidal anti-inflammatory drugs are poor inhibitors of cyclooxygenase (COX) activity, little is known about the pharmacologic activities or targets of the R-enantiomers. The objective of this study was to investigate inhibition of Rac1

and Cdc42, and associated functional activities by R-ketorolac and R-naproxen in an ovarian tumor model. Cheminformatics approaches predict that the R-enantiomers of naproxen and ketorolac bind Rac1 and Cdc42 in the inactive GDP-bound state whereas binding of the S-enantiomers was not favored and enantiomer-selective inhibition of Rac1 and Cdc42 was detected in cell-based assays. The R-enantiomers inhibited cell:cell adhesion as measured by formation of multicellular aggregates and cell migration. The cellular responses to R-naproxen and R-ketorolac were equivalent to those detected using the established Rac1 inhibitor NSC23766; the S-enantiomers were essentially inactive. An intra-peritoneal xenograft model of tumor implantation was used to determine the effects of drugs *in vivo*. Both R-naproxen and racemic [R,S]-ketorolac decreased the number of implanted tumors by 70% with little observed effect of S-naproxen or the structurally related metabolite of nabumetone 6-methoxy naphthalene acetic acid. Together, these findings indicate that R-naproxen and R-ketorolac are novel inhibitors of Rac1 and Cdc42, and inhibit cellular processes necessary for ovarian cancer metastasis. In the future, these drugs may offer benefit to ovarian cancer patients through inhibition of these GTPase targets.

1364

Insights into the Molecular Mechanism of a Novel Microtubule Stabilizer Taccalonolide A.

C. C. Rohena[1], S. L. Mooberry[1,2]; [1]Pharmacology, University of Texas Health Science Center San Antonio, San Antonio, TX, [2]Cancer Therapy and Research Center

The discovery and development of microtubule stabilizers represents one of the most useful advances in the field of cancer therapeutics. Despite their success, intrinsic and acquired resistance occurs, all of which limit their use. The taccalonolides are a class of mechanistically distinct microtubule-stabilizing agents. In cells they increase microtubule density, cause microtubule bundling and shift the equilibrium of tubulin towards the polymerized state and as a consequence, disrupt mitotic spindles, leading to mitotic arrest and cell death. The molecular events responsible for the formation of aberrant spindles and subsequent arrest and cell death are poorly understood. We hypothesize that taccalonolide A initiates aberrant mitotic signaling cascades leading to abnormal entry into mitosis and the formation of defective mitotic spindles. HeLa cells were used to probe for changes in protein expression upon treatment with taccalonolide A or taxol. Here we show that the expression and localization of proteins involved in centrosome maturation and mitotic spindle formation are altered upon treatment with taccalonolide A. Additionally taccalonolide A treatment leads to severe defects in centrosome separation which are not seen in taxol treated cells.

1365

Generation of high-grade spindle multipolarity by centrosome hyperamplification and declustering: A novel chemotherapeutic approach.

V. Pannu[1], R. Padmashree[1], R. Aneja[1]; [1]Department of Biology, Georgia State University, Atlanta, GA

Extra centrosomes pose serious organizational challenges to cancer cells. Although amplified centrosomes would be expected to compromise cell viability by compelling cells to form multipolar spindles resulting in chromosomal instability, cancer cells can turn things in their favor by employing clever mechanisms to suppress multipolarity by clustering supernumerary centrosomes. As a result, cancer cells are able to maintain bipolar spindle phenotypes with low grade aneuploidy, an edge to their survival. Since cancer cells rely on these clustering mechanisms for survival, interfering with centrosome clustering can severely jeopardize cancer cell viability. Disruption of centrosome clustering is thus an attractive tumor-selective

chemotherapeutic strategy. We have previously shown that a microtubule-modulating noscapinoid, 9-bromonoscapine (EM011) induces formation of multipolar spindles containing 'real' centrioles, indicating drug-induced centrosome amplification and declustering. We also showed that EM011 treatment dampened microtubule dynamics and impaired the association of plus-end tracking proteins like EB1 and CLIP-170 with microtubule plus-ends. Drawing from these findings, we are comprehensively exploring how EM011 induces centrosome declustering by investigating the intricate interplay between microtubule and actin cytoskeletons. Dampened microtubule dynamics accompanied by diminished articulation between microtubule plus-end binding proteins (CLIP-170 and EB-1) and actin cytoskeleton can disrupt crucial forces required to keep the centrosomes coalesced at the poles. On the other hand, within the spindle apparatus, diminished activity of minus-end-directed microtubule motors (dyenin and HSET) is responsible for impaired cross-linking and focusing of microtubules from different centrosomes to the center of the spindle apparatus. We observed that EM011 treatment caused reduced expression and activity of HSET, evidencing its multifaceted role in the disruption of centrosome clustering. In conclusion, understanding key centrosome clustering pathways will aid in identification and development of novel molecules that exacerbate spindle multipolarity, induce high-grade aneuploidy and subsequent death, selectively in cancer cells.

1366

Detection of a human anti-PDGFRα therapeutic antibody in a human GBM orthotopic rat model.

K. P. Schifferli[1], T. Barone[2], M. Czapiga[1], L. Wetzel[1], M. Mense[1], R. Plunkett[2], P. Steiner[1];
[1]Medimmune, LLC, Gaithersburg, MD, [2]Roswell Park Cancer Institute, Buffalo, NY

Glioblastoma multiforme (GBM) is the most common malignant brain tumor in adults with median survival time of one year which presents a challenge for clinical treatment. The standard of care includes tumor resection, followed by radiation and chemotherapy with temozolomide (TMZ). Despite treatment, most GBM tumors develop resistance to treatment and outcome of patients remains dismal. GBM contains several genetic alterations affecting proliferation; most commonly upregulation of autocrine signaling of platelet-derived growth factor (PDGF) and its receptor PDGFRα, which in tumor cells acts as a receptor tyrosine kinase as well as a mediator of stromal support for cancer growth.
MEDI-575 is a human monoclonal antibody that selectively targets PDGFRα. To determine anti-tumor activity in GBM tumors expressing PDGFRα, MEDI-575 was administered at 1 mg/kg or 3 mg/kg (2x/wk) to athymic nude mice bearing three different human GBM ectopic tumors (U118, U251 and SNB-19). We found anti-tumor activity of 118%, 71%, and 78% tumor growth inhibition (dTGI), respectively, and drug exposure levels in mouse serum of 30 to 80 µg/ml of MEDI-575.
The blood brain barrier (BBB), a highly specialized zone of astrocyte and endothelial cells separating circulating blood from brain tissue, is an obstacle to delivery of targeted treatment to brain tumors. To determine levels of MEDI-575 in GBM, immunofluorescence of rat brains harboring orthotopic human GBM demonstrated staining of human antibodies in GBM of rats treated with 10 mg/kg of MEDI-575 (2x/wk, 5 doses) while normal brain tissue did not show any staining. Furthermore, immunohistochemistry of rat brains with human GBM confirmed tumoral expression of PDGFRα. Surprisingly, host stromal cells within the tumor mass as well as in normal brain tissue stained for PDGFRα.
Pharmacokinetic analysis of serum from rats with orthotopic GBM showed MEDI-575 did not drop below 100 µg/mL for 3 days after five doses of MEDI-575 at 10 mg/kg, while in the brain MEDI-575 was detected at 26.0 µg/mL 48 hours after the final dose. This indicated that the BBB of rats with implanted GBM allowed MEDI-575 to pass into the rat brain. The resulting exposure levels of MEDI-575 in the GBM tumor might be sufficient to elicit a response based on active

serum levels in mouse GBM xenograft studies (30 to 80 µg/ml). These observations support ongoing Phase 2 clinical development of MEDI-575 to treat patients suffering from GBM after relapse from treatment and surgery.

1367

Development of PTK6 inhibitor which inhibits tyrosine phosphorylation in vivo.

H. Shim[1], H. Kim[1], Q. Li[2], K. No[3,4], Y. Jung[2], S-T. Lee[1]; [1]Department of Biochemistry, College of Life Science and Biotechnology, Yonsei University, Seoul, Korea, [2]College of Pharmacy, Sungkyunkwan University, Suwon, Korea, [3]Bioinformatics and Molecular Design Research Center, Seoul, Korea, [4]Department of Biotechnology, College of Life Science and Biotechnology, Yonsei University, Seoul, Korea

PTK6 (also known as breast tumor kinase, Brk) is a member of a novel family of non-receptor protein tyrosine kinases that include PTK6, Srm, and Frk. PTK6, which is closely related with Src family, has an SH3, SH2 and catalytic domain but lacks myristoylation signal. PTK6 is found in more than 60% of breast tumors and breast cancer-derived cell lines but not in normal mammary tissues and benign lesions. Upregulation of PTK6 plays a role in proliferation, anti-apoptosis, migration, and anchorage-independent growth in diverse cell lines. Thus, development of PTK6 inhibitor would be important to control PTK6-positive hyperplasia including breast cancer. In an attempt to screen inhibitors of PTK6, a non-isotopic PTK6 assay system was established using GST-PTK6-Linker(ΔN)-Kinase, which is a minimal domain for catalytic activity. Using the assay system, chemicals which inhibited the catalytic activity of PTK6 were selected from a chemical library. Derivatives of a lead compound which has a novel scaffold were synthesized and further analyzed for the PTK6 inhibitory function in vitro. Then, selected compounds were examined for in vivo inhibition of PTK6 catalytic activity using PTK6-expressing HEK 293 cells and cytotoxicity to human foreskin fibroblasts using MTT assays. Finally, BC-223 (IC50 = 0.50 uM) showed the strongest inhibition to PTK6 in vivo and little cytotoxicity. BC-223 would be a valuable candidate for PTK6-inhibiting drug which can be applied for treatment of PTK6-positive carcinomas including breast cancer. [Supported from Seoul Research and Business Development grant and BK21 trainee program]

1368

Synthesis of Polyaza[N] Helicenes Potential Inhibitors of Telomerase.

A. K. Epps[1]; [1]Albany State University, Albany, GA

Telomeres consist of DNA and bound proteins located at the end of human chromosomes. Telomeric DNA are double stranded and contain the sequence (TTAGGG/CCTAAA). Telomeric DNA are known to form four-stranded complexes called G-quadruplexes in which four Guanine bases are linked to one another. The enzyme telomerase catalyzes the synthesis of telomeric DNA repeats and has been associated with cell immortalization. Because telomerase is over expressed in cancer cells, it makes a valuable target in oncology. G-quadruplex stabilization has been shown to directly inhibit telomerase catalytic activity. G-quadruplex formation at the telomeres can be promoted by natural proteins and small molecules and thereby interfere with gene expression. Such Potential inhibitors of telomerase have been found to be either large in size or helical in shape in order to effect binding. Helix-shaped molecules also known as [N]helicenes have emerged as potent ligands to G-quadruplex and therefore as telomerase inhibitors. We have synthesized polyaza[N]helicenes, compounds 7 and 9 as potential inhibitors to telomerase. Our synthesis was based on an iterative tandem of reactions, Ullmann coupling followed by diazotization first to produce substituted benzo[c]cinnoline and then to afford racemic polyaza[5]- and [7]helicenes 7 and 9.

1369

Anthracenedione-methionine conjugates as a novel class of topoisomerase II-targeting anticancer drugs with favorable resistance profiles.

C-H. Lee[1], M-Y. Hsieh[1], N-L. Chan[1], L-W. Hsin[1], H-C. Chen[1], S-C. Lo[1], J-R. Fan[1], W-R. chen[1], H-W. chen[1], T-K. Li[1]; [1]National Taiwan University, Taipei, Taiwan

Mitoxantrone (MX) and ametantrone (AT) represent two anticancer anthraquinones inducing topoisomerase II cleavable complex (TOP2cc) and cell death. However, the contributions of two human isozymes (hTOP2α and hTOP2β)-mediated DNA breaks to cancer cell-killing and other biological responses remained unknown. We studied and cross-related the cell-killing, TOP2-targeting and DNA-interacting activities of 1,4-bis(2-amino-ethylamino) MX- and AT-amino acid conjugates (M/AACs) as a potential solution to address their structure-associated isozyme targeting and drug resistance. The cell-killing ability of M/AACs correlate with amounts of DNA breaks induced. Notably, the 1,4-bis-L/L-methionine-conjugated MAC (L/LMet-MAC) induces DNA breaks, cancer cell-killing, apoptosis and anti-tumor activity rivaling those of MX whereas D/DMet-MAC is largely ineffective. Roles of hTOP2α and hTOP2β in the M/AAC-induced cellular responses were studied: (i) MACs induced reversible DNA breaks which can be effectively antagonized by TOP2 inhibitors; (ii) DNA M/AAC-induced breaks, cytotoxicity and apoptosis were reduced in TOP2-deficient conditions; (iii) MACs induced hTOP2α/βcc formation in cells and TOP2-mediated DNA cleavage in vitro. Interestingly, all steric-specific L- and D-form-Met-M/AACs significantly compromise the DNA-unwinding activity associated with MX and AT. Additionally, Met-MACs are poor MDR-1 substrates. These results suggested that both enzyme- and DNA-drug interactions contribute to TOP2 isozyme-targeting and cell death induced by M/AACs and L/LMet-MAC represents a promising class of TOP2-based anticancer drugs with reduced side-effects.

1370

The Mitotic Parameters of HeLa Cells are Altered by Dehydroleucodine.

L. Lopez[1], V. Costantino[1], C. Amaya[1], A. Losinno[1], V. Bertoldi[1]; [1]IHEM, Mendoza, Argentina

Cancer is a set of diseases in which the body´s cells become abnormal and divide without control. There are countless efforts to find agents to block the uncontrolled cell proliferation. Many sesquiterpene lactones (SL) have been isolated from medicinal plants and present a wide spectrum of biological activity. Dehydroleucodine (DhL) is a SL isolated from Artemisia douglasiana Besser, a plant that grow up in the west of Argentina. Previous results from our laboratory showed that DhL delays the proliferation of HeLa cells, arresting them in G2/M phase of the cell cycle. In this work we analyzed whether DhL affects M phase of HeLa cells. Cells synchronized in G1/S by double thymidine treatment, were stimulated to proliferate with 10% fetal bovine serum in presence of 0-20 μM DhL. The cells were photographed since time 0h of treatment, every 15 min during 32h using a Nikon Eclipse TE 2000-U microscope. The treatment with 10 and 20 μM DhL delayed the entry of cells to mitosis (4.33 ± 1.85 and 4.52 ± 1.06 h respectively) and increased the time that the cells spend in division (7.01 ± 1.07 and 6.43 ± 0.58 h respectively). 20 μM DhL extended 0.17 ± 0.04, 5.07 ± 0.58 and 1.78 ± 0.24 h the time of prophase, metaphase-telophase and cytokinesis respectively. These results show that DhL generated a delay of HeLa cell to enter to mitosis and an increase of the time that spend in division.

1371

Cloning of a novel centrin target.

A. M. Rodriguez[1], A. M. Gomez[1], B. Pastrana[1]; [1]University of Puerto Rico At Mayaguez, Mayaguez, PR

The origin of many disease states has been linked to genetic mutation, defects in gene expression, nuclear excision repair and ribosome biogenesis. Centrin, a calcium binding protein, has recently been found to regulate some of these processes along other target proteins within the nucleus. One target, Krr1, contains a K homology (KH) domain; which has been identified as a nucleic acid recognition motif, required for proper processing of pre-rRNA, for synthesis of 18S rRNA, and for the assembly of the 40S subunit. Our initial findings have identified a putative centrin binding site located within the KH domain of Krr1 within the Homo sapiens (Hs) centrin 2 (Hscen2-HsKrr1 complex) using bioinformatics tools. In this study, the KH domain (192 bp) was amplified by PCR and then ligated to the expression vector pET100 which adds a His tag to the peptide. Colony PCR was performed to identify the E. coli colonies that have been transformed effectively with the desired recombinant. The KH domain was then expressed in E. coli cells. To identify the presence of this peptide in the bacteria, an SDS-PAGE was performed. The overexpressed KH domain peptide will be purified and used for interaction studies with Hscen2.

1372

Tissue Inhibitors of Metalloproteinase 2 Up-regulates Beta-catenin Activity in Melanoma Cells.

Y. Xia[1,2], S. Wu[3], J. Sun[4]; [1]University of Rochester, Rochester, NY, [2]Brighton High School, Rochester, NY, [3]Medicine, University of Rochester, [4]Medicine, University of Rochester, Rochester, NY

The tissue inhibitor of metalloproteinases family including tissue inhibitor of metalloproteinases-2 (TIMP-2) regulates the activity of multifunctional metalloproteinases, which regulate the pathogenesis of melanoma and other diseases. Beta-catenin plays a critical role in cell proliferation and tumorigenesis. We have established stable melanoma cell lines: parental A2058 expressing, A2058T2 overexpressing and A2058T2R underexpressing TIMP-2. In the current study, we used these cell lines to examine the relationship between TIMP-2 expression and beta-catenin activity. The TIMP-2 regulation of the beta-catenin activity was investigated at different levels, including total and phosphorylated beta-catenin, cellular location of beta-catenin, beta-catenin transcriptional activity, target gene expression, and cell proliferation. We found that the beta-catenin significantly increased in the A2058T2 overexpressing TIMP-2. TIMP-2 overexpressed cells had the lower basal level beta-catenin compared to the parental A2058 cells. The distribution of beta-catenin was also altered by TIMP-2-over-expression. Beta-catenin showed strongest immunofluorescence in circumfrential rings around each cell at sites of cell-cell contact in A2058T2, weaker staining in A2058T2R. Functionally, the cells growth was slower in TIMP-2 under-expression cells compared to A2058 cells and A2058T2 overexpressing TIMP-2. Our data demonstrate that the expression level of TIMP-2 protein can directly modulate the beta-catenin pathway in human melanoma cells. We explored the mechanisms of TIMP and beta-catenin in regulating proliferation in the cancer cells. Insights in the molecular mechanisms of TIMP in cancer will provide promising opportunities for therapeutic intervention.

1373

A novel ATM inhibitor that can target cell cycle checkpoints and increase radiosensitivity.

C. Lin[1], Y. Cui[2]; [1]Jilin University First Hospital, Changchun, China, [2]Harbin Medical University

The ATM kinase is one of the essential DNA damage response elements that play critical roles in regulation of cell cycle checkpoints in the presence of DNA damage. The enzymatic activity of ATM, enhanced after ionizing radiation (IR), is responsible for ample phosphorylation of downstream targets. The functional role of phosphorylation is to activate cell cycle arrest in order to coordinate DNA repair. Specific inhibitors that can interference with the kinase activity of ATM deem to be valuable for studying DNA damage response mechanisms as well as to be explored as sensitizing agents to cancer radiotherapy. Here we report that Quercetin (3, 3 ', 4', 5, 7 - Five-flavonoids) , a main component of flavonoids, with multifunctions on immune function, anti-oxidation, anti-viral, anti-inflammatory, and cardiovascular protection, possess properties to inhibit ATM in the DNA damage response. We show that quercetin abrogates the activation the G2/M checkpoint in response to IR. Further we show that ATM activation is diminished after IR when treated with quercetin. We also tested the *in vitro* radio-sensitization activity of quercetin in DLD1, HeLa and MCF-7 tumor cell lines by colony formation assays. We find that quercetin can significantly increase tumor radiosensitivity. The *in vitro* Sensitization Enhancement Ratio in DLD1, HeLa and MCF-7 cells were 1.87, 1.65, and 1.74, respectively. However, ATM-deficient cells failed to be sensitized by quercetin, indicating a specific inhibitory effect of quercetin on ATM. We also assessed *in vivo* activity in the DLD-1 human colorectal cancer xenograft model in nude mice. We find that the mean doubling time of tumor xenografts is significantly increased in irradiated mice treated with quercetin. Taken together, we have identified that quercetin is a novel ATM inhibitor that can target ATM-mediated pathways and enhance tumor radiosensitivity.

1374

Enhancement of Hepatic Phase I and Phase II Enzyme in the Carcinogenesis Prevention by an Anti-inflammatory Sesquiterpene α-Humulene.

K. Sasaki[1], K. Wada[2], E. Kimura[2], T. Yoshimura[2], K. Matuoka[1]; [1]Chiba Institute of Science, Choshi, Japan, [2]Health Sciences University of Hokkaido

Hepatocytes play a primary role in carcinogen detoxification through the functions of "phase I" and "phase II" drug-metabolizing enzymes, which also work in other cell systems and organs. Cancer chemoprevention is suppression of carcinogenesis by means of naturally occurring or synthetic chemicals and, as the molecular mechanism, those enzymes are considered to protect cells from various xenobiotics. In the present study the effects of α-humulene (HUM) on the expression and activities of hepatic phase I and phase II enzymes have been analyzed. HUM is a sesquiterpene compound found in the essential oils of various plant species and is suggested to be anti-inflammatory and anticarcinogenic. First, the antitumor activities of HUM were confirmed by two-stage mouse skin carcinogenesis test. Skins were exposed to a tumor initiator 7,12-dimethylbenzo[a]anthracene and one week later were treated repeatedly with HUM followed by a tumor promoter 12-O-tetradecanoylphorbol 13-acetate for 20 weeks: HUM suppressed tumor formation by 75%. Next, hepatic enzymes were analyzed by using the tissues from mice treated orally with HUM once a day for 4 successive days. The contents of total cytochrome P450 and cytochrome b5 increased by up to 54% and 32% due to HUM. The activities of hepatic phase I enzymes 7-ethoxycoumarin O-deethylase, 7-ethoxyresorufin O-deethylase and 7-propoxyresorufin O-depropoxylase increased by up to 92, 47 and 885%, respectively. As to hepatic phase II enzymes, glutathione S-transferase (GST) activities toward 1-chloro-2,4-dinitrobenzene and 1,2-dichloro-4-nitrobenzene increased by up to 67% and 178%,

respectively, with western blotting analysis showing slight elevation of the GST subtype contents. Moreover, HUM significantly elevated the GST activity toward potent carcinogen 4-nitroquinoline 1-oxide, NAD(P)H:quinone reductase activity and hepatic glutathione contents. Taken together, HUM has been demonstrated to be a bifunctional inducer, which enhances both the phase I and phase II enzymes of the liver. The present results suggest that the carcinogenesis suppression by such anti-inflammatory or anticarcinogentic molecules as HUM involves modulations of the phase I and/or II drug-metabolizing enzymes.

The Effects of Chitosan on Localization, Expression and Secretion of Osteopontin in an Ovarian Cancer Cell Line, SKOV-3.

A. M. Hicks[1], J. Stone[1,2], T. Taylor[1], E. Williams[1], D. Peterson[1], L. Carson[2], G. Regisford[1]; [1]Department of Biology, Prairie View A&M University, Prairie View, TX, [2]Cooperative Agricultural Research Center, Prairie View A&M University, Prairie View, TX

The most fatal of the gynecological cancers, epithelial ovarian cancer has a high recurrence rate despite current treatments of surgery, followed by chemotherapy and radiation. Although elevated levels of osteopontin (OPN) are always present in the ovaries, recent studies have implicated this protein as a novel biomarker for ovarian cancer. Novel treatments with fewer adverse effects than current treatments are currently being investigated. Chitosan, a natural polysaccharide that is biodegradable and biocompatible, may serve as a potential alternative treatment for ovarian cancer, and may function by regulating OPN expression and secretion. Therefore, the objective of this study was to determine the effects of chitosan on the localization, expression, and secretion of OPN in SKOV-3 cells. We hypothesized that the expression and secretion of OPN protein will be down-regulated in a dose-dependent manner. To test this hypothesis, SKOV-3 cells were treated with 0, 50, 100, 250, and 500, ng/mL of chitosan for 48 hours. Cells were harvested; total protein isolated and then subjected to SDS-PAGE and Western blot analysis. Immunocytochemistry was also used to determine localization of OPN in SKOV-3 cells, while an ELISA assay was used to determine OPN secretion. Osteopontin (OPN) was localized on the membrane of SKOV-3 cells. The expression and secretion of OPN was significantly decreased in chitosan treated-SKOV-3 cells in a dose-dependent manner. These data suggest that chitosan may inhibit ovarian cancer cell growth by decreasing the expression and secretion of OPN.

A Natural Product, Schweinfurthin A, Inhibits the Growth Kinetics of Malignant Peripheral Sheath Tumor Cells with Quantitative Effects on Actin Cytoskeleton Morphology.

T. Turbyville[1], D. Chen[1], A. Hott[1], J. Donkor[1], J. Kirkwood[1], A. Brafman[1], J. Beutler[2], K. Reilly[3], S. Lockett[1]; [1]Optical Microscopy and Image Analysis Lab, SAIC-Frederick, Inc, Frederick, MD, [2]Molecular Targets Laboratory, Center for Cancer Research, NCI Frederick, Frederick, MD, [3]Mouse Cancer Genetics Program, Center for Cancer Research, NCI Frederick

Malignant Peripheral Nerve Sheath Tumors (MPNST) are a frequent cause of morbidity and mortality in Neurofibromatosis type 1 patients. One of the driving forces in the development of these tumors is loss of function of the NF1 gene. We previously found that NF1-deficient astrocytoma and MPNST tumor cell lines derived from both patients and a Nf1-/+;Trp53-/+ (NPcis) mouse model are highly sensitive to a natural product Schweinfurthin A (SA). Conversely, when the NF1 Ras Regulatory domain was re-expressed in these cells, they became resistant to SA. (Turbyville, et al 2011). In addition to effects on proliferation, this small molecule has unique effects on the actin cytoskeleton mediated, at least in part, by the Rho pathway, which is downstream of NF1. The objective of this study is to better characterize the

effect on proliferation and on the actin cytoskeleton, and to see whether these effects are related or merely epiphenomena. Here we show that two independently isolated MPNST cell lines from the NPcis mouse are differentially sensitive to SA, that the more sensitive cells have slower growth kinetics and are unable to recover log growth kinetics as quickly as the more resistant cells. In order to elucidate further the cytoskeleton changes we attached SA and DMSO treated cells to concave fibronectin micropatterns on coverslips. We observed differences in the ability of the cell lines treated with DMSO control to maintain convexity on the non-adhesive edges of the cells, which is masked by the random morphology observed when cells are grown on regular coverslips. Specifically, quantification of cortical actin curvature between the two untreated cell lines was significantly different ($p < 0.01$) implicating a functional relationship between membrane tension and proliferation. Treatment of cells on micropatterns with 100 nM SA revealed remarkable morphological differences that were not observed in normal culture. On micropatterns the more sensitive cells showed greater concavity as compared to the more resistant cells, which were markedly more convex. Taken together these results suggest a functional relationship between cell shape, membrane tension, adhesion and proliferation. Future studies will attempt to elucidate these findings using quantitative mathematical modeling.

Crude Rosehip Extracts Prevent AKT/mTOR and MAPK Signaling in Glioblastoma Cells Which Results in Cell Cycle Arrest.

P. Cagle[1], O. Idassi[1], J. Carpenter[1], P. M. Martin[1]; [1]Biology, North Carolina A&T State University, Greensboro, NC

Glioblastoma multiforme (GBM) are aggressive malignant tumors that develop in the brain. GBMs demonstrate increased rates of cell proliferation, a lack of apoptosis as well the propensity to migrate to distal sites in the brain. The clinical management of glioblastoma consists of surgical resection followed by radiotherapy and chemotherapy. However, this treatment regimen is not very effective and more effective therapies need to be developed. Therefore, we investigated the use of natural products as anti-tumor agents against brain tumors. We tested the antiproliferative capacity of extracts from the Rosehip (*Rosa* canina) plant. Rosehip extracts have been used as dietary supplements to relieve symptoms associated with diarrhea, gastritis, rheumatoid arthritis and have recently been shown to have anti-oncogenic properties. We tested the efficacy of rosehip extracts in three human GBM cell lines A-172, U-251MG and U-1242MG. All of the cell lines treated with Rosehip extracts (1 mg/ml - 25 µg/ml) demonstrated a decrease in cell proliferation. The Rosehip extract-mediated decrease in cell proliferation was equal or greater than the decrease of cell proliferation observed when LY294002 (20 µM) or U0126 (10 µM), known Akt and Mek inhibitors respectively, were utilized. Additionally, pretreatment of the U-1242 MG cells with the Rosehip extracts (1 mg/ml - 25 µg/ml) decreased Akt and p70S6K as well as Erk and Fra-1 phosphorylation, suggesting these extracts prevent GBM cell proliferation by blocking Akt/mTOR and MAPK signaling mechanisms. Results from colorimetric apoptotic assays and flow cytometry studies demonstrate that rosehip extracts are inhibiting cell proliferation by promoting cell cycle arrest but does not elicit apoptosis. Taken together these data suggest that Rosehip extracts are capable in slowing GBM cell proliferation by altering the cell cycle. More importantly, rosehip extracts may serve as an alternative or supplement to current therapeutic regimens for GBMs.

Cytotoxic Properties of Natural Plant Extracts on Various Human Malignant Cell Lines.

Y. Ni[1], C. Liu[1], Y. Yang[1]; [1]Biological Science, Emporia State University, Emporia, KS

OBJECTIVE: This work aims to compare the cytotoxic properties of various natural plant extracts (phytochemicals) on human malignant tumor cell lines, and to investigate the mechanisms through which phytochemicals exert the cytotoxic effect on tumor cells. METHODS: 10 natural plant extracts (cinnamon leaf oil, its constituents including eugenol, methyl eugenol, o-eugenol, isoeugenol and trans-cinnamaldehyde, resveratrol, luteolin, zerumbone, oleanolic acid) were screened for cytotoxicity against human malignant melanoma cell line (WM1552C) by using a MTS proliferation assay in vitro. The two plant extracts that showed the highest cytotoxicity were tested on three additional more invasive human malignant melanoma cell lines (A-375, SK-MEL-5,SK-MEL-28), three human breast cancer cell lines (MDA-MB-468, BT-20, T47D) and a human prostate cancer cell line (PC-3). The apoptosis induction of WM 1552C cells was examined by Annexin V- FITC/PI staining followed by flow cytometry, Hoechst 33342 stain, pan-caspase inhibitor and determination of caspase 3 expression by RT-PCR and Western Blot. RESULTS: All natural plant extracts except o-eugenol, isoeugenol and methyleugenol showed strong inhibitory effect on the proliferation of maglignant melanoma WM1552C cells in both time and dose-dependent manners, with IC50 values at 48h of the range between 10.8 - 39.2 μM. Zerumbone exhibited significant cytotoxicity on all four malignant melanoma cell lines, three breast cancer cell lines and prostate cancer cell line PC-3. Zerumbone significantly increased the percentage of Annexin V- FITC positive WM1552C cells, and caused apoptosis-characteristic fragmented nuclei in WM1552C cells. The expression of apoptosis executor caspase 3 were elevated at both mRNA and protein levels in response to zerumbone. In addition, pan-caspase inhibitor Z-VAD at 0.5, 1 or 5 μM significantly alleviated the cytotoxicity of zerumbone at 5, 10 or 25 μM, and decreased the percentage of Annexin V- FITC positive WM1552C cells. Furthermore, pre-treatment with reducing agent glutathione significantly reduced the cytotoxicity of zerumbone on WM1552C cells. CONCLUSION: Zerumbone exhibited strong cytotoxicity to various human malignant cell lines. Zerumbone exerts its cytotoxic effect on malignant melanoma WM1552C cells by inducing apoptosis and oxidative stress. Zerumbone and its derivatives may be promising chemo-preventive and chemotherapeutic agents for cancers.

Drosophila Nurse Cell Dumping: Providing New Insights into Prostaglandin-Dependent Actin Remodeling.

A. J. Spracklen[1], S. A. Meyer[1], T. L. Tootle[1]; [1]Anatomy and Cell Biology, University of Iowa, Carver College of Medicine, Iowa City, IA

Prostaglandins (PGs) are small bioactive lipids that function as paracrine/autocrine hormones that have been shown to mediate actin cytoskeletal remodeling in a cell-type dependent manner. Previously, we have shown that PGs temporally and spatially regulate actin cytoskeletal dynamics during *Drosophila* nurse cell dumping, providing a novel, developmental model in which to study PG-dependent actin remodeling. Lasting just thirty minutes, *Drosophila* nurse cell dumping is a highly dynamic process requiring spatial and temporal coordination of active actin cytoskeletal remodeling in order for the nurse cells to supply their cytoplasmic contents to the oocyte. Specifically, disruption of PG signaling results in temporal, spatial, and structural defects in cytoplasmic actin filament bundles. Using both fixed and live imaging, we are developing quantitative parameters to define precise roles for PG signaling in mediating actin remodeling. In particular, we are interested in how filament length, width, number, density, elongation rate, and overall structure, are altered upon pharmacologic and genetic perturbation of PG signaling. In order to visualize real-time actin dynamics *in vivo*, we have generated transgenic flies expressing either Lifeact::mEGFP or Ftractin::mEGFP/tdTomato under the control of the UAS/Gal4 system. We have observed that germline expression of Lifeact results in disruption of normal actin remodeling during follicle development, leading to female sterility; both actin remodeling and fertility appear normal when Ftractin::tdTomato or Utophin::GFP (gift from Thomas Lecuit) is expressed within the germline. In addition to quantitatively characterizing the morphological defects associated with loss of PG signaling, we are working to uncover the mechanism by which PG signaling converges upon the actin cytoskeleton. In order to address this question, we are using an ongoing pharmaco-genetic interaction screen to identify actin binding proteins and regulatory molecules acting to mediate actin cytoskeletal dynamics downstream of PG signaling during late-stage *Drosophila* oogenesis. By combining quantitative morphometric analysis with robust genetic tools, we can begin to elucidate the mechanisms by which PG signaling mediates actin cytoskeletal remodeling.

1380

Drosophila nurse cell dumping reveals a novel interaction between prostaglandin signaling and Fascin.

C. M. Groen[1], A. J. Spracklen[1], T. N. Fagan[1], T. L. Tootle[1]; [1]Anatomy and Cell Biology, University of Iowa, Carver College of Medicine, Iowa City, IA

While actin cytoskeletal dynamics are known to be regulated by prostaglandins, lipid signals produced downstream of cyclooxygenase (COX) enzymes, the mechanisms by which PGs mediate this remain unknown. *Drosophila* oogenesis provides a model for studying how prostaglandin signaling affects actin remodeling. During oogenesis, a process called nurse cell dumping occurs. This process requires active remodeling of the actin cytoskeleton to allow the nurse cells to squeeze their cytoplasmic contents into the growing oocyte. Using this model, we have previously shown that prostaglandins are required for actin remodeling during nurse cell dumping, and that Pxt is the *Drosophila* COX-like enzyme. A screen utilizing our *in vitro* follicle

maturation assay (Spracklen, Meyer, and Tootle, unpublished data) identified Fascin (*singed* in *Drosophila*) as a downstream target of prostaglandin signaling. Fascin is an actin bundling protein that has previously been shown to be required for actin filament formation during oogenesis and nurse cell dumping. Here, we show that *fascin* and *pxt* mutants display similar actin remodeling defects in nurse cells. Reduced Fascin levels enhance the nurse cell dumping, and thus actin remodeling, defects of both COX inhibition and reduced Pxt levels. Additionally, over-expression of Fascin in the germline, using the UAS-Gal4 system, suppresses the effects of COX inhibition. Importantly, Fascin levels, both mRNA and protein, are not affected by alterations in prostaglandin signaling. Prostaglandin signaling does not appear to globally affect actin bundling, as another actin bundling protein Villin fails to interact with Pxt or COX inhibition. These data indicate that one role of prostaglandin signaling in regulating actin remodeling is to modulate Fascin activity. Current efforts are focused on determining the mechanism by which prostaglandins regulate Fascin. This novel interaction between prostaglandin signaling and Fascin has implications beyond nurse cell dumping, as Fascin is required for filopodia formation and cell migration, including during cancer cell migration.

The role of F-actin in vesicular secretion.

Y. Jang[1], P. Thorn[1]; [1]School of Biomedical Sciences, The University of Queensland, Brisbane, Australia

Acute pancreatitis is an inflammatory process that leads to auto-digestion of pancreatic tissue by premature activation of digestive enzymes within pancreatic acinar cells. One of the prominent cellular events in acute pancreatitis is formation of vacuoles and rapid disruption of the actin cytoskeleton surrounding the lumen of pancreatic ducts. Many observations have shown that secretory granules are coated with F-actin in response to secretagogue stimulation in healthy pancreatic acinar cells however the role of F-actin remodeling during granular secretion has remained unclear. Therefore, this study investigates the regulatory role of F-actin coating of secretory granules in pancreatic acinar cells. It is hypothesized that F-actin coating stabilizes the fused granule during exocytosis and this F-actin framework resists the force of granule content expansion.

Experiments were performed using clusters of acini, freshly isolated from the pancreas of 6-8 week-old male CD-1 mice. Acini were bathed in extracellular dye, sulforhodamine B before two-photon exicitation imaging was performed. The diameter of fusing granules was measured over a short period of time as they appeared after stimulation with the agonist, acetylcholine (600 nM). Under normal conditions, the granule size transiently increased at 5 seconds compared to the time of appearance and it remained constant after transient granule expansion. After treatment with Latrunculin B, actin perturbing drug, the granule diameter increased 1.25 fold of the initial diameter after 20 seconds of fusion. Also our preliminary data examined in confocal microscopy has shown that Latrunculin B inhibited F-actin coating of secretory granules. To determine the time-course and kinetics of F-actin coating of secretory granules in real time, we employed transgenic mice which express pEGFP-Lifeact (Riedl et al. 2008), which is a short peptide that has low affinity binding to F-actin. Two- photon live imaging of acinar cells from the transgenic mice was performed. A number of regions of interest were selected on the granule fusion site and the F-actin signal during granule fusion was tracked. It was observed that F-actin coating forms 6.48 +/- 0.94 s (n=55 granules) after the point of granule fusion followed by a monotonic rise as the granule becomes fully coated.

In conclusion, the results of this study suggest that loss of F-actin during secretion weakens the secretory vesicle membrane and destabilizes granules. This supports the idea that impaired F-actin polymerization leads to retention of enzymes in the cytosol which may contribute to auto-digestion of the vacuolar membrane in acute pancreatitis. Also it is further hypothesized that F-

actin granule coating will be delayed in models of pancreatitis that allows swelling of the retained content to drive dramatic increase in granule volume. We are currently working on examining the kinetics of F-actin coating during granule swelling to define the potential relationship between F-actin coating and acute pancreatitis.

Timing of endocytic actin patch assembly in fission yeast.

E. Barone[1], M. James[1], V. Sirotkin[1]; [1]Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Yeast actin patches assemble at the sites of clathrin-mediated endocytosis, where actin assembly by the Arp2/3 complex helps promote endocytic internalization using mechanism conserved from yeast to man. The Arp2/3 complex is controlled by several nucleation promoting factors including Wiskott-Aldrich Syndrome protein Wsp1 and myosin-1 Myo1. Although previous work has shown that the presence of Myo1 and activation of the Arp 2/3 complex by Wsp1 are essential for patch internalization, there is limited information on the mechanisms responsible for Wsp1 and Myo1 localization and regulation. To dissect these mechanisms, we determined the timing of localization for actin patch components in a model organism, fission yeast Schizosaccharomyces pombe, and dependencies of their localization on Wsp1 or Myo1. We selected 24 proteins that either were expected to arrive at patches early and might assist in localizing Wsp1 to the patch, or were homologs of proteins that had previously been shown to interact with WASp in other systems, such as budding yeast. We used genetic crosses and tetrad analysis to combine each specific protein tagged with Green Fluorescent Protein (GFP) either with mCherry-tagged actin-binding protein Fim1 or with myo1 and wsp1 deletions. We imaged the strains by spinning disk confocal microscopy and carried out detailed image analysis to classify proteins into four different classes. The first class included Chc1, Ede1, End3, Ent1, Sla1, Pan1, and End4. These early proteins arrived at the patch earlier than Wsp1 by at least 10 seconds. The second class included Hob1, Hob3, Bzz1, Lsb1, Lsb4, Lsb5, and Ldb17. These potential regulating proteins arrived at either the same time as Wsp1 or after Wsp1. The third class included two proteins, Cdc15 and Bbc1, that assembled into patches and remained at the plasma membrane with Myo1, suggesting that they function together with Myo1 rather than Wsp1. Analysis of genetic dependencies of localization confirmed this classification. The fourth class included Lsb6, Nak1, Ucp8, and Ent3. These proteins did not localize to patches despite prior reports that Lsb6 and Nak1 interact with WASp in vitro. Some of the examined markers also localized to other cellular structures in addition to the patches (Cdc15, Bbc1, Lsb1) or instead of the patches (Nak1, Ent3). This classification has allowed us to concentrate on proteins that potentially recruit and regulate Wsp1 and Myo1 during endocytosis, in particular BAR domain proteins that may directly link membrane curvature with regulation of actin assembly.

1383

Multifunctionality of WH2 domains : lessons from Spire, Cordon-Bleu and VopF.

M-F. Carlier[1], C. Husson[2], L. Renault[2], D. Didry[2], J. Orban[2], J. Pernier[2]; [1]UPR 3082 CNRS, CNRS-UPR 3082, Gif-Sur-Yvette, France, [2]UPR 3082 CNRS, France

WH2 domains are ~ 30 residues long, intrinsically disordered, actin binding modules, functionally evolved from ß-thymosins, that are present in a large number of proteins involved in motility. In spite of a poor signature, they all bind actin identically. Their acknowledged functional

versatility is amplified in tandem repeats found in proteins like Spire (4 WH2) and Cordon-Bleu (3 WH2), which play a role in early development and axis patterning processes, and in the bacterial effectors VopF from Vibrio cholerae and VopL from Vibrio parahaemolyticus. Their multiple functions in the regulation of actin assembly include G-actin sequestration, participation in filament barbed end assembly, filament nucleation, regulation of barbed end dynamics and filament severing. We are interested in understanding the structural basis for the multifunctional regulation of actin and how diverse profiles of regulation emerge from different selections of these multiple activities. Comparative biochemical analysis of Spire, Cordon-Bleu and VopF allows to propose simple models for filament nucleation and severing by WH2 domains.

1384

Fimbrin organizes the fission yeast actin cytoskeleton by competing with tropomyosin and crosslinking actin filaments.

C. T. Skau[1], V. Sirotkin[2], D. R. Kovar[1]; [1]The University of Chicago, Chicago, IL, [2]SUNY Upstate Medical University

Cells simultaneously coordinate the assembly and maintenance of different actin filament-based structures to facilitate diverse fundamental processes. Fission yeast builds actin filaments with precise architectures and dynamics for Arp2/3 complex-dependent endocytic patches, and formin-dependent polarizing actin cables and the cytokinetic contractile ring. Partially overlapping sets of actin-binding proteins are required for the establishment, maintenance, and disassembly of the actin filaments within these structures. A major challenge is to determine how specific subgroups of actin-binding proteins localize to a particular structure and collectively influence actin filament organization and kinetics. Through a combination of in vitro and in vivo approaches, we discovered a novel paradigm for controlling actin filament dynamics in fission yeast. A primary role of the actin filament crosslinker fimbrin Fim1 is as a ‘gatekeeper’ that controls the access of other actin-binding proteins to filaments. Specifically, we found that Fim1 prevents tropomyosin Cdc8 from binding to actin filaments, permitting cofilin Adf1-mediated filament disassembly. Therefore, the balance between Fim1 and Cdc8 is important for both endocytic actin patches and contractile ring assembly. On the other hand, filament crosslinking by Fim1 is also critical. Examination of cells exclusively expressing a truncated version of Fim1 that can bind but not crosslink actin filaments revealed that the crosslinking activity of Fim1 is important for all three actin structures. Therefore fimbrin Fim1 has diverse roles as both a filament ‘gatekeeper’ and as a filament crosslinker.

1385

Cytoskeletal tension modulates cellular responses to mechanical stimuli.

S-M. Lim[1], J. Trzeciakowski[1], H. Sreenivasappa[2], A. Trache[1]; [1]Texas A&M Health Science Center, College Station, TX, [2]Texas A&M University

The ability to measure real-time mechanosensitive events at sub-cellular level in response to discrete and physiologically relevant mechanical stimulation is the critical component in understanding mechanically-induced cellular remodeling. RhoA activation increases vascular smooth muscle cell (VSMC) contraction by promoting actin polymerization and focal adhesion (FA) formation. It has been shown that the RhoA/Rho-kinase pathway is up-regulated in animal models and also in human patients with hypertension and atherosclerosis, and treatment with Y-27632, a specific Rho-kinase inhibitor, has a protective effect inducing a decrease in VSMC proliferation and contraction. Our data show that RhoA-T19N induces low cytoskeletal tension measured by the absence of stress fibers in the cell body with actin fibers present only at the cell edges, while RhoA-Q63L induces FA and F-actin fiber formation, hence high cytoskeletal tension. The F-actin area measurements present the highest F-actin in RhoA-Q63L expressing

cells and lowest F-actin in RhoA-T19N expressing cells. Moreover, cell stiffness is directly dependent upon the cytoskeletal tension. Thus, the cells expressing RhoA-T19N are indeed much softer than the ones expressing RhoA-wt or RhoA-Q63L, while the RhoA-Q63L expressing cells are stiffer than both other treatments, respectively. This result independently verifies the decrease in the cytoskeletal tension when RhoA/Rho-kinase pathway is inhibited and the increase in the cytoskeletal tension when it is activated. Thus, our imaging data correlate well with the stiffness measurements. Further, we tested whether the cell response to tensile stress induced by AFM tips modified with glass beads coated with fibronectin depends upon cytoskeletal tension. Cells expressing RhoA-T19N are detaching from the AFM tip at a low force level because the FA formed around the AFM tip is weak due to absence of F-actin network. However, RhoA-Q63L expressing cells are found to resist to the tensile stress and exhibited a high reactive response with time. By contrast, cells treated with ML7, a potent myosin inhibitor in VSMC, show a saturation curve due to the blocking of the actomyosin contractile apparatus, hence a reduced cytoskeletal tension without F-actin disassembly. Taken together, these data show that cell-adaptive response to the applied force is modulated by the cytoskeletal tension.

1386

Mechanism of the actin cortex and shape stability during cytokinesis.

J. Sedzinski[1], M. Biro[1], A. Oswald[2], J-Y. Tinevez[3], G. Salbreux[4], E. Paluch[1]; [1]MPI-CBG Dresden and IIMCB Warsaw, Dresden, Germany, [2]MPI-CBG Dresden, Dresden, Germany, [3]MPI-CBG Dresden, Germany and Pasteur Institute, Paris, France, [4]MPI-PKS Dresden, Dresden, Germany

The formation and ingression of the cleavage furrow during cytokinesis relies on a controlled reorganization of the actin cortex. Starting from anaphase, the cortical network redistributes from the poles to the cell’s equator and gives rise to the cytokinetic ring, which separates the two daughters cells. Strikingly, cleavage does not only result from localized constriction of the ring, but also requires coordination of cortical activities at the poles of the cell. Here, we demonstrated that the presence of contractile polar cortex makes cytokinesis an inherently unstable process, where any imbalance in contractile forces between the two poles compromises the accurate positioning of the constriction ring. We show that limited asymmetric polar contractions occur during cytokinesis, and perturbing the polar cortex by number of treatments leads to oscillations in cell shape, resulting in furrow displacement and aneuploidy. A theoretical model based on a competition between cortex turnover and contraction dynamics accurately accounts for the oscillations. We further propose that blebs, membrane protrusions that commonly form at the poles of dividing cells and whose role in cytokinesis has long been enigmatic, stabilize the position of the cleavage furrow by acting as valves releasing cortical contractility. Our findings reveal an inherent instability in the shape of a dividing cell and unveil a novel, spindle-independent mechanism ensuring the stability of cleavage furrow positioning.

1387

Formation of stress-fiber arrays in fibroblasts spreading on circular adhesive islands.

Y. Tee[1], T. Shemesh[2], M. Kozlov[3], A. Bershadsky[1,2]; [1]Mechanobiology Institute, National University of Singapore, Singapore, [2]Weizmann Institute of Science, [3]Sackler Faculty of Medicine, Tel Aviv University

Well-organized system of focal adhesion-associated actomyosin cables (stress fibers, SFs) plays a major role in the maintenance of cell shape, generation of cell traction forces, and regulation of cell migration. To study the process of the organization of SF arrays, we plated human fibroblasts onto microfabricated fibronectin-coated circular adhesive islands. Cells spread isotropically over the entire area of such islands, acquiring discoid shape but not being

able to elongate. Despite isotropic morphology, many of these cells eventually form a system of parallel SFs, thus developing an intrinsic polarity. This process takes about ten hours and usually proceeds through several distinct stages. The first SFs appear at the cell periphery and form circumferential ring adjacent to the cell edge. Then the radial SFs begin to grow from the peripheral focal adhesions towards the cell center, while circumferential ("tangential") SFs move centripetally in between the radial SFs, simultaneously undergoing shortening. At this "radial stage" that can persist for several hours, the SF system still preserves the radial symmetry. A prominent transient stage that often precedes the formation of parallel SFs array is synchronous turn of the radial SFs ("cytoplasmic swirl" phenomenon). With some few exceptions, the swirl was oriented anti-clockwise, demonstrating intrinsic chirality of the SF system. Critical size of the adhesive island is required for the proper SF organization. While all the aforementioned stages in the process of SF array organization could be observed on the islands with the area of 1600 μm^2 or larger, the cells on smaller islands (1100 and 700 μm^2) are usually arrested at the stage of circumferential ring or at radial stage, which never succeeded by swirling, and were not able to organize the system of parallel SF. The unifying physical model explaining the main aspects of the SF array organization is presented.

1388

Model of Actin Turnover in the Lamellipodium that Reconciles Prior Experiment Results.

M. B. Smith[1], N. Watanabe[2], D. Vavylonis[1]; [1]Lehigh University, Bethlehem, PA, [2]Tohoku University, Japan

The structure of the lamellipodium is a brush-like network of actin filaments interacting with many regulatory proteins. While the role of actin in the lamellipodium is functionally well understood, the local rate of actin turnover appears different in different experiments. Prior FRAP experiments suggested that the fluorescence of the F-actin network rapidly recovers at the leading edge but away from the leading edge the recovery is very slow. Single-molecule fluorescence microscopy (SMFM), however, shows turnover of labeled actin monomers far into the lamellipodium. To investigate this apparent discrepancy we developed models that simulate actin turnover using parameter values and rates obtained from SMFM. We simulate actin in the lamellipodium using a reaction diffusion model where actin changes between F-actin and G-actin. We use two techniques: an approximate PDE method and a stochastic simulation of individual monomers. In the first method concentrations of actin species are considered. The PDE model calculates bulk properties of the actin network, demonstrates time scales for gross changes and aids in initialization of our second approach: simulating individual actin monomers that can transition between G-actin and F-actin. In the stochastic model actin monomers diffuse freely in the lamellipodium; if they transition to F-actin then they stop diffusing and undergo retrograde flow until they transition back to G-actin. This technique produces simulated images to compare to images acquired from experiments. We find that including a range of diffusion coefficients (that effectively simulates oligomers and actin binding to protein complexes) can explain both sets of experimental data. With this assumption: (i) fast diffusing monomers contribute to an overall treadmilling-type turnover with a majority of the polymerization happening at the leading edge and depolymerization happening away from the leading edge (ii) slowly diffusing monomers appear and disappear throughout the lamellipodium and contribute to local remodeling. By making these assumptions we can reproduces FRAP recovery curves and speckle statistics.

1389

Dynamic instability of actin-like ParM proteins: Theory and experiment.

F. Myers[1,2], R. S. McIssac[2,3], S. Milne[4], R. D. Mullins[2,5]; [1]Bioengineering, UC Berkeley, Berkeley, CA, [2]Physiology Course, Marine Biological Laboratory, Woods Hole, MA, [3]Princeton University, Princeton, NJ, [4]Mathematics, Ohio State University, Columbus, OH, [5]Univ California-San Francisco, San Francisco, CA

Although microtubule dynamic instability was discovered more than 20 years ago, no analytical theory has succeeded in connecting the phenomenology of catastrophe and rescue to underlying biochemical parameters (e.g. rate constants for elongation and GTP hydrolysis). Attempts to formulate such a theory are complicated by the fact that: (1) microtubules probably do not grow by linear, helical assembly; (2) key rate constants, including the rate of GTP hydrolysis within a microtubule, have never been measured; and (3) structural transitions at the ends of growing and shortening microtubules are not well understood. We previously showed that the bacterial actin-like protein ParM, whose assembly drives segregation of large plasmids, is also dynamically unstable. ParM filaments are simpler than microtubules and provide an ideal system for quantitative analysis. In this study we develop an analytical theory of ParM dynamic instability based on a minimal set of assumptions and compare its predictions to stochastic simulations and quantitative experiments. To study ParM assembly dynamics we created stable, chemically crosslinked ParM filaments and used them as seeds to initiate assembly of wildtype ParM. By TIRF microscopy we observed repeated rounds of growth and catastrophe from these stable seeds. Using this system we confirmed that both ends of ParM filaments elongate at the same rate and discovered that they also switch to catastrophic shortening at the same rate. Consistent with a simple cap model, we found that both the filament length and lifetime are exponentially distributed and that the major catastrophe rate decreases with filament elongation rate. Comparing measured parameters to those predicted by theory indicate that the minimal ATP cap is 3-4 protomers and is the same for both ends of the filament. Finally, we observed that 3% of all major catastrophic shortening events experienced ‘rescue’ and switched back to steady elongation after significant periods of shortening.

1390

F-actin dynamics and migration of human oral keratinocytes are affected specifically by aspartyl proteases 4-6 secreted by *Candida albicans*.

T. Woellert[1], G. M. Langford[1]; [1]Biology Department, Syracuse University, Syracuse, NY

Cell migration of human oral keratinocytes is affected when the cells are exposed to the pathogenic fungus *Candida albicans*. In a previous study, we showed that the virulence factors, secreted aspartyl proteases (Saps), produced by *C. albicans* target the actin cytoskeleton and stimulate migration of keratinocytes by ~ 2-fold. The mechanism by which Saps affect cell migration is not known. Sap proteins are encoded by a family of 10 *SAP* genes; eight of which (Sap1-Sap8) are secreted into solution by the fungus. To determine the effect on migration of individual Sap family members, we treated keratinocytes with individual GFP-*SAP* promoter strains (*SAP4-SAP6*) and a *SAP4-6*-deficient triple mutant. We used OKF6/TERT-2 cells, an immortalized cell line of human oral keratinocytes co-cultured with hyphae-forming *C. albicans*. Rates of keratinocyte migration and the cellular redistribution of actin-binding proteins (ABP’s) vinculin and the Arp2/3 complex were determined at 0, 3 and 6 hours by multi-mode high resolution microscopy and quantitative image analysis.
OKF6/TERT-2 cells exposed to wild-type *C. albicans* showed that protrusion velocities exhibited migration rates, which were significantly greater than in untreated cultures. The changes in cell migration correlated with changes in the actin filament dynamics and the distribution of ABP’s. Vinculin was localized to newly formed focal adhesions (FAs) after 3 hours of treatment and was

excluded from the leading edge of the lamellipodia that formed after 6 hours of treatment. In contrast, Arp2/3 was absent from actin stress fibers and FAs that formed at 3 hours, but localized at the leading edge of newly formed lamellipodia at 6 hours. Fluorescence intensity profiles illustrated both the coordinated redistribution of ABP's and their colocalization with the actin cytoskeleton. Exposure of OKF6/TERT-2 cells to individual Sap4-6 proteins secreted by *C. albicans* promoter strains also induced actin cytoskeleton alterations and keratinocyte responses appeared similar to those that were co-cultured with wild-type *C. albicans*. These, Sap-induced cellular changes were not observed when OKF6/TERT-2 cells were co-cultured with the *sap4-6Δ/sap4-6Δ* mutant. We conclude that the specific virulence factors Sap4-6 increase cell migration through the activation of a signaling pathway that leads to the simultaneous reorganization of the actin cytoskeleton and its associated proteins. The effect of Sap4-6 on the actin cytoskeleton of oral keratinocytes may be part of fungal invasion strategies.

LIM-kinase Dually Regulates Lamellipodium Extension by Decelerating Both the Rate of Actin Retrograde Flow and the Rate of Actin Polymerization.

K. Mizuno[1], K. Ohashi[1], S. Fujiwara[1], T. Watanabe[1], H. Kondo[1]; [1]Grad. Sch. Life Sciences, Tohoku University, Sendai, Japan

Actin filament dynamics play a fundamental role in cell migration, spreading and morphogenesis. During migration, cells extend F-actin-dense lamellipodia at the leading edge. Structurally, lamellipodia consist of polarized networks of actin filaments, with barbed ends toward the plasma membrane and pointed ends toward the rear. Whereas polymerization of actin monomers at the tip of lamellipodia is essential for lamellipodium protrusion, it also causes an actin retrograde flow. The speed of actin retrograde flow is controlled by the rate of actin polymerization, the stiffness of cortical membranes, the stability of actin filaments, and the rigidity with which actin filaments are anchored to the substratum. The rate of lamellipodium extension is determined by the balance between the rate of actin polymerization and the rate of actin retrograde flow. However, the cellular mechanisms regulating the rate of lamellipodium extension are not well understood. Cofilin is a key regulator of actin filament dynamics by stimulating actin filament disassembly near the pointed ends of actin filaments. LIM-kinase-1 (LIMK1) regulates actin dynamics by phosphorylating and inactivating cofilin. In this study, we examined the roles of LIMK1 and cofilin in lamellipodium extension by measuring simultaneously the rates of actin polymerization, actin retrograde flow and lamellipodium extension, using time-lapse imaging of fluorescence recovery after photobleaching (FRAP) of YFP-actin. In the non-extending lamellipodia of active Rac-expressing N1E-115 cells, LIMK1 expression decelerated and LIMK1 knockdown accelerated the rates of actin polymerization and actin retrograde flow, while cofilin expression accelerated and cofilin knockdown decelerated these rates, indicating that LIMK1 has a role in decelerating actin turnover by inhibiting cofilin. In the extending lamellipodia of neuregulin-stimulated MCF-7 cells, LIMK1 knockdown accelerated both the rate of actin polymerization and the rate of actin retrograde flow, but the accelerating effect on retrograde flow was greater than the effect on polymerization, thus resulting in a decreased rate of lamellipodium extension. These results indicate that LIMK1 has a dual role in regulating lamellipodium extension by decelerating both the rate of actin retrograde flow and the rate of actin polymerization and that in MCF-7 cells, endogenous LIMK1 contributes to increase the rate of lamellipodium extension by decelerating actin retrograde flow more effectively than decelerating actin polymerization.

1392

Remodeling and Generating the Cortical F-actin Array.

R. C. Augustine[1], M. Li[1], K. A. Pattavina[1], P. van Gisbergen[1], M. Bezanilla[1]; [1]Univ Massachusetts-Amherst, Amherst, MA

Dynamic remodeling of cortical actin is essential for polarized growth in plant cells. To investigate factors that drive cortical actin dynamics, we imaged F-actin in cells lacking particular actin binding proteins. We found that proteins that mediate actin depolymerization, not polymerization, are essential for driving rapid remodeling. For example, RNAi of actin depolymerizing factor (ADF)/cofilin inhibits polarized growth and results in a cortical F-actin array that has dynamics similar to cells treated with the actin stabilizing drug, Jasplakinolide. Knock out of Actin Interacting Protein (AIP) 1 results in an intermediate phenotype. Although detailed analysis of cortical F-actin dynamics did not reveal a difference in severing between ΔAIP1 and wildtype plants, we did observe that ΔAIP1 plants had three-fold less dynamic filament ends as well as a dramatic increase in bundling. These data suggest that AIP1 is a negative regulator of actin bundling *in vivo*.
To study the contribution of proteins that promote polymerization, we investigated the role of formins in the cell cortex. Formins are evolutionarily conserved and promote actin polymerization by nucleating and elongating actin filaments. In plants, class II formins are essential for polarized growth. Class II formins have an N-terminal phosphatase tensin (PTEN) domain that binds $PI(3,5)P_2$ and is essential for interacting with the cell cortex. Using variable angle epifluorescence microscopy, we show that cortical formin localizes to discrete spots, suggesting that there are $PI(3,5)P_2$ rich islands on the membrane. 29% of cortical formin spots move rapidly in and out of the imaging field, remaining for less than one second on the cortex. The remaining cortical formin trajectories grouped into three main categories: linear, random, and stationary (no movement greater than 0.4 µm from the origin). Treatment of cells with latrunculin B reduced cortical formin dynamics, increasing the stationary population from 58% to 91%. The random population was reduced 2.8-fold and the linear population was eliminated. These data suggest that cortical formin movement depends on actin. Importantly, actin is essential for the linear trajectories. Based on formin's ability to processively polymerize actin filaments while remaining associated with the growing barbed end, we hypothesized that the cortical formin spots moving in linear trajectories were generating actin filaments. We used simultaneous imaging of actin and formin to test this and found that cortical formin generates actin filaments *de novo* and along pre-existing filaments. Formin-mediated actin polymerization along pre-existing filaments provides a novel mechanism for bundling and organization of the cortical array.
Taken together, we have found that actin depolymerization via ADF and AIP1 promote rapid remodeling of the cortical array. In contrast, formins do not appear to drive global dynamics, rather they remodel the cortical actin array via polymerization of new filaments. Both generation and rapid remodeling of the actin array are essential for polarized growth.

1393

Excitable Actin Dynamics in Leading Edge Protrusion and Retraction.

G. L. Ryan[1], N. Watanabe[2], D. Vavylonis[1]; [1]Department of Physics, Lehigh University, Bethlehem, PA, [2]Department of Biomolecular Sciences, Tohoku University, Sendai, Japan

Periodic patterns of protrusion and retraction have been observed along the leading edge of various cell types during spreading and motility, with many cells exhibiting wave-like propagation of protrusions along the cell membranes. Research has surged in this area as the reproducibility of these patterns offers opportunities to better quantify the regulatory mechanisms of actin polymerization at the leading edge. Previous works suggest possible roles

for membrane-curvature sensing proteins, actin filament nucleators, Rho signaling, myosin contraction, and severing in this process. We imaged the lamellipodia of XTC cells using Lifeact as marker for actin, and analyzed the position of the leading edge using active contours. Constant retrograde flow indicated that protrusions and retractions were driven by fluctuations of the actin polymerization rate. We developed a 1D model of these actin dynamics as an excitable system in which a diffusive, autocatalytic activator causes free barbed end formation and actin polymerization; F-actin accumulation in turn inhibits further activator accumulation. According to the model, the leading edge protrusion rate spikes before the maximum of the free barbed end concentration. To gain mechanistic insight into how polymerization is converted into protrusion, we extended the model in 2D and compare models of free barbed end generation to experiment, using spatiotemporal correlations of leading edge velocity with concentrations of Arp2/3 complex, capping protein and VASP, as a function of distance from the leading edge. Our findings suggest that the Arp2/3 complex participates in an activation mechanism that includes additional diffusive components.

1394

Numerical analysis of dendritic actin networks formation in relation to cell movement.

M. Sugawara[1,2]; [1]Graduate School of Engineering, Chiba University, Chiba, Japan, [2]PRESTO, Japan Science and Technology Agency (JST), Kawaguchi, Japan

Actin dynamics is essential mechanism for cell movements. Recent studies have revealed a number of proteins that control actin dynamics in cells: for example, G-actin for assembly and disassembly, Arp2/3 for filament branching, ADF/cofilin for filament severing, and capping protein for termination of filament elongation. Regulatory control of these proteins causes dendritic actin networks to form close to the edge of the cell, which mediates cell protrusion, the first step in cell movements. However, because of the difficulty in measuring actin network dynamics in a living cell, it is unclear how the actin network is dynamically remodeled. Therefore, in this study, we developed a computational stochastic model of actin network dynamics based on the dendritic-nucleation hypothesis using Gillespie's algorithm. Because the protruding edge of the cell is thin, and to avoid complicating the model, we assumed growth of the cell edge to be two dimensional. As a first step, velocity of a single actin filament was analyzed based on the reaction rate equations for G-actin polymerization and depolymerization, aging of F-actin, Pi release from F-actin, and nucleotide exchange between G-actin-ADP and G-actin-ATP. As a result, the rate constant of Pi release from F-actin greatly affected its velocity. In addition, from the comparison of the velocity of the single actin filament and that of the protruding edge of the cell, it can be expected that the concentration of free G-actin should be locally high at the protruding edge. We are currently developing a dendritic actin model which includes branching of F-actin via Arp2/3, severing of F-actin by ADF/cofilin, and capping of the barbed end of F-actin by capping protein. Collaboration of ADF/cofilin and capping protein could be an important factors for actin dynamics mediating the local supply of free G-actin.

1395

Dynamic Localization of Actin Monomers Drives Actin-based Membrane Protrusion and Directional Steering of Nerve Growth Cones.

C. Lee[1], J. Zheng[1]; [1]Department of Cell Biology, Emory University School of Medicine, Atlanta, GA

Nerve growth cones of axons use actin-based motility to extend and navigate to their specific targets for brain wiring. Dynamic assembly and disassembly of actin filaments (F-actin) from monomeric globular actin (G-actin) generate lamellipodia and filopodial protrusions that, coupled with selective adhesion, steer and drive the growth cone forward. Very little is known about the

role of G-actin in spatiotemporal regulation of actin dynamics underlying growth cone motility. Here we report that dynamic localization of G-actin to the leading edge of growth cones creates regions of high G-/F-actin ratio that promote membrane protrusions for growth cone extension and guidance responses. Using various specific probes for actin monomers, we first showed the local enrichment of a pool of endogenous G-actin at the leading edge of membrane protrusions of the growth cone. Ratiometric live imaging also confirmed the localization of G-actin and further revealed its dynamic nature and association with membrane protrusions of the growth cone. We consistently observed an elevated level of G-/F-actin ratio at the leading edge of protruding lamellipodia and filopodia, which was lost when the protrusion ceased and started to retract. Importantly, the observed localized high G-/F-actin ratio was abolished when pharmacological agents were used to alter the actin dynamics. Finally, a gradient of attractive guidance molecules was found to induce an asymmetric elevation of G-/F-actin ratio that was followed by preferential membrane protrusion and growth cone extension. Together, our results indicate that dynamic localization of actin monomers may represent an important mechanism to create spatiotemporally-restricted regions of high G-/F-actin ratio to promote site-directed actin assembly and membrane protrusion during growth cone migration and directional steering in response to extracellular signals.

1396

Dynamics of actomyosin bundles in migrating keratocytes of goldfish.

H. Ikoma[1], M. Goda[1], Y. Fujiyoshi[1]; [1]Biophysics, Kyoto University, Kyoto, Japan

Fish epidermal keratocytes constitute multi-cellular layers on the outside of scales. When fish skin is injured, the wound is rapidly closed up by multilayered epidermal keratocytes migrating from the wound margin. Individual keratocytes have been often studied as a model system of cell migration. During migration, solitary keratocytes maintain a relatively constant shape with extended broad, fanlike lamellipodia at the front. It was previously reported that actomyosin bundles parallel to the leading edge were located at the boundary between the lamellipodia and the cell body. In this study, we found that thick filament bundles could exist at the rear of the cell body, utilizing a special polarized light microscope, called LC-PolScope, developed by R. Oldenbourg. Furthermore, our fluorescence microscopic studies confirmed that signal of actin filaments and phosphorylated myosin II overlapped the bundles in the birefringence patterns, but distribution of β-tubulins didn't. We also investigated the dynamics of the actin bundles with the LC-PolScope. It was revealed in the time-lapse observations that the transverse bundles form alternately at both the front and back of the cell body during the migration, and the thick actin bundles at the rear often compressed the nucleus. These results suggest that the actomyosin bundles at the rear push the heavy nucleus, contributing to the forward movement of the cell body.

1397

Investigation of the Actin Binding and Bundling Properties Of Fission Yeast Alpha-actinin Ain1.

Y. Li[1], A. Fok[1], D. R. Kovar[2]; [1]Committee of Genetics, Genomics & Systems Biology, University of Chicago, Chicago, IL, [2]Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

The actin cytoskeleton is vital for many cellular processes in eukaryotes. It provides the forces for movement during cell migration, cleaves the cell during cytokinesis, and maintains cell polarity. Multiple actin-binding proteins work together to establish a dynamic and regulated actin network that must be assembled at the right time and place for specific cellular functions. One class of actin-binding proteins consists of actin filament crosslinkers. We are focused on the

activities and cellular functions of the crosslinking protein alpha-actinin Ain1 in fission yeast Schizosaccharomyces pombe. Ain1 is thought to be the main actin crosslinker required for cytokinesis in fission yeast, since it is found specifically at the contractile ring and deletion of Ain1 results in cytokinesis defects. Alpha-actin functions as a homodimer that dimerizes via spectrin repeats. Compared with animal alpha-actinin, fission yeast Ain1 contains only two spectrin repeats instead of four. We expect that Ain1 may dimerize weakly, which may have important consequences on binding and bundling actin filaments. Therefore we have expressed and purified full length and fragments of Ain1 from bacterial and insect expression systems, and are utilizing a range of bulk and single filament assays to characterize their actin binding and bundling properties.

1398

Dynamic imaging of free barbed ends in living cells.

G. Marriott[1], M-M. Dong[1], C. Petchprayoon[1]; [1]Bioengineering, UC-Berkeley, Berkeley, CA

The regulation of polymerization from the barbed (+)-end of the actin filament is essential for motility, cytokinesis, cell polarity and endocytosis. The actin protomer at the barbed-end is unique among the ~2000 protomers within a typical filament, as it is the site of rapid polymerization, it interacts with a unique set of actin binding proteins and is juxtaposed to the plasma membrane. Understanding the mechanisms that control free barbed ends in living cells is made difficult owing to the rarity of the (+)-end protomer and transient (seconds) bursts of actin polymerization. Here we demonstrate high-contrast imaging of free barbed ends in living cells by using Kabiramide C (KabC), linked to tetramethylrhodamine (TMR). TMR-KabC binds selectively and tightly (nM) to the “barbed-end" of the actin protomer. Live cell imaging of TMR-KabC reveals transient accumulation at sites of membrane protrusion in particular within lamellipodia and on motile vesicles. On the other hand, TMR-KabC is absent from older, established filament assemblies that are brightly stained with fluorescent phalloidin, including stress fibers and focal contacts. The high quantum yield of TMR-KabC allows for few-single molecule imaging of free barbed-ends in complex samples.

1399

Effect of antioxidants on cadmium-induced actin glutathionylation and actin dynamics in rat mesangial cells (RMC).

G. Choong[1], D. M. Templeton[1]; [1]Dept of Laboratory Medicine & Pathobiology, University of Toronto, Toronto, ON, Canada

OBJECTIVES: Cadmium (Cd) is a nephrotoxic metal that accumulates in the proximal tubule and the glomerulus, disrupting normal hemodynamics. In particular, Cd has been shown previously to disrupt F-actin and shift the equilibrium towards a G-actin state in rat mesangial cells (RMC). Additionally, Cd induces oxidative stress by binding to thiol groups with high affinity thereby inhibiting redox enzymes and depleting intracellular glutathione (GSH). Glutathione is a tripeptide antioxidant capable of post-translational modification of protein thiols during oxidative stress, potentially protecting cells from irreversible protein damage. We hypothesized that i) Cd can induce actin glutathionylation in RMC, ii) the antioxidants *N*-acetyl-L-cysteine (NAC) or *tert*-butyl-4-hydroxyanisole (BHA) can attenuate this effect, iii) changes to total GSH (tGSH) levels are correlated with actin glutathionylation, and iv) actin glutathionylation affects actin dynamics *in vitro*. METHODS: RMC were serum-starved prior to treatment with 0.5-10 μM $CdCl_2$. Cells were pre-treated for 1 hr with either 50 mM NAC or 5 μM BHA. Actin polymerization was detected using pyrene-labeled actin, treated with GSH and diamide to induce glutathionylation. Finally, total GSH (tGSH) was measured at 412 nm using the DTNB GSH recycling assay. RESULTS: Cd induces glutathionylation of a 45 kDa protein in RMC in a dose- and time-

dependent manner that is reversible upon DTT treatment. By immunoprecipitation and LC-MS, we identified this glutathionylated protein to be actin. Inhibition of GSH synthesis by buthionine sulfoximine (BSO) resulted in a subsequent decrease in actin glutathionylation. Co-treatment with Cd and either NAC or BHA significantly decreased actin glutathionylation compared to Cd treatment alone, despite significant increases in tGSH. Furthermore, investigation into the effects of glutathionylation on actin dynamics *in vitro* showed that actin glutathionylation decreased the efficiency of actin polymerization. CONCLUSIONS: Cd induces actin glutathionylation in RMC and this can be attenuated by co-treatment with antioxidants BHA and NAC, though this was not correlated with tGSH levels. The shift in actin towards a depolymerized state with actin glutathionylation suggests that glutathionylation may be a potential mechanism of Cd-induced F-actin disruption in RMC.

1400

Role of CaMK-IIδ in cadmium-induced actin cytoskeleton disruption.

Y. Liu[1], D. Templeton[1]; [1]Laboratory Medicine and Pathobiology, University of Toronto, Toronto, ON, Canada

OBJECTIVES: Cadmium (Cd) is a toxic metal with significant environmental impact. We have shown that Cd activates Ca^{2+}/calmodulin-dependent protein kinase II (CaMK-II) and initiates CaMK-II-dependent apoptosis in rat renal mesangial cells (RMC). Cd also causes a selective disruption of the F-actin cytoskeleton, and inhibition of CaMK-II with KN93 partially prevents this effect. Additionally, Cd induces translocation of gelsolin to the cytoskeleton, and gelsolin is involved in Cd-induced F-actin disruption. The present study was undertaken to investigate the influence of Cd on the role of CaMK-IIδ in RMC cytoskeletal dynamics. METHODS: RMC were treated in serum-free conditions with up to 40 μM $CdCl_2$ with or without KN93. Actin polymerization was followed *in vitro* by changes in pyrene-labeled actin fluorescence. Implication of CaMK-IIδ's involvement was achieved by overexpression and silencing. RESULTS: CaMK-IIδ associates with monomeric G-actin and forms a complex with gelsolin in RMC. Partially purified recombinant CaMK-IIδ suppresses actin polymerization, suggesting it sequesters actin monomer. Cd also causes a dose-dependent increase in CaMK-IIδ association with the cytoskeleton. The cytoskeletal fraction from Cd-treated cells was found to decrease actin polymerization; KN93 significantly suppressed CaMK-IIδ cytoskeletal translocation and restored the Cd-dependent decrease in actin polymerization. The cytoskeletal fraction from Cd-treated cells overexpressing CaMK-IIδ showed a decrease in actin polymerization compared to transfeced-control cells, or compared to vector-transfected cells treated with Cd and KN93. On the other hand, silencing of CaMK-IIδ resulted in increased actin polymerization compared to the cytoskeletal fraction from control-transfected cells. Furthermore, both depletion and inhibition of CaMK-IIδ prevented translocation to the cytoskeleton of both full length gelsolin and its cleaved fragment. CONCLUSIONS: CaMK-IIδ plays a critical role in Cd-dependent disruption of the actin cytoskeleton in RMC, both through its association with actin and its influence on gelsolin translocation.

1401

Stoichiometry of Actin Regulatory Mechanisms Involving the Nck Adaptor Protein.

J. Ditlev[1,2], P. Michalski[2], G. Huber[2], L. Loew[2], B. Mayer[1,2]; [1]Raymond and Beverly Sackler Laboratory, Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT, [2]Richard D. Berlin Center for Cell Analysis and Modeling, University of Connecticut Health Center, Farmington, CT

Regulation of actin dynamics through the Nck/N-WASp/Arp2/3 pathway is essential for invadopodia formation during metastasis, development of various organ systems, and pathogen

infection. While upstream and downstream binding partners for Nck are known, the mechanism by which Nck activates nucleation promoting factors (NPFs), such as N-WASp, remains unknown. To examine the mechanism by which the Nck/N-WASp/Arp2/3 pathway induces actin polymerization, we employed a two-stage strategy involving both computational modeling and experimentation. First, we adapted the previously developed and publicly available “dendritic model of actin nucleation” using The Virtual Cell software system to test the effect of various proposed mechanisms by which Nck activates N-WASp and Arp2/3 on actin polymerization. Secondly, we tested the model predictions by implementing precise experimental manipulation in which we use antibody-induced aggregation of membrane-bound Nck SH3 domains to study the effect of the number of molecules in and the density of Nck aggregates on actin polymerization. The experimental results demonstrate that at a given Nck density, the amount of actin polymerization is only weakly dependent on the size of the Nck SH3 cluster. Rather, actin polymerization increases in a non-linear manner as local Nck SH3 density increases. This suggests that cellular responses to external stimuli involving Nck-dependent actin polymerization may be tunable simply by increasing or decreasing the density of Nck at sites of actin polymerization. In addition to this observation, our model predictions coupled with our experimental results revealed a previously unappreciated mechanism by which Nck molecules can activate N-WASp, which then binds and activates Arp2/3. The results of this study indicate that Nck-induced local actin polymerization is dependent on the density of Nck SH3 domains upstream of N-WASp and Arp2/3 and that the Nck/N-WASp/Arp2/3 pathway functions through a 4:2:1 Nck:N-WASp:Arp2/3 stoichiometry. (Supported by NIH Grants P41RR013186 and R01 CA82258)

1402

Extremely low polymerizability of a highly-divergent *Chlamydomonas* actin (NAP) as examined by ectopic expression in amphibian cultured cells.

T. Kato-Minoura[1]; [1]Chuo University, Bunkyo-ku, Japan

Novel actin-like protein (NAP), a highly divergent actin expressed in *Chlamydomonas*, shares only 65% amino acid identity with conventional actin. It is scarcely expressed in wild-type cells but is abundant in *ida5*, a mutant that lacks the conventional actin gene. Because *ida5* fails to produce actin-containing fertilization tubules, it is uncertain whether NAP can polymerize into filaments. Here I assessed the polymerizability of NAP by ectopically expressing enhanced green fluorescent protein–tagged NAP (EGFP-NAP) in cultured amphibian cells. EGFP-NAP was excluded from stress fibers but partially co-localized with endogenous actin in the cell periphery. Fluorescence recovery of NAP after photobleaching was not directional, and its turnover rate was similar to the estimated diffusion rate of monomeric actin. Therefore, EGFP-NAP likely accumulates by diffusion, not by addition to existing actin filaments. These findings suggest that NAP has extremely poor ability to polymerize and is not as effective as the conventional actin in forming actin meshwork in the cell periphery.

1403

Regulation of stereocilia length by myosin XVa and whirlin depends on the actin-regulatory protein Eps8.

U. Manor[1], A. Disanza[2], M. Grati[1], L. Andrade[1], H. Lin[3], P. Di Fiore[2], G. Scita[2], B. Kachar[1];[1]Laboratory of Cell Structure and Dynamics, National Institute on Deafness and Other Communication Disorders, NIH, Bethesda, MD, [2]The FIRC Institute of Molecular Oncology, Fondazione IFOM, Milan, Italy, [3]Department of Otolaryngology, Head and Neck Surgery, Massachusetts Eye and Ear Infirmary

Proper hearing and balance depend on the staircase shaped bundle of inner ear hair cell stereocilia, which are the actin-based protrusions or “hairs” inside our cochlear and vestibular organs which move in response to sound vibrations and head movement. In comparison to other actin protrusions (e.g. microvilli), stereocilia are extraordinary in at least 2 ways: 1) Differential regulation - in each hair cell there are rows of stereocilia with lengths that increase in height by several micrometers, but stereocilia within the same row vary in height by no more than several nanometers. 2) Length – normal epithelial microvilli are ~500 nanometers long, while stereocilia are up to 120 micrometers long. A large number of mutations that cause deafness affect proteins involved in regulating stereocilia length. Our recent work has revealed that stereocilia are dynamic structures undergoing constant renewal and regulation via the activities of numerous myosin motor proteins and their actin-regulatory cargoes. Myosin XVa (MyoXVa) and its cargo whirlin are implicated in deafness (DFNB3 and DFNB31, respectively) and have been shown to localize at stereocilia tips and to be essential for stereocilia elongation. Given that whirlin is a scaffolding protein with no actin-regulatory activity, it remains unclear how these proteins work together to elongate stereocilia. Here we show that the actin-regulatory protein Eps8 interacts with MyoXVa and whirlin, and that mice lacking Eps8 have very short stereocilia similar to MyoXVa- and whirlin-deficient mice. We also show that Eps8 localizes to stereocilia tips in concentrations directly proportional to length, showing for the first time a relationship between the amounts of an actin-regulatory protein and stereocilia length, revealing a biochemical mechanism for differential stereocilia elongation. We show that Eps8 fails to accumulate at the tips of stereocilia in the absence of MyoXVa, that overexpression of MyoXVa results in both elongation of stereocilia and increased accumulation of Eps8 at stereocilia tips, and that the exogenous expression of MyoXVa in MyoXVa-deficient hair cells rescues Eps8 tip localization. We also found that both MyoXVa and Eps8 appear in reduced amounts at the tips of whirlin-deficient stereocilia, which suggests that whirlin plays an integral role in the efficient accumulation of the MyoXVa:Eps8 complex at stereocilia tips, perhaps via its scaffolding activity. Our data demonstrates that MyoXVa, whirlin, and Eps8 are integral components of a stereocilia tip complex, where Eps8 is a central actin-regulatory element transported by MyoXVa to stereocilia tips for elongation of the stereocilia actin core. This work provides insight towards DFNB3 and DFNB31 pathologies, and identifies EPS8 as a candidate deafness gene.

1404

Adult hair cell stereocilia actin cores undergo dynamic renewal.

L. R. Andrade[1,2], U. Manor[1], B. Kachar[1]; [1]NIDCD, NIH, Bethesda, MD, [2]Institute of Biomedical Sciences, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil

Inner ear hair cell (HC) stereocilia contain parallel, uniformly polarized and crosslinked actin filaments. In earlier studies we showed that in developing neonatal HC stereocilia actin filaments are continuously polymerizing and depolymerizing in a treadmilling process that results in dynamic renewal while maintaining steady-state lengths. Whether stereocilia actin filaments are dynamically turning over throughout the lifetime of the HC, and whether mature stereocilia have any structural plasticity have remained important open questions in the hearing

research field. Furthermore, structural plasticity in HC stereocilia may be an important consideration for the development of therapeutic interventions for both inherited and acquired hearing losses. Here we report the successful culturing and transfection of adult vestibular HCs with GFP-beta- and gamma-actin. Our experiments revealed that actin filaments in mature HC stereocilia (P30) are continuously polymerizing, albeit at a much slower rate than developing HC stereocilia. Similar to what has been shown in earlier studies on neonatal tissue, the actin polymerization rate was proportional to the stereocilia length; i.e., longer stereocilia had a higher rate of actin polymerization than shorter stereocilia. Using immunogold labeling, we also show that both the beta- and gamma-actin isoforms colocalize in stereocilia actin filaments as early as embryonic day 16.5, with 40% more gamma-actin than beta-actin. In contrast, in adult mouse stereocilia, beta- and gamma-actin are homogeneously distributed in a 1:1 ratio. Interestingly, stereocilia from aging 2-year-old mice presented an almost 3:1 ratio of beta- to gamma-actin, suggesting that the expression levels of each actin isoform may be modulated throughout the lifetime of the organism. Furthermore, we show that stereocilia in aging mice often vary in size and shape, including extremely long stereocilia, revealing intrinsic plasticity in the dynamics and structure of stereocilia actin cores. Notably, these very long stereocilia are similar to the stereocilia found in various mice with mutations in stereocilia proteins such as myosin VI, gelsolin, and PTPRQ. Overall, our data provide evidence for continuous structural plasticity of adult HC stereocilia actin cores, which may lend important insight towards future attempts at therapeutic treatment of acquired and inherited hearing loss.

Actin-Membrane Interactions

1405

Modulation of Beta Actin Filament Network along the Rat Seminiferous Epithelium Cycle.

A. Lossino[1], L. Lopez[2], F. Capani[3], M. Fóscolo[1], J. Cavicchia[1]; [1]Histol/Embryol, Cuyo Univ Med Sch, Mendoza, Argentina, [2]Histol/Embryol, Cuyo Univ Med Sch, [3]UBA (Univ.Nac.Bs As Argentina)

Junctional devices in Sertoli cells play a key role in maturation and differentiation of germ cells. However it is not totally understood the cellular and subcellular organization of these specializations. By combining light and electron microscopic techniques using β-actin with prosaposin and glutaredoxin antibodies (to stain Sertoli cytoplasm) we observed the structural (confocal microscopy) and ultrastructural (electron microscopy) organization of tight and adherent junctions, which are the morphologic substrate of the blood testis barrier (BTB). Beta actin also characterizes ectoplasmic specializations found at different level of the seminiferous epithelium. Actin was quantified (western blot technique) in relation to the spermiation period in different segments of the seminiferous tubules visualized by transillumination under stereomicroscopy. We analyzed by freeze fracture the characteristics of tubular bulbar complexes, a known component of ectoplasmic specializations.All together, these different approaches also allowed us to study the complex arrangement of actin cytoskeleton of Sertoli cells branches, which surround germ cells in different stages of the spermatogenic cycle. Overall, our results show a consistent labelling of β- actin before, during and after the release of spermatozoa in the tubular lumen (spermiation) suggesting a significant role of the actin network in spermatic cells differentiation. In conclusion, significant interrelations among the β-actin network, the junctional complexes of the BTB and the ectoplasmic specializations were detected at different stages of the seminiferous cycle.

Photoinactivation of dynamin reveals its essential role in invadosomes, actin-rich adhesion sites implicated in invasion.

O. Destaing[1], S. Ferguson[2], A. Grychine[1], C. Oddou[1], P. De Camilli[2], C. Albiges-Rizo[1], R. Baron[3]; [1]Institut Albert Bonniot CNRS U823, Grenoble, France, [2]Yale university, [3]Harvard University

In addition to its role in endocytosis, dynamin has been shown to be associated with actin rich structures. To explore the specific role of dynamin in actin dynamics, we investigated its functions in invadosomes; 3-dimensional actin-rich adhesion structures, homologous to podosomes and invadopodia. Invadosomes are implicated in adhesion, motility and invasion and are constituted of actin cores, formed of long F-actin bundles maintained perpendicularly to the substratum, linked by F-actin fibers parallel to the substratum, the actin cloud. We show here that dynamin depletion by conditional gene knockout in v-Src-transformed fibroblasts triggers a complete disorganization of invadosomes and inhibition of their invasive properties. To regulate actin, dynamin acts not only as a simple adaptor protein for actin regulatory proteins but as a membrane interacting GTPase-mechanoenzyme. Using an optogenetic approach based on the photosensitizer KillerRed, we found that dynamin photo-inactivation leads to the disorganization of the actin cloud and decrease of cores height, but without affecting their initiation. Dynamin is therefore involved in the coupling these two actin components of invadosomes and is a regulator of their actin architecture.

Antiparallel subunit contacts are present in supramolecular actin structures related to the endocytic compartment.

U. Silvan[1], C. Boiteux[2], R. Sütterlin[2], H. G. Mannherz[3], B. M. Jockusch[4], S. Bernèche[2], U. Aebi[1], C-A. Schoenenberger[1]; [1]MIH, Biozentrum, University of Basel, Basel, Switzerland, [2]Biozentrum, University of Basel, [3]University of Bochum, [4]Technische Universität Braunschweig

The transient formation of an antiparallel actin dimer, also called 'lower dimer' (LD), was first described more than 20 years ago, when chemical crosslinking with 1,4-phenylenebismaleimide (1,4-PBM) of polymerizing actin resulted in two different dimers (Millonig et al., 1988). The ability of the actin-binding proteins gelsolin and toxofilin to stabilize two actin subunits in an antiparallel configuration (Hesterkamp et al., 1993; Lee et al., 2007) provided first evidence for a role of the LD in cellular actin patterning. However, a clear link of this unconventional actin species to a specific cellular function could not be established. Since antibodies represent powerful tools to detect different actin forms in the cell (Schoenenberger et al., 2005; Schroeder et al., 2009), we generated an antibody that selectively binds to LD and not to G-actin in actin assemblies. Using this antibody, we were able to unveil the presence of LD in several cell lines by immunofluorescence and immunoelectron microscopy. Co-labeling with different marker proteins suggested an association of LD with the endocytic compartment of the cell. Our results provide strong evidence that LD contributes to the supramolecular patterning of actin assemblies in mammalian cells.

Dynamics of the Membrane Cortex in Cleavage Stage Sea Urchin Embryos.

H. F. McKay-Gudejko[1], L. M. Alford[1], D. R. Burgess[1]; [1]Biology, Boston College, Chesnut Hill, MA

The cytoskeleton is involved in the establishment and maintenance of the non-uniform distribution of membrane domains in the plasma membrane. It has been previously reported

that the lipid raft marker ganglioside GM1 is preferentially localized to the free, apical surface of cleavage stage sea urchin embryos as early as the two cell stage (Alford, et al. 2009). We investigated the spatial and temporal regulation of this polarity as well as the actin cytoskeleton using FRAP analysis of zygotes and two cell stage sea urchin embryos. The mobility of GM1 was found to be dependent on myosin light chain kinase (MLCK) activity and cytokinesis. When myosin II phosphorylation was inhibited by treatment with the MLCK inhibitor ML-7, GM1 was found to become more mobile within the plasma membrane regardless of the cell cycle stage. Compounds that inhibit cytokinesis, such as cytochalasin D and nocodazole, led to a decrease in GM1 mobility. Contrary to previous studies, we found the rate of actin recovery to be similar between the cleavage furrow and the cell pole. In addition, the rate of actin mobility increased in two cell stage embryos compared to zygotes. These studies suggest that MLCK activity is involved in the organization of lipid rafts within the plasma membrane, and that actin is highly dynamic within the cell cortex during early sea urchin development.

Cofilin is Excluded from Clusters of Influenza Hemagglutinin at the Host Cell Membrane.

M. V. Gudheti[1], T. J. Gould[1], D. Kim[1], N. M. Curthoys[1], K. A. Gabor[1], M. S. Gunewardene[1], V. V. Verkhusha[2], J. Zimmerberg[3], J. A. Gosse[4], C. H. Kim[4], S. T. Hess[1]; [1]Physics and Astronomy, University of Maine, Orono, ME, [2]Anatomy and Structural Biology, Albert Einstein College of Medicine of Yeshiva Unviersity, [3]Cellular and Molecular Biophysics, National Institutes of Health, [4]Molecular and Biomedical Sciences, University of Maine

Viruses can hijack host-cell actin to aid in entry, assembly, and exocytosis. Cell membrane organization depends on the actin cytoskeleton, and influenza virus depends on cell membrane organization for entry and assembly. Influenza infectivity relies on high concentrations of the viral protein hemagglutinin (HA) for entry by fusion with the host cell endosomal membrane. In infected cells the host-cell plasma membrane contains HA clusters that accompany other viral components to form new viruses and bud. Despite interactions between actin and other viral components, no direct HA-actin interaction has yet been reported. The aim of this study was to characterize the association between HA and host cell actin, and investigate the mechanisms which underpin this association. Results using the super-resolution method fluorescence photoactivation localization microscopy (FPALM) in non-polarized cells show that HA clusters are correlated with actin, suggesting that HA associates with specific cortical actin structures. Disrupting actin affected HA cluster organization: treatment with the actin stabilizer Jasplakinolide or the actin barbed-end binding Cytochalasin D (CytoD) each resulted in larger HA cluster areas; treatment with CytoD or the actin monomer sequestering Latrunculin A each resulted in lower HA density in clusters as compared to controls. HA molecules were also found to move along actin-rich membrane regions. We hypothesize that HA drives structural changes in cortical actin. In support of this hypothesis, relationships between influenza virus infectivity and the mitogen-activated protein kinase (MAPK) and RhoGTPase pathways have been previously observed. To test this hypothesis, confocal and FPALM were used to image photoactivatable fluorescent protein (PAFP)-tagged versions of HA and the actin binding protein cofilin, and the relative distributions of each were determined at nanometer and micrometer length scales. Cofilin molecules are excluded from HA clusters on length scales of tens to hundreds of nanometers. The anti-correlation of HA molecules and cofilin suggests that HA may be influencing local actin structure through RhoA activation. Understanding these interactions could provide novel means to target HA-actin associations without disrupting the entire cytosolic actin pool, and thus identify specific new anti-viral therapies.

Dynamic Super-Resolution PALM Imaging of the Actin Cytoskeleton in Living Mammalian Cells.

J. Higgins[1], A. Weigel[1], E. Akin[2], A. Shaw[3], M. Tamkun[2,3], D. Krapf[1,4]; [1]School of Biomedical Engineering, Colorado State University, Fort Collins, CO, [2]Department of Biomedical Sciences, Colorado State University, [3]Department of Biochemistry and Molecular Biology, Colorado State University, [4]Department of Electrical and Computer Engineering, Colorado State University

The actin cytoskeleton plays a crucial role in the organization of the plasma membrane into segregated microdomains as well as in the regulation of membrane protein localization and trafficking. Standard diffusion-limited light microscopy fails to capture the structure of the cytoskeleton since the characteristic distance between actin filaments is below 100 nm. We imaged the actin network in the vicinity of the plasma membrane in living mammalian cells using photoactivated localization microscopy (PALM). This technique enabled the observation of actin motion and turnover with super-resolution. We transfected ND7/23 and HEK293 cells for the expression of Dendra2 labeled actin, a photoswitchable fluorophore suitable for PALM imaging. The cells were imaged in a custom-built total internal reflection microscope with the capability to maintain the cells under physiological conditions for prolonged times. Images of the actin cytoskeleton with a resolution of 50 nm were obtained within an imaging time of 5 seconds.
We further used live-cell PALM imaging to study the role of the actin cytoskeleton in the maintenance of Kv2.1 channel clusters on the cell surface. Kv2.1 channels form stable clusters in the plasma membrane of hippocampal neurons and transfected HEK cells. The mechanism by which the cell maintains these clusters of mobile proteins is still not well understood. By labeling voltage gated Kv2.1 channels with quantum dots, we were able to track individual Kv2.1 channels while simultaneously imaging the actin cytoskeleton with super-resolution. Kv2.1 channels were labeled with QD705 quantum dots, which are well separated from Dendra2, enabling two-color imaging. The combination of single molecule tracking with PALM imaging revealed a complex set of interactions between the cytoskeleton and the Kv2.1 channels by which actin is actively involved in localizing the channels to specific microdomains. This work shows that the ability of PALM to generate super-resolution imaging in live cells opens the way to probe the dynamic interaction between cellular components at nanometer length scales.

Membrane tension in rapidly moving cells is determined by the balance between actin network assembly, adhesion and contraction.

K. Keren[1], A. Lieber[1], S. Yehudai-Reshef[1]; [1]Physics Department, Technion, Haifa, Israel

While the important role of membrane tension in cell motility is becoming apparent, little is known about how membrane tension is set and regulated. We measure membrane tension in rapidly moving fish epithelial keratocytes using a tether pulling assay. Membrane tension is found to range between 200-600 pN/µm in a population of keratocytes, values which are substantially higher than what has been measured for slower moving cells. To investigate the interplay between the motility machinery and membrane tension, we use various perturbations known to alter actin filament density, adhesion and contraction and study their effect. We find that decreasing the number of pushing filaments along the leading edge leads to a significant decrease in membrane tension. Moreover, we find that decreasing the adhesiveness of the substrate or increasing myosin-induced contraction also leads to lower membrane tension, whereas stronger adhesion or weaker contraction results in higher tension. These results suggest that tension is generated by growing actin filaments at the leading edge pushing against the inextensible membrane, and is relieved due to centripetal actin flow generated by myosin-powered contraction and mediated by the adhesion strength; stronger actin pushing

forces at the leading edge and/or a trailing edge which is harder to retract lead to higher tension. This notion is further supported by experiments in which large amounts of membrane are added to motile keratocytes, without changing their biochemical content, by fusion with giant unilamellar vesicles. In response to the significant increase in surface area (~25%) fused cells rapidly expand their lamellipodium, but continue to move with only minor changes in aspect ratio, speed and membrane tension. Together these results indicate that membrane tension is largely determined by the mechanical interplay between cytoskeletal forces and the membrane, and is not regulated through endo/exocytosis or other means, at least in rapidly and steadily moving cells such as keratocytes.

Microtubules and Associated Proteins

1412

Pac1p/Lis1 regulation via sumoylation.

A. Alonso[1], S. D'Silva[2], N. Meednu[2], H. Hoops[3], J. Keeling[4], M. Rahman[4], R. K. Miller[4];
[1]Biochemistry, Oklahoma State University, stillwater, OK, [2]Biology, University of Rochester, [3]Biology, State University of New York, Geneseo, [4]Biochemistry, Oklahoma State University

Microtubules are proteineceus polymers within the cell that make key contributions to cell motility and cell division. Microtubules are highly dynamic, continuously growing and shrinking. Because microtubules are fundamental for cell division, it is important to understand the molecular mechanisms that regulate them. Pac1p, the Lis1 homologue in yeast, is a microtubule plus-end-tracking protein. Mutations in the Lis1 gene have been correlated with Miller-Dieker lisssencephaly syndrome due to defects in neuronal migration. Spindle positioning in yeast is an essential process during cell division that is regulated by the KAR9 and dynein pathways. The KAR9 pathway guides cytoplasmic microtubule into the bud. Dynein pulls the spindle across the bud neck via the forces it exerts on the cytoplamic microtubule from the cortex. As part of the dynein pathway, Pac1p is important for recruiting dynein to the plus end of the microtubule. Pac1p interacts with other plus-end microtubule binding proteins including Bik1p, the CLIP-170 homologue in yeast. Although Pac1p plays vital roles for microtubule function, little is known about its regulation.

Sumoylation is a post-translational modification that covalently attaches a Small Ubiquitin-like Modifier (SUMO) protein to the target substrate. Sumoylation regulates many cellular processes such as cellular transport, protein stability, and cell cycle progression. Recently a few microtubule associated proteins including Kar9p have been shown to be conjugated to SUMO. Using a two-hybrid assay, Pac1p interacts with SMT3, the SUMO homologue in yeast, and other key players of the sumoylation pathway. Ubiquitin-Like Protein-1 (Ulp1) is a protease that specifically cleaves Smt3p from its protein conjugates. Using a temperature sensitive strain that inactivates the Ulp1p protease activity at 37°C, we observe an accumulation of higher molecular weight Pac1p bands. This suggests that the higher molecular weight forms of Pac1p are due to the accumulation of SMT3 conjugates. In contrast to ubiquitination, sumoylation is not a modification that tags the target substrate for direct degradation. However, SUMO-targeted ubiquitin ligases (STUbLs) can recognize a sumoylated substrate and promote its degradation of the substrate via ubiquitination. Using a two-hybid assay, we show that Pac1p interacts with the STUbL enzyme Nis1p/Ris1p. Strains deleted for RIS1 display an accumulation of higher molecular weight Pac1p conjugates, in comparison to WT. This suggests a novel model in which Pac1p is regulated via STUbLs.

1413

Structure-function Analysis of the Septin GTPase Interaction with Microtubules.

X. Bai[1], E. T. Spiliotis[1]; [1]Biology, Drexel University, Philadelphia, PA

The microtubule (MT) cytoskeleton is important for many cellular processes including vesicle transport and mitosis. MTs are highly organized structures and are tightly regulated. Besides well known regulators like microtubule associated proteins and plus end binding proteins, it was recently found that septins (SEPTs), a group of filament-forming GTPases, colocalize with MTs and affect MT organization and dynamics. However, how septins interact with microtubules is unknown. Mammalian septins are classified into 4 groups: SEPT2, SEPT6, SEPT7 and SEPT9. The building block of septin filaments is a SEPT9/7/6/2-2/6/7/9 octamer, in which each septin is replaceable by other members of the same group. By modeling the interaction of SEPT2/6 with microtubules, we identified a positively charged a-helix and loop domain within the SEPT2 structure. We hypothesized that these domains interact with the negatively charged C-terminal tails of tubulin. Alanine scanning mutagenesis of the positively charged residues in the a-helix of SEPT2 decreased the number of MT-associated septin filaments, while mutations in the loop region had no effect. Overexpression of the a-helix tagged with GFP led to less number of endogenous MT-associated SEPT2 filaments. This phenotype was rescued when the positively charged residues of the a-helix were mutated to alanine. These results indicated that the a-helix domain may mediate the interaction of SEPT2 with MTs. On going experiments aim at investigating whether SEPT2 interacts directly with MTs and how other septin subunits may contribute to the septin-MT interaction.

1414

Molecular Determinants for Regulation of Microtubule-Severing by Katanin.

K. D. Grode[1], J. Diaz-Valencia[2], J. L. Ross[2], S. L. Rogers[1]; [1]Department of Biology, University of North Carolina - Chapel Hill, Chapel Hill, NC, [2]Department of Physics, University of Massachusetts - Amherst, Amherst, MA

Microtubules are dynamic cytoskeletal polymers that form complex and highly organized arrays essential for cell motility, morphogenesis, and division. Microtubule-severing is a reaction that generates an internal break in the microtubule polymer and catalysis of microtubule-severing is required for the proper formation and function of microtubule-based arrays in a wide range of eukaryotic cells. The microtubule-severing enzyme Katanin is a conserved heterodimeric ATPase that severs and disassembles microtubules, but the regulatory mechanisms that control microtubule-severing by Katanin are poorly defined. To better understand the molecular regulation of Katanin, we conducted a structure-function study of the *Drosophila* Katanin catalytic subunit, termed Kat-60, using a combination of cell-based and cell-free approaches. To assess the contribution of each putative microtubule-binding region of Kat-60 to its microtubule-severing activity, we devised a quantitative assay to measure the relative loss of microtubule polymer in a large number of Kat-60 expressing cells using high-throughput microscopy. Using this assay, we found that certain microtubule-binding domains and residues of Kat-60 were more important than others for regulation of microtubule-severing. By expressing eGFP-tagged deletion derivatives and mutants of Kat-60 in living cells, we also discovered that the dynamic localization of Kat-60 on microtubules is dependent on both its microtubule-targeting and catalytic activities. Furthermore, we observed similar microtubule-severing and microtubule-targeting activities of purified eGFP-tagged full-length Kat-60 in cell-free assays compared to those found in cell-based assays, indicating that future in vitro studies of eGFP-tagged deletion derivatives and mutants of Kat-60 will be generally significant. Taken together, our results suggest that the putative microtubule-binding regions of the Katanin catalytic subunit cooperate to regulate its activity and dynamics in living cells.

1415

Single molecule studies of microtubule severing enzymes reveals their specific biophysical activities.

J. Diaz[1], M. Bailey[2], M. Morelli[1], D. Zhang[3], S. Mukherje[3], D. Sharp[3], J. Ross[1]; [1]Physics, University of Massachusetts-Amherst, Amherst, MA, [2]Physics and Molecular and Cellular Program, University of Massachusetts-Amherst, Amherst, MA, [3]Physiology and Biophysics, Albert Einstein College of Medicine, New York, NY

The spatio-temporal dynamics of microtubules is finely tuned in cells by the orchestrated activity of microtubule-associated proteins (MAPs). Severing of microtubules in vivo is performed by microtubule severing enzymes of the AAA+ family of ATPases. The initial member of this novel class of microtubule-associated proteins is katanin-60, the catalytic subunit of katanin complex that regulates microtubule length and dynamics of cell during interphase and mitosis. Other members of microtubule severing enzymes include spastin in which mutations result in hereditary spastic paraplegia, and fidgetin, which is involved in mammalian development. We have performed the first single molecule characterization of katanin-60 and first biophysical characterization of fidgetin in vitro. Interestingly, at a low concentration both enzymes remove tubulin dimers from filament ends, which appear to depolymerize. Katanin-60 prefers the plus-end and fidgetin prefers the minus-end. At higher concentration both proteins sever microtubules, but they have different localization patterns. We find katanin-60 preferentially targets to and severs at lattice defects. Fidgetin preferentially removes GMPCPP stabilized tubulin and removes extended regions of protofilaments, an activity we call “protofilament stripping”. Our results indicate that katanin-60 and fidgetin are microtubule severing enzymes with specific biophysical abilities and targeting on microtubules.

1416

Defining the Critical Function of Tubulin Carboxy-terminal Tails.

J. K. Moore[1,2], S. Swaminathan[1], J. A. Cooper[1]; [1]Department of Cell Biology and Physiology, Washington University, St Louis, MO, [2]Department of Cell and Developmental Biology, University of Colorado Health Science Center, Aurora, CO

Microtubule tracks establish transport and signaling relationships between distant sites within the cell. Microtubules are navigated by motor proteins that use energy from nucleotide hydrolysis to drive a cycle of interactions, producing movement for force generation and cargo trafficking. Although these processes depend on interactions between tubulin subunits and motor proteins, the molecular features of tubulin subunits that contribute to these interactions are poorly understood. Important questions include whether different motors utilize distinct binding sites on tubulin, and how transport may be differentially regulated at the level of the microtubule. Here we employ genetics, quantitative live-cell microscopy, and biochemical assays to examine the role of the carboxy-terminal tail regions (CTTs) of α- and β-tubulin subunits. CTTs contain an abundance of negatively-charged residues that are thought to engage in electrostatic interactions with microtubule-associated proteins, are major sites of tubulin posttranslational modification, and exhibit high sequence variation amongst tubulin isoforms in humans. Our preliminary findings identify specific pathways that depend on CTTs for function, including the microtubule motor dynein. We explore the basis for this dynein phenotype in vivo and in biochemical assays. This work provides a foundation for the study of diverse motors and features on microtubules, and will offer new insights into the mechanics of evolutionarily distinct motors.

1417

Microtubule dynamics and maintenance of fission yeast cells morphology.

P. Recouvreux[1], M. Dogterom[1]; [1]FOM Institute AMOLF, Amsterdam, Netherlands

Microtubules (MTs) are central to the organization of the eukaryotic intracellular space and are involved in the control of cell morphology. In fission yeast cells MTs transport polarity factors to poles where growth is located, thus ensuring the establishment and maintenance of the characteristic spherocylindrical shape. For this purpose, MT polymerization dynamics is tightly regulated. Using home-made automated image analysis software, we can measure the spatial dependence of MT dynamics in interphase fission yeast cells [1]. This systematic and quantitative analysis provides a tool to study the role of MT regulators. In combination with genetic modifications we aim to understand the function of +TIPs (plus-end tracking proteins) in the spatial regulation of MT dynamics. We analyze MT dynamics in round fission yeasts in order to observe the role of Tip1 during cortical contact of MT tips when generated compressive forces co-regulate MT dynamics [1]. In these mutated cells it is possible to resolve such contacts, while one cannot exclude the possibility of a contact in spherocylindrical cells [2]. Furthermore we try to decipher how the linear transport by MT interferes with the feedback circuitry that assures the correct spatial distribution of Tea1, the main polarity factor in fission yeast cells. Tea1 is delivered as packets of molecules at growing MT tips and is anchored at the membrane via a mechanism involving interaction with the membrane protein Mod5. This protein acts as a catalyst for the incorporation of Tea1 in a bipolar cluster [3]. In order to bypass this complex Mod5-mediated feedback mechanism we tagged Tea1 with a modified GFP allowing its attachment to the plasma membrane. The localization of the polarity factor at the cell pole is then expected to be due to MT-based transport only.

1418

The structural basis of microtubule end recognition by EB proteins.

S. P. Maurer[1], F. Fourniol[1], C. Moores[2], T. Surrey[1]; [1]Cancer Research UK London Research Institute, London, United Kingdom, [2]Birkbeck College, Institute of Structural and Molecular Biology, London, United Kingdom

The dynamic properties of the microtubule cytoskeleton are crucial for many cellular functions. Growing microtubule ends serve as transient binding platforms for a variety of essential proteins that regulate both microtubule dynamics and interactions with cellular substructures. End binding proteins (EBs) are crucial for the recruitment of most of these factors, as they have the unique ability to autonomously recognize an extended region at growing microtubule ends. The nature of this end region is unknown due to the lack of high-resolution structural information. Here we show, using cryo-electron microscopy (cryo-EM) and subnanometer single particle reconstruction, a pseudo-atomic model of how the calponin homology (CH) domain of the fission yeast EB Mal3 binds to GTPγS microtubules, a static mimic of the growing microtubule end region. We found that GTPγS microtubules have more extensive inter-protofilament lateral contacts than GDP microtubules. The Mal3 CH domain contacts 4 neighbouring tubulin subunits and also senses the additional, nucleotide-dependent inter-protofilament connection.
Single point mutational analysis and fluorescence imaging of microtubule end tracking in a reconstituted in vitro system confirm the relevance of the identified contacts for dynamic

microtubule end tracking in the presence of GTP. These results provide the first subnanometer resolution structure of a microtubule in a GTP-like state. They reveal the structural origin of selective binding of EBs to growing microtubule ends and strongly suggest that the entire EB binding region is an extended nucleotide-induced structural cap crucial for microtubule stability.

1419

+TIP interactions with EB1 are tuned by multisite phosphorylation and sequestration of distributed arginine residues.

P. Kumar[1], M. Chimenti[2], H. Pemble[1], M. Jacobson[2], T. Wittmann[1]; [1]Cell And Tissue Biology, Univ California-San Francisco, San Francisco, CA, [2]Department of Pharmaceutical Chemistry, Univ California-San Francisco, San Francisco, CA

Microtubule (MT) plus-end tracking proteins (+TIPs) reversibly bind to growing MT ends through interactions of a SxIP motif with EB1. +TIPs are functionally diverse and implicated in the regulation of MT dynamic instability and in transient MT interactions with other proteins and intracellular structures. In cells, +TIP interactions are thus expected to be highly spatiotemporally controlled. Consequently, plus-end-tracking of several +TIPs is inhibited by phosphorylation but the underlying molecular mechanism is not understood. CLASPs, as representative +TIPs, contain a short tandem repeat of two SxIP motifs embedded in an arginine-rich basic region, and SxIP motifs are required for EB1-mediated plus-end-tracking in vitro. Either SxIP motif is functional and can mediate specificity of plus-end-tracking. However, the SxIP motifs alone are not sufficient. We demonstrate that in cells a major part of the binding energy results from electrostatic interactions that are negatively regulated by distributed multisite phosphorylation by GSK3β, and a large degree of flexibility exists in how these binding interactions are controlled. GSK3β phosphorylation requires prior phosphorylation by a priming kinase, and both interphase and mitotic cyclin-dependent kinases (CDKs) phosphorylate priming sites in the CLASP plus-end-tracking domain. CDK1-dependent CLASP hyperphosphorylation of CLASP2 completely inhibits plus-end-tracking in mitosis. Using an in vitro fluorescence anisotropy assay to measure equilibrium binding constants we show that priming site phosphorylation alone reduces affinity for EB1 only moderately. In contrast, complete phosphorylation of the GSK3β motif abolishes the interaction with EB1. To further elucidate the mechanism by which multisite phosphorylation regulates CLASP-interactions, we employed molecular dynamics simulations of EB1 binding to a minimal CLASP plus-end-tracking module. We find that arginine residues in non-phosphorylated CLASP form extensive bidentate H-bond networks with negatively charged glutamate residues predominantly in the unstructured C-terminal tail of EB1. This ‘molecular Velcro’ is largely disrupted when the CLASP GSK3β sites are phosphorylated, and arginines are tied up in intramolecular interactions with phospho-serines, which was further confirmed by NMR spectroscopy. This results in an overall reduction of H-bond formation between EB1 and phospho-CLASP indicative of a substantially reduced binding energy, and may represent an example of a more general mechanism by which multisite phosphorylation controls protein-protein interactions.

1420

Microtubule +TIPs protein, EB1 is critically involved in Paclitaxol mediated cell cycle arrest in cancer cells.

G. E. Thomas[1], T. K. Manna[2]; [1]School of Biology, Indian Institute of Science Education & Research (IISER), Thiruvananthapuram, India, Trivandrum, India, [2]Indian Institute of Science Education & Research (IISER), Thiruvananthapuram, India, Trivandrum, India

Microtubule targeting agent, paclitaxol has been known to be most effective anticancer drug in cancer chemotherapy. It induces G2/M cell cycle arrest and kills cancer cells primarily by

interfering microtubule assembly-dynamics and associated signaling pathways. Despite its extensive clinical use, potentiality of paclitaxol is often limited duo to development of its resistance in tumor. Factors responsible for altered paclitaxol sensitivity and the mechanisms underlying remain poorly understood. Recent evidences suggest that the sensitivity of cancer cells to microtubule targeting agents is associated with the proteins involved in regulation of microtubules. In this study, we have found that paclitaxol mediated cell cycle arrest is regulated by microtubule plus end binding protein, EB1. EB1 regulates microtubule dynamics by localizing at microtubule plus end tips and has been implicated to be involved in tumorigenesis. We found that paclitaxol at sub-stoichiometric concentration increased the level of EB1 in MCF-7 breast cancer cells. SiRNA mediated knock down of EB1 resulted increased proliferation of cancer cells under paclitaxol treatment and released cells from paclitaxol mediated cell cycle arrest. Results suggest of an important role of EB1 in paclitaxol mediated mitotic arrest. Experiments are underway to uncover the molecular pathways associated with EB1 in paclitaxol mediated cell cycle arrest.

1421

Does EB1 bind to the Microtubule seam or to the lattice?

E. Ottenweller[1], J. Philip[1], H. Goodson[1]; [1]Univ Notre Dame, Mishawaka, IN

EB1 is a highly conserved microtubule plus end tracking protein (+ TIP) involved in regulating microtubule dynamics, but the mechanisms of its +TIP behavior and MT stabilizing ability remain undefined. Microtubules consist of protofilaments associated in a cylindrical lattice that closes upon itself at a seam; this seam is generally believed to be weaker than the rest of the lattice. Previous electron microscopy has suggested that EB1 binds specifically to this seam, implying that EB1 promotes MT polymerization by stabilizing the seam (Sandblad et al., Cell 2006). Microtubule binding experiments in this manuscript were interpreted as supporting the idea that EB1 binds strongly to the MT seam, providing further evidence for this model (Sandblad et al., 2006). However, close inspection of the data suggests that the reported MT binding experiments are equally consistent with weak binding along the microtubule body. Moreover, the published work was performed with S. pombe Mal3, leaving open the question of how mammalian EB1 behaves. To resolve the question of whether mammalian EB1 binds primarily to the MT seam, we are using a combination of MT binding assays and theoretical modeling with MTBindingSim. Our results argue against strong seam binding for EB1, and suggest instead that binding of EB1 to stabilized MTs is best explained by weak binding along the lattice, perhaps with concomitant binding to the seam. These observations will help establish how EB1 interacts with microtubules, which in turn is essential for fully understanding how cells regulate the dynamics of the microtubule plus end.

1422

Acetylation-dependent regulation of kinetochore microtubule dynamics by PCAF acetyltransferase.

X. Peng[1], Z. Wang[2], L. Zhang[2], B. Wu[1], T. Ward[2], X. Yao[1,2]; [1]Anhui Laboratory for Cellular Dynamics and Chemical Biology, Hefei, China, [2]Physiology, Morehouse School of Medicine

Microtubule is a key cytoskeleton network essential for cellular plasticity and dynamics in all eukaryotes. Reversible acetylation of tubulin has been implicated in regulating microtubule stability and function. Here we show that PCAF acts as an intrinsic negative modulator of microtubule stability in mammalian cells. We show that acetylation of the EB1 on conserved lysine reduces the amplitude of microtubule plus-end growth by minimizing EB1 binding to the plus-end tracking proteins. PCAF associates with EB1 and functions as a cognate EB1 acetylase, which opposes the acetylation-induced microtubule stabilization at the kinetochore.

Using fluorescence resonance energy transfer (FRET)-based sensors in living HeLa cells, we show that kinetochore-associated PCAF activity peaks during chromosome congression and declines as sister chromatids segregate. Consequently, mitotic cells expressing acetylation-mimicking EB1 are delayed in metaphase alignment, resulting in impaired checkpoint silencing, thereby promoting a chromosome instability phenotype. Our findings identify reversible acetylation of EB1 as a molecular mechanism to orchestrate the dynamics of kinetochore signaling, and indicate that PCAF acts as rheostat to fine-tune microtubule dynamics in mitosis.

1423

Augmin promotes Meiotic Spindle Formation and Bipolarity in Xenopus Egg Extracts.

S. Petry[1], C. Pugieux[2], F. Nedelec[2], R. Vale[1]; [1]UCSF, San Francisco, CA, [2]EMBL

Female meiotic spindles in many organisms form in the absence of centrosomes, the organelle typically associated with microtubule (MT) nucleation. Previous studies have proposed that these meiotic spindles arise from RanGTP–mediated MT nucleation in the vicinity of chromatin; however, whether this process is sufficient for spindle formation is unknown. Here, we investigated whether a recently proposed spindle–based MT nucleation pathway that involves augmin, an 8-subunit protein complex, also contributes to spindle morphogenesis. We used an assay system in which hundreds of meiotic spindles can be observed forming around chromatin-coated beads after introduction of Xenopus egg extracts. Spindles forming in augmin-depleted extracts showed reduced rates of MT formation and were predominantly multipolar, revealing a new function of augmin in stabilizing the bipolar shape of the acentrosomal meiotic spindle. Our studies also have uncovered an apparent augmin-independent MT nucleation process from acentrosomal poles, which becomes increasingly active over time and which appears to partially rescue the spindle defects that arise from augmin depletion. Our studies reveal that spatially and temporally distinct MT generation pathways from chromatin, spindle microtubules and acentrosomal poles all contribute to robust bipolar spindle formation in meiotic extracts.

1424

Spatial organization of self-organized microtubule arrays: role of MAP65.

D. Portran[1], M. Zoccoler[1], J. Gaillard[1], E. Neumann[2], I. Arnal[3], J-L. Martiel[1], M. Vantard[1]; [1]iRTSV, CEA Grenoble, Grenoble, France, [2]IBS, CEA Grenoble, Grenoble, France, [3]GIN, INSERM/UJF, LaTronche, France

In most differentiated cells, including muscle, epithelial and neuronal cells, as well as in most fungi and plant cells, microtubules (MT) are not organized radially from the centrosome but form bundles that assume different configurations depending on the cell type. Although the mechanisms responsible for the formation of these self-organized MT arrays are not yet well understood, we outline the general features for their initiation and organization. These basic mechanisms include (i) MT nucleation, (ii) the release of the MTs from their nucleation sites, (iii) their transport in the cytoplasm by MT motor or treadmilling, (iv) their co-alignment with resident MTs leading to bundle formation (i.e. MTs present in already formed bundles). In vivo observations in acentriolar plant cells show that collisions between mobile and resident MTs can result for the mobile MTs in crossover, depolymerization or co-alignment depending on the encounter angle. In this study, we address the question of the self-organization of MT bundles induced by MT cross-linkers MAP65-1/Ase1/PRC1. Note that MAP65-1 (in plants), and its orthologs Ase1 (fungi) or PRC1 (vertebrate) are members of the non-motor MAP65 family. We systematically analyzed MT-MT (or MT-bundles) encounters of growing MTs in the presence of MAP65-1 and Ase1 in biomimetic assays using TIRF microscopy. In addition, we developed a biophysical model to determine the persistence length of single/bundled MT in the presence of

MAP65-1. Our data show that physical collisions of growing MT bundles have different outcomes depending of the encounter angles: (i) at shallow angle (<45°), MAP65-1 triggers MT zippering; (ii) steep-angle collisions (>45°) promote MT catastrophe, MT-MT crossing-over or MT-buckling. Bending stiffness being a crucial parameter to understand deformation resulting from MT-zippering, we measured the persistence length (Lp) of MTs in the presence of MAP65-1. Using active hydrodynamic flow or thermal fluctuations methods, we demonstrated that MAP65-1 has a strong softening effect for single MTs (the persistence length of single MT in the presence of MAP65-1 is six times smaller than that of single MTs without MAP) and lowers the global rigidity of MT bundles. In addition, this effect does not depend of the MT length. These data show how the key protein MAP65-1, by modifying the mechanical properties of MTs, controls the issue between MT-MT encounters resulting into the spontaneous formation of ordered MT bundle arrays.

1425

Spatial Localization Regulated By the Microtubule Network.

J. Chen[1], J. Liu[1]; [1]NIH, Bethesda, MD

The commonly recognized mechanisms for spatial regulation inside the cell are membrane-bounded compartmentalization and biochemical association with subcellular organelles. We use computational modeling to investigate another spatial regulation mechanism mediated by the microtubule network in the cell. Our results demonstrated that the mitotic spindle can impose strong sequestration and concentration effects on microtubule-binding molecules, especially dynein-associated cargoes. We applied our model to recapitulate the essence of three experimental observations on different organizations of the microtubule network: the sequestration of germ plasm components by the mitotic spindles in the *Drosophila* syncytial embryo, the asymmetric cell division initiated by the time delay between the centrosome maturation in the *Drosophila* neuroblast, and the diffusional block between neighboring nuclei in the *Drosophila* syncytial embryo. Our model thus suggests that the microtubule network provides an spatially extensive docking platform for the microtubule-binding molecules and gives rise to a “structured cytoplasm”, in contrast to a free and fluid environment. The cell cycle-dependent changes in the microtubule network is critical for achieving differential spatial regulation effects.

1426

Doublecortin specifies 13-protofilament microtubules by wrapping around the microtubule lattice.

S. Bechstedt[1], G. Brouhard[1]; [1]Biology, McGill University, Montréal, QC, Canada

Neurons, like all cells, face the problem that tubulin forms microtubules with too many or too few protofilaments (pfs). Cells overcome this heterogeneity with the γ-tubulin ring complex, which provides a nucleation template for 13-pf microtubules. Doublecortin (DCX), a microtubule-associated protein expressed in developing neurons, also nucleates 13-pf microtubules *in vitro*. Using fluorescence microscopy assays, we show that the binding of DCX to microtubules is optimized for the lateral curvature of the 13-pf lattice. We discovered that this sensitivity depends on a cooperative interaction wherein DCX molecules decrease the dissociation rate of their neighbors. Mutations in DCX found in patients with subcortical band heterotopia disrupt the specificity for 13-pf microtubules and weaken cooperative interactions. Using truncation constructs, we argue that these interactions "wrap around" the microtubule. These results support a mechanism for stabilizing 13-pf microtubules that, *in vitro*, allows DCX to template new microtubules through lateral associations that arrange tubulin dimers into a 13-pf nucleus.

1427

Regulation of minus-end directed microtubule transport of membrane organelles by the microtubule-associated protein 4 (MAP4).

I. Semenova[1], K. Ikeda[1], P. Kraikivski[1], I. Zaliapin[2], M. Aguiar[3], S. Gygi[3], V. Rodionov[1]; [1]University of Connecticut Health Center, Farmington, CT, [2]University of Nevada, [3]Harvard Medical School

Microtubule (MT)-based transport of organelles is driven by opposing MT motors, plus-end directed kinesins and minus-end directed dynein, simultaneously bound to the organelle surface. The direction of MT-based transport is regulated through changes in the lengths of plus- and minus-end runs, via as yet poorly understood mechanisms. Regulation might involve reversible binding to the MT wall of microtubule-associated proteins (MAPs), which has been shown to differentially affect the movement single kinesin and dynein molecules along MTs *in vitro*. However, whether binding of MAPs to MTs control the direction of organelle transport in cells remains unknown. Here, we tested the regulation of MT transport by MAPs using *Xenopus* melanophores as an experimental system. The main function of these cells is transport of melanosomes, which move along MTs to the cell center (aggregation) or to the periphery (dispersion) by means of cytoplasmic dynein and kinesin-2, respectively. The direction of transport is regulated by changes in the levels of cAMP, which induce opposite changes in the lengths of plus- and minus-end MT runs. We compared phosphoprotein profiles of cells stimulated to aggregate or disperse melanosomes and found that phosphorylation of *Xenopus* MAP4 (XMAP4) at Thr752 and Thr756, which has been shown to inhibit binding of MAP4 to MTs in mammalian cells, was significantly increased (~5.5-fold) in cells induced to aggregate melanosomes. Overexpression of wild-type XMAP4 or the XMAP4 Thr752A/Thr756A dephosphomimetic mutant substantially inhibited melanosome aggregation (~3-fold) but did not have a significant effect on their dispersion. This effect was explained by the shortening of MT minus-end runs. In contrast to the Thr752A/Thr756A mutant, overexpression of a Thr752E/Thr756E MAP4 phosphomimetic mutant had a weaker inhibitory effect. Our data are consistent with a model for the regulation of MT transport in melanophores in which binding of MAP4 to MTs stimulated to disperse melanosomes selectively suppresses their minus-end directed runs. Phosphorylation at Thr752 and Thr756 during aggregation reduces binding of MAP4 to MTs thus stimulating minus-end directed melanosome movement.

1428

MAP65-1 and MAP65-2 promote axial growth and cell proliferation in plant roots.

J. R. Lucas[1], M. Hassfurder[1], S. L. Shaw[1]; [1]Indiana University, Bloomington, IN

We investigated the role of MAP65-1 and MAP65-2 in root growth in the model plant, *Arabidopsis thaliana*. Native promoter, fluorescent reporter fusions to genomic sequences revealed that both MAP65-1 and MAP65-2 accumulated in the actively growing regions of the root: the tip and the elongation zone. Similar expression patterns were found using a constitutively active promoter, which suggested that strong post-transcriptional control restricted MAP65-1/2 accumulation to growing portions of the root. We observed a complete overlap in MAP65-1 and MAP65-2 localization in the root interphase cortical arrays, preprophase bands, and phragmoplasts. Genetic analysis of insertion mutant alleles showed that MAP65-1 and MAP65-2 proteins play a functionally redundant role in etiolated (dark grown) root growth. Plants deficient for both proteins exhibited stunted root growth due to a drastic reduction in the total cell number and to a defect in the elongation of the mature root cells. We did not observe obvious defects in cytokinesis, such as wall stubs and misplaced cell walls, in the double mutant roots. The overall morphology of the double mutant roots was not drastically altered, beyond

being short. Overall, these data suggest that MAP65-1 and -2 are important for cell growth and proliferation in the *Arabidopsis* root.

1429

Genetic and physical characterization of Chlamydomonas reinhardtii mutant strain cmu1-1.

M. C. Haven[1], A. L. Ambrose[1], C. J. Horst[1]; [1]Carroll University, Waukesha, WI

Chlamydomonas mutant strain *cmu1-1* was initially identified based on its unusual cell shape. Cells tend to be tear-drop shaped rather than ovoid like wild-type cells. Further investigation revealed the cell body microtubules in *cmu1-1* are unorganized and frequently longer than those seen in wild-type cells, providing a possible explanation for the altered cell shape. Current studies show this change in microtubule organization also leads to changes in the distribution of organelles such as the pyrenoid. To determine pyrenoid position, the midplane of the cell was defined as the plane running from the base of the flagella at the anterior end of the cell to the cell's posterior end, thus bisecting the cell. In 66% of wild-type cells the pyreniod is centered within 10 degrees either side of the midplane. In contrast, only 30% of *cmu1-1* cells position the pyrenoid within 10 degrees either side of the midplane. *cmu1-1* was created by insertional mutagenesis to facilitate gene identification. The plasmid used was derived from pUC119 and contained *nit1* and *nar1* genes. Investigations into the identity of the defective gene in *cmu1-1* revealed several rearrangements occurred during insertion. Consistent with the ability of *cmu1-1* to reduce nitrate, almost all of *nit1* was inserted. However, the 3' UTR became attached to the 5' regulatory region. All of *nar1* was inserted except for part of the 3' UTR. None of the pUC sequences were inserted. Investigations of the insertion site region reveal that two adjacent genes were knocked out by the insertion. Interestingly, both genes code for divergent cytoskeletal proteins. Current investigations are focused on using complementation to determine the relative contributions of the two knocked out genes.

1430

Depletion of Spindle Pole Protein, CKAP2, Increases Chromosomal Instability in Colorectal Cancer Cells.

C. Case[1,2], D. Wangsa[1], D. Sackett[3], T. Ried[1], J. Camps[1]; [1]National Cancer Institute, National Institutes of Health, Bethesda, MD, [2]Institute of Biomedical Sciences, George Washington University, Washington, DC, [3]National Institute of Child Health and Human Development, National Institutes of Health

Introduction: Cytoskeletal-associated protein 2, *CKAP2*, is a microtubule-associated protein that colocalizes with spindle pole and aids in microtubule stabilization. CKAP2 is over-expressed in a variety of cancers, including colorectal, but the exact function and mechanism of action are poorly understood. Experimental changes in CKAP2 expression results in spindle abnormalities, and thus, we hypothesize that CKAP2 could play an active role in aneuploidy, a common feature of colorectal cancers.

Methods: RNAi technology was utilized to determine the extent to which the over-expression of CKAP2 plays a role in chromosomal segregation using a diploid (DLD1) colorectal cell lines as a model. Endogenous expression and localization of CKAP2 was confirmed with immunocytochemistry and Western blot analysis. Knockdown efficiency was determined using QRT-PCR and Western blot. Aneuploidy was assessed by chromosome counts and structural aberrations were assessed by spectral karyotyping (SKY) analysis.

Results: We found that in DLD1, CKAP2 colocalizes with the spindle but not the centrosomes. Analysis of the cell cycle profile, after mitotic block, showed that CKAP2 protein levels are dramatically reduced post-mitosis, indicative of degradation by APC/C. Transfection with shRNA against CKAP2 results in a 15% increase of multi-polar spindles, 30% increase of centrosomal aberrations, and lack of centrosome clustering. Transfected cells also have an increase of lagging chromosomes and micronuclei, suggestive of errors in chromosome attachment or segregation. This finding is validated by an increase of average chromosome number in 50% of cells where expression of CKAP2 is inhibited.

Conclusion: We propose that CKAP2 depletion negatively impacts spindle tension, by affecting either the microtubule kinetochore attachments or microtubule cross-linking, ultimately resulting in a decreased capability to cluster extra centrosomes into a bipolar spindle.

1431

The minus-end-directed motor Kar3p drives nuclear congression through spindle pole body-cytoplasmic microtubule interactions.

R. Gibeaux[1], A. Politi[1], E. Schiebel[2], F. Nédélec[1], M. Knop[2], C. Antony[1]; [1]CBB, EMBL, Heidelberg, Germany, [2]ZMBH, Heidelberg, Germany

After cell fusion during mating in Saccharomyces cerevisiae the two nuclei are pulled towards each other through a microtubule-dependent process called nuclear congression. This process has been intensively studied using genetics and live cell fluorescence microscopy analysis of various mutants displaying specific defects in the mating process. However, the organisation and the interaction between cytoplasmic microtubules nucleated from opposite spindle pole bodies (SPBs) as well as the mode of force generation for nuclear migration remained unclear (Rose, 1996; Molk et al., 2006; Molk and Bloom, 2006). To approach this question we resolved the three-dimensional microtubule organisation during nuclear congression using electron tomography carried out on mating cells at different stages in the process. The models show no particular connections between microtubules emanating from opposite SPBs, for instance no microtubule overlaps or microtubule-end interactions. Strikingly, in these models we always observed long microtubules passing the opposite SPB with an average distance between the SPB and these microtubules compatible with the size of a molecular motor. The minus end-directed kinesin Kar3p is known to be essential for nuclear congression (Meluh and Rose, 1990; Endow et al., 1994). Therefore, we used a fully functional GFP labelled Kar3p for live cell imaging and confirmed its localization at the cytoplasmic side of the SPB. We also validated the significance of long cytoplasmic microtubules during nuclear congression. Subsequent work using genetics and live cell microscopy demonstrated that in fact no inter-microtubule interaction between mating partners is necessary for efficient nuclear congression. We identified the molecular anchor of Kar3p at the cytoplasmic side of the SPB and found an additional dependency on Cik1p, one of the two light chains of Kar3p. Altogether, our results support a model in which Kar3p drives nuclear congression by directly connecting SPBs through microtubules nucleated at the opposite SPB.

1432

Fission yeast Rad26^{ATRIP} and Ase1^{PRC1} delay spindle pole body separation in response to interphase microtubule damage.

M. Herring[1], S. Campbell[1], N. Davenport[1], R. White[1], S. Verde[1], E. Baschal[1], L. Elliott[1], K. Stephan[1], K. Chen[1], L. Anaya[1], Z. Krych[1], J. Kark[1], T. D. Wolkow[1]; [1]UCCS, Colorado Springs, CO

Interphase microtubules position organelles and transport cellular components. We report that damage to interphase microtubules in fission yeast activates a checkpoint that delays spindle pole body separation, an early event of mitotic entry. This interphase microtubule damage checkpoint is dependent upon Rad26^{ATRIP}, a regulatory subunit of Rad3^{ATR} that occupies central positions within DNA checkpoint pathways. Specifically, we find that mutation of a putative nuclear export sequence in Rad26^{ATRIP} disrupts this microtubule checkpoint without affecting DNA checkpoints. This Rad26^{ATRIP} mutation also compromises cellular morphology and mini-chromosome stability, suggesting that this interphase microtubule checkpoint facilitates proper morphology and chromosome segregation. Double mutant and overexpression analyses show that Ase1^{PRC1} also operates in this pathway. We discuss how Rad26^{ATRIP} and Ase1^{PRC1} may function in this checkpoint-response to interphase microtubule damage.

1433

A Role for SUMO-Targeted Ubiquitin Ligases in Spindle Positioning.

L. Stevermann[1], D. Kammerer[2], D. Liakopoulos[1]; [1]Biochemistry Center Heidelberg, Heidelberg, Germany, [2]University of Fribourg

Asymmetric cell divisions are crucial during development of multicellular organisms as well as to control cell fate between stem cells and differentiating cells. The crucial step in asymmetric cell division is orientation of the mitotic spindle along the axis of cell polarity. One mechanism to ensure spindle positioning is orientation of spindle microtubules (MTs) along the actin cytoskeleton by protein complexes that link astral MTs with cortical actin. In budding yeast, a complex consisting of the MT plus end-interacting protein Bim1, the linker protein Kar9, and the myosin motor Myo2 ensures spindle orientation along the mother – bud axis of the dividing cell.
Function of Kar9 as a crucial player in this complex is regulated by posttranslational modifications, i. e. phosphorylation, SUMOylation, and ubiquitylation. Specifically, phosphorylation and SUMOylation regulate asymmetric Kar9 localization on the spindle. Ubiquitylation targets Kar9 for proteasomal degradation and is dependent on actin-based transport to the bud neck and on the septin ring. Localized Kar9 degradation at the bud neck seems to be required to destabilize the Kar9 – Bim1 – Myo2 complex. Ubiquitylation of Kar9 depends on prior phosphorylation, unphosphorylated Kar9 is highly stable and stabilizes MT interactions with the bud neck.
Here, we investigate the interplay of SUMOylation and ubiquitylation. Kar9 interacts with the SUMO-targeted ubiquitin ligases (STUbL) Slx5 and Ris1 in a yeast two hybrid analysis. Deletion of Slx5, Slx8 (which acts in a complex with Slx5), and Ris1 leads to a reduction in Kar9 ubiquitylation and to Kar9 stabilization, suggesting that these enzymes are required for Kar9 ubiquitylation. In support of this idea, Kar9 is also partially stabilized upon inactivation of SUMO protein (*smt3-331* strain). Furthermore, in an *slx5slx8ris1Δ* strain, overall Kar9 levels are significantly increased, suggesting that the protein accumulates due to a defective degradation mechanism.
Thus, we propose that Kar9 SUMOylation promotes subsequent ubiquitylation and that Kar9 degradation is at least partially dependent on the STUbL Slx5 – Slx8 and Ris1. To our knowledge, this is the first demonstration of a cytoplasmic target for SUMO-targeted ubiquitin ligases.

1434

Proteomic and morphology-based approaches to microtubule nucleation in meiotic spindles.

A. C. Groen[1], M. H. Wuehr[1,2], S. Gygi[2], T. J. Mitchison[3]; [1]Systems Biology, Harvard Medical School, Boston, MA, [2]Cell Biology, Harvard Medical School, Boston, MA

Microtubules nucleate throughout Xenopus egg meiosis-II spindles by an unknown mechanism, and spatial regulation of this nucleation is central to spindle morphogenesis. We addressed the mechanism by which Ran.GTP promotes microtubule nucleation using proteomic and morphology-based approaches. We curated a database of Xenopus laevis proteins, and used it to enable differential proteomics in Xenopus egg extracts. We showed previously that Ran-dependent microtubule nucleation factors could be captured on beads coated with antibody to XRHAMM, a spindle pole protein (Curr Biol. 2004 Oct 26;14(20):1801-11.). We were able to repeat this reaction in high-speed supernatant of egg extract, provided glycogen was added (see Groen et al, MBC, 2011, for glycogen effects). We applied differential proteomics to investigate factors that were recruited to XRHAMM coated beads that do, and do not, nucleate microtubules. In parallel, we investigated the spatiotemporal regulation of TPX2, a key intermediate between Ran.GTP and microtubule nucleation. Using a novel immuno-EM approach in egg extract, we localized TPX2 to microtubule bundles in the center of spindles and well as to poles. We hypothesize TPX2 may trigger microtubule nucleation from these bundles.

Cilia and Flagella III

1435

Three-dimensional analysis of airway cilia motility.

K. Ikegami[1], T. Masaike[2], T. Nishizaka[2], M. Setou[1]; [1]Hamamatsu Univ Sch Med, Hamamatsu, Japan, [2]Gakushuin Univ, Tokyo, Japan

Cilia and flagella are evolutionally-conserved organelles and observed in a variety of organisms ranging from protozoa to mammals. Cilia and flagella show highly coordinated motility. The ciliary and flagellar motilities have been well investigated for several decades, for example, as to the beating frequency, the beating amplitude, or the beating pattern. These have been examined so far with normal microscopy. The data obtained by the normal microscopy have only two-dimensional information. Thus, it is very difficult to analyze clearly the three-dimensional motility. In addition, the fluid flow generated by millions of cilia hampers the precise analysis of cilia motility as it can interfere with the ciliary motility through fluid dynamics. To overcome these two problems, we isolated ciliary axonemes from mouse tracheal cilia, reactivated them with ATP in vitro, and recorded the motion of fluorescent bead attached to the axonemal tip with recently-developed three-dimensional tracking microscope. The reactivated cilia showed three-dimensionally different trajectories in preparative and effective strokes. In particular, majority of cilia moved slightly counterclockwise when they were observed from top. In conclusion, we were able to observe and analyze the pure motion of ciliary strokes.

1436

The importance of *Ccdc42* in motile cilia function in *Tetrahymena thermophila* and flagella formation in *Mus musculus.*

R. C. Pasek[1], L. Tres[2], N. Sharma[1], L. Johnson[3], R. A. Kesterson[3], A. L. Kierszenbaum[2], B. K. Yoder[1]; [1]Department of Cell Biology, Univ Alabama-Birmingham, Birmingham, AL, [2]Department of Cell Biology and Anatomy, The City University of New York Medical School, New York City, NY, [3]Department of Genetics, Univ Alabama-Birmingham, Birmingham, AL

The motile cilium, referred to as a flagellum in certain cells, is a highly conserved microtubule based structure found in a diverse array of eukaryotic organisms. For example, homologous genes essential for the assembly of motile cilia are found in both the unicellular alveolate *Tetrahymena thermophila*, as well as in *Mus musculus* (house mouse). As motile cilia are essential to human development and fertility, the study of genes necessary for their function can advance our understanding of this organelle's importance. To help achieve this, we have embarked on a study of the cilia gene *Ccdc42* in both *T. thermophila* and in *Mus musculus*. This work has yielded a somatic knockout of *Ccdc42* in *T. thermophila* which results in defective motility and a defect in motile cilia assembly. This data strongly suggests the gene is necessary for proper motile cilia function in this organism. Strikingly, when we created a mouse homozygous for a null allele of *Ccdc42*, we found that the mutants do not display hydrocephalus or female infertility, phenotypes that are typically associated with defective motile cilia. However, further analysis revealed that male *Ccdc42* mutants were sterile due to a defect in flagellum assembly during spermatogenesis, in addition to displaying abnormal placement of the head-tail coupling apparatus, a spermatogonia structure homologous to the basal body. These results indicate an evolutionarily conserved function of *Ccdc42* between *T. thermophila* cilia and mouse spermatogonia that does not extend to all other mammalian cells possessing motile cilia.

1437

The cytoskeleton interprets PCP cues to promote establishment of cilia polarity and metachronic synchrony in multiciliated cells by connecting individual basal bodies.

M. Werner[1], P. Hwang[1], F. Huisman[2], P. Taborek[2], C. Yu[2], B. Mitchell[1]; [1]Cell and Molecular Biology, Northwestern University Feinberg School of Medicine, Chicago, IL, [2]Department of Physics and Astronomy, University of California, Irvine

Motile cilia driven directed fluid flow plays an important role in a variety of different biological processes such as mucus clearance from the respiratory tract, oocyte migration, movement of cerebral spinal fluid through the ependyma and establishment of left-right axis during development. Ciliated epithelia rely on planar cell polarity (PCP) signaling to establish cilia polarity, as demonstrated for the mammalian embryonic node and ependyma as well as the skin of *Xenopus* tadpoles; however the mechanistic details downstream of PCP signaling remain largely unknown. Remarkably, both actin and microtubules interact with basal bodies in multiciliated cells and have been linked to PCP signaling in other systems. Using multiciliated cells in the skin of *Xenopus* tadpoles, we have investigated the role of cytoskeletal dynamics during the establishment and maintenance of cilia polarity. Multiciliated epithelia have to evenly space and orient individual cilia within a single cell to establish rotational polarity. Using fluorescent markers for basal bodies and rootlets we can score the position and orientation of individual cilia during establishment of cilia polarity. High resolution confocal imaging reveals that both actin and microtubule networks at the apical surface of ciliated cells undergo structural rearrangements during establishment of rotational polarity connecting individual basal bodies to their neighbors as they become oriented. These connections reflect the polarization state of the cell and pharmacological disruption of both actin and microtubule dynamics differentially perturbs the establishment of rotational polarity without affecting cilia structure or beat

frequency. In addition to establishment of rotational polarity, multiciliated cells have to temporally coordinate cilia beating in order to achieve metachronic synchrony. We show that actin filaments connecting individual rootlets to their neighboring posterior basal bodies along the axis of cilia beating are required to maintain the organization of the metachronic wave. Taken together our data suggest that the cytoskeleton is essential for the spatial interpretation of polarity cues downstream of PCP signaling as well as the temporal coordination of cilia beating. More specifically while cytoplasmic microtubules coordinate polarity between neighboring cilia, a distinct subset of cytoplasmic actin filaments are required for proper cilia spacing, integration global polarity cues and coordination of metachronic cilia beating.

1438

Flagellar Levels of Lis1 are Dynamically Modulated in Response to Alterations in Beat Frequency.

P. Rompolas[1,2], S. M. King[1]; [1]Molecular, Microbial and Structural Biology, University of Connecticut Health Center, Farmington, CT, [2]Genetics, Yale University, New Haven, CT

Lis1 is a key regulator of cytoplasmic dynein and is also present in motile mammalian cilia and the flagella of wildtype Chlamydomonas. Lis1 associates with the outer dynein arms and is missing from flagella of mutants which lack this entire structure or just the outer arm alpha heavy chain. We have now found that Lis1 levels are significantly enhanced (5-10 fold) in flagella of impaired-motility or paralyzed mutants lacking various dyneins or motor units, the radial spokes or central pair microtubule complex. Analysis of double mutants defective for both outer arms and radial spokes (oda1pf14) or the central pair (oda1pf18) indicate that outer arms are required for localization and/or retention of these enhanced levels of Lis1 within the flagellum. Extraction of wildtype and pf14 mutant axonemes with increasing amounts of K acetate and NaCl revealed that Lis1 is more tightly bound to pf14 axonemes than to wildtype suggesting that the interaction is specifically modulated. As Lis1 levels were increased in motility-deficient mutants, we also tested whether the amounts varied with the ability of wildtype flagella to beat normally. Therefore, we reduced the beat frequency of wildtype flagella by placing the cells under high viscous load (16% Ficoll) and found that the flagellar levels of Lis1 increased significantly. We observed a similar (~5-fold) response when beat frequency was reduced from ~50 Hz to 20 Hz by placing the cells under high reductive stress. Within cytoplasm, Lis1 localized to the base of the flagella and was also detected in a second punctate structure towards the opposite end of the cell. Fractionation of wildtype cell body extracts identified Lis1 within three major cytoplasmic complexes with masses of ~1.1 MDa, 158 kDa and 40 kDa. In contrast, oda6 extracts which do not assemble intact outer arms contained mainly the 40 kDa peak which likely represents monomeric Lis1. These data suggest that Lis1 levels within the flagellum are dynamically modulated in response to alterations in flagellar motility; i.e. the cell responds to an imposed reduction in beat frequency (through mutation, viscous load or reductive stress) by increasing flagellar Lis1.

1439

Axoneme distortion in sea urchin sperm flagella evaluated by a geometric analysis of bending and shear.

C. B. Lindemann[1], T. G. dePinho[1], D. W. Pelle[1], K. A. Lesich[1]; [1]Biological Sciences, Oakland University, Rochester, MI

When the axoneme of a flagellum or cilium bends, it is an accepted maxim that the resulting interdoublet shear can be found by multiplying the interdoublet spacing in the bending plane by the shear angle. Shear angle is the difference in angle of the flagellum (radians) from the flagellar base to the point of interest. This relationship rests on the assumption that the outer

doublet microtubules of the axoneme are relatively inextensible and incompressible under physiological loading; an assumption that was tested by Brokaw (1991, J. Cell Biol. 114: 1201-1215) and found to be essentially correct. Due to the presence of interdoublet elastic linkages (nexin links) in an intact sea urchin flagellum, the unrestrained passive flagellum can only be straight when the interdoublet shear is zero. Sea urchin sperm that are treated with 50 μM sodium metavandate in the presence of 0.1 mM Mg-ATP are rendered passive by inactivation of the dyneins. When sperm in this condition are bent with a glass microprobe, the flagellum distal to the probe develops a “counterbend”, which is a bend of opposite curvature to the imposed bend (Pelle et al., 2009, Cell Motil. Cytoskeleton 66: 721-735). When bends were imposed on passive sea urchin flagella, the resulting counterbend was generally insufficient to bring the tip of the flagellum back to the shear angle of the flagellar base. Most often, when the flagellum was bent in the middle or basal region, the tip of the flagellum was straight; this indicates that there is no residual interdoublet shear at the tip. At the same time, the shear angle of the tip was as often as much as one radian different from the base angle. Under these circumstances, either the assumption that the doublets are incompressible and inextensible is incorrect, or the interdoublet spacing must be reduced in the bent region. Since the imposed bends were similar in magnitude to normal physiological bending during the beat cycle, the assumption of incompressibility/inextensibility of the doublets is likely valid. Therefore, we must conclude that the interdoublet spacing of the axoneme distorts appreciably (as much as 40 %) under physiological loading. Supported by grant MCB-0918294 from the National Science Foundation.

Localization of TGFβ signaling components and Wnt receptors to primary cilia during neurogenesis.

S. K. Brorsen[1], C. A. Clement[1], S. T. Christensen[1]; [1]Department of Biology, University of Copenhagen, Copenhagen, Denmark

Transforming growth factor (TGF)-ß and Wingless/Int (Wnt) signaling controls various physiological and pathophysiological processes of the brain, e.g. through the regulating of proliferation and differentiation of neural stem cells, neuronal progenitor cells and mature neurons that possess primary cilia, which play a role in neuronal signaling, adult neurogenesis, and brain tumor formation. Here we investigated the link between primary cilia and regulation of Wnt and TGFβ signaling in NT2 cells, a human embryonic carcinoma stem cell line, which can be differentiated into neurons using all-trans-retinoic acid (ATRA). Undifferentiated NT2 cells have primary cilia and are positive for stem cell markers OCT2/3, Nanog and Sox2. Upon cell differentiation in the presence of ATRA, expression of stem cell markers is gradually replaced by increased expression of neuronal markers, PAX6, NEUROD1 and ß III tubulin. ß III tubulin marks mature neurons from day 12 of ATRA stimulition. Since TGFβ signaling inhibits neural cell differentiation, we initially studied the localization of TGFß-receptor 1 (TGFßR1) to primary cilia in non-differentiated NT2 cells and after stimulation with ATRA. Our studies show that TGFßR1 uniquely localize to the ciliary tip and at the ciliary base of non-differentiated NT2 cells, and that ciliary localization is abolished during the early steps of differentiation and prior to formation of mature neurons. Similarly, the Wnt receptor, Frizzled-3, localizes along the entire length of the primary cilium in non-differentiated cells. In line with this observation, activation of TGFßR1 signaling through phosphorylation of the transcription factors, SMAD2/3, was reduced at the ciliary base during the differentiation of NT2 cells. This is the first report on the localization of TGFβ signaling components and Frizzled-3 to primary cilia in neuronal stem cells. We hypothesize that primary cilia take part in coordinating TGFß and Wnt signaling to regulate maintenance of pluripotency and prevent neural cell differentiation, and when aberrantly regulated by defects in ciliary assembly or by mislocalization to primary cilia may lead to developmental brain defects and/or glioblastoma development from neural stem cells.

Flagellar adhesion and cilium-generated signaling in *Chlamydomonas* trigger flagellar mobilization and shedding the adhesion receptor of SAG1.

O. Belzile[1], C. Hernanadez-Lara[1], W. Snell[1]; [1]Cell Biology, Univ Texas Southwestern Med Ctr-Dallas, Dallas, TX

The cellular and molecular mechanisms that specify the concentrations of membrane proteins in cilia and flagella at steady state and during cilium-generated signaling are poorly understood. Our laboratory uses the biflagellate green alga *Chlamydomonas* as a model system to study regulated movement of the flagellar adhesion receptor SAG1 from the cell body to the flagella. Binding between the mating type + (mt+) flagellar adhesion receptor (agglutinin) SAG1 to its cognate receptor SAD1 on flagella of mt- gametes induces flagellar adhesion and activation of an IFT-requiring, cilium-generated signaling pathway ultimately leading to cell-cell fusion and zygote formation. Previous work from our laboratory and others using bioassays for SAG1 suggested that pathway activation triggers mobilization of a pool of SAG1 from the cell body to the flagella. Our work indicated that the cell body form was on the external side of the plasma membrane in an inactive form that became active upon recruitment to the flagellar membrane. Here, we report use of new tools to study regulation and properties of SAG1. We show that the *SAG1* gene bearing a C-terminal HA tag and driven by its endogenous promoter rescues flagellar adhesion and cell fusion in the flagellar adhesion mutant, *sag1-5*. Consistent with previous bioassays, immunofluorescence studies of resting *SAG1-HA-sag1-5* mt+ gametes show that the protein is present at the cell body and the flagella. As has been shown for a small number of other ciliary membrane proteins, we determined that SAG1 undergoes cleavage soon after its synthesis, and we detect only the HA-tagged, 65 kDa, C-terminal portion (SAG1-HA-C65). The full length, non-glycosylated form is predicted to be ~330 kDa, and the glycosylated form likely is much larger. SAG1-HA-C65 is not detected in vegetative *SAG1-HA-sag1-5* cells. Consistent with predicted C-terminal transmembrane domains, solubilization of SAG1-HA-C65 requires detergent and is not achieved upon mechanical disruption, high salt or high pH treatments. Cell fractionation demonstrates that in resting gametes the majority of SAG1-HA-C65 is present in cell bodies and only a small portion (~7%) is in flagella. Within minutes after cilium-generated signaling is triggered by flagellar adhesion, however, pre-existing SAG1-HA-C65 on the cell body is mobilized to the flagella. In cells undergoing prolonged flagellar adhesion and signaling, we detect larger molecular weight precursors in the cell body, but only the 65 kDa form is detected in the flagella. Finally, we demonstrate that flagellar adhesion and cilium-generated signaling leads to loss of SAG1-HA-C65 from the flagella and concomitantly we find that large amounts of the protein appear in particulate form in the medium. Our work suggests that *Chlamydomonas* controls the flagellar amounts of the membrane protein SAG1 by at least two mechanisms. In resting cells, movement into flagella is restricted by an uncharacterized barrier; and in cells undergoing flagellar adhesion and signaling, SAG1 levels are reduced by release or shedding of SAG1. Such a model could explain regulated increase and loss of other ciliary proteins such as Patched and Smoothened in vertebrate cells. Experiments are underway to determine whether the SAG1 released into the medium is in the form of large non-membranous aggregates or if it is in membrane vesicles.

1442

Evidence for G Protein-coupled receptor dimerization in neuronal ciliary signaling.

J. A. Green[1], K. Mykytyn[1]; [1]Pharmacology, The Ohio State University, Columbus, OH

Primary cilia are specialized organelles that perform important sensory and signaling functions and are required for cellular homeostasis and proper development. Defects in the formation or function of primary cilia have been implicated in the pathogenesis of many human

developmental disorders and diseases, collectively termed ciliopathies. Although great progress has been made in elucidating the functions of primary cilia on some cell types, the precise functions of most primary cilia remain unknown. The importance of neuronal cilia function is highlighted by the fact that ciliopathies can be associated with neurological phenotypes, such as cognitive deficits. Interestingly, disruption of certain signaling molecules which normally localize to neuronal cilia, such as adenylyl cyclase type III (ACIII) and the G protein-coupled receptors (GPCRS) Melanin concentrating hormone receptor 1 (Mchr1) and Somatostatin receptor 3 (Sstr3) is associated with learning and memory deficits in mice. This suggests neuronal ciliary signaling is required for proper learning and memory. For the first time, we have detected Mchr1 and Sstr3 colocalizing within the same cilium in distinct brain regions. In addition, we have evidence suggesting Mchr1 and Sstr3 heterodimerize. GPCR dimerization can affect ligand binding properties as well as down stream signaling. Therefore, our findings add an additional layer of complexity to neuronal ciliary signaling. Understanding the functional relevance of ciliary GPCR heterodimerization could elucidate the roles neuronal cilia play in non-synaptic signaling and could provide insight into potential therapeutic targets for ciliopathies.

1443

Hedgehog signaling regulates the myelination of peripheral nerve axons through the primary cilia.

S. Takeda[1], K. Yoshimura[1]; [1]Anatomy and Cell Biology, University of Yamanashi, Chuo, Japan

Myelin formation is an essential prerequisite for the nervous system to transmit an impulse efficiently by a saltatory conduction. In the peripheral nervous system (PNS), Schwann cells (SCs) engage in the myelination, whilst a detailed mechanism underlying the myelination is still an open question. In this study, we assume that the primary cilium of Schwann cells is a regulator of myelination from the following reasons; (1) Our previous results on Kif3B hypomorph mutants suggested that primary cilia may be responsible for the myelination of PNS, since these mutants showed severely disorganized PNS (Takeda et al., 44th ASCB, 2004). (2) Previous study has shown that Dhh-null mutant mice showed abnormal development of perineurium, and reduced number of myelinated axon as well as leanness of myelin sheath. (3) Molecular machineries for Hh signaling are specifically localized on the primary cilia. Taking these lines of evidence into account, we hypothesize that Hh signaling received and transduced by a primary cilia play an important role in modulating the myelination of the PNS.

To testify our hypothesis, we used the co-culture system of mouse dorsal root ganglion (DRG)/SC, wherein the behavior of SCs can be analyzed by maintaining the interaction of SCs with DRG neurons intact. Under this condition, SCs had primary cilia, and Hh signaling molecules were accumulated on the primary cilia. When the SCs were stimulated by an addition of Dhh or SAG, a Smo agonist, formation of myelin segments on the DRG axons was facilitated. On the contrary, upon administration of cyclopamine (CPN), an inhibitor of Hh signaling, myelin segments became comparable to those of controls. Of noteworthy, the ratio of SCs harboring the primary cilium reached highest during the pre-myelination stage. Furthermore, strongest effects of Hh on the myelination were encountered during the same stage. These results collectively indicate that the Hh signaling regulate the myelin formation through the primary cilia in the PNS.

Cilia in Neural Progenitor Cells in the Adult Hippocampal Subgranular Zone: Relation to Cell Cycle.

S. R. Bhattarai[1], J. L. Fuchs[1]; [1]Biological Sciences, University of North Texas, Denton, TX

Primary cilia are critical for the genesis of the mammalian brain, as evidenced by the marked reductions in neural cell populations of cilia-deficient transgenic mice. New neurons are generated throughout adulthood in the hippocampal subgranular zone, where cilia-mediated sonic hedgehog signaling promotes proliferation. In the present immunohistochemical study of the mouse subgranular zone, cilia were characterized in the neuronal lineage, which includes neural stem cells, progressively more committed progenitor types, neuroblasts, and neurons. Both the length and incidence of cilia were lower in the more proliferative populations, consistent with the need for cilium withdrawal before mitosis. Cilia were seen in a substantial percentage of Ki67+ cells (engaged in the active cell cycle), but rarely in cells expressing phospho-histone 3 (late G2, S). Thus, primary cilia may be retained through much of the cell cycle. Cilia of Ki67+ cells were distinctive in having faint ACIII immunostaining despite strong Arl13b immunoreactivity; ciliary ACIII levels were notably higher in Ki67- cells, which are post-mitotic or non-cycling. The differential expression of these two proteins might be important for cilium resorption and cell cycle progression. Data from the present study were incorporated into a model of cilia assembly and disassembly in relation to the cell cycle during neurogenesis.

1445

NHE1 trafficking in fibroblasts with primary cilia.

M. Lethan[1], D. Hansen[2], J. Kolstrup[1], S. Pedersen[2], L. Hodgson[1], S. Christensen[2], P. Satir[1]; [1]Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, [2]Biology, University of Copenhagen

We previously showed that Platelet-Derived Growth Factor Receptor alpha ($PDGFR_{\alpha}$) is upregulated and targeted to the primary cilium in growth arrested wt mouse embryonic fibroblasts (MEFs)and that $PDGFR_{\alpha}$ signaling is coordinated by the cilium to control directional cell migration and chemotaxis [Schneider et al., 2010, Cell Physiol. Biochem. 25:279-292]. The $PDGFR_{\alpha}$-mediated signaling cascade activated by its specific ligand, PDGF-AA, runs through the Mek1/2-Erk1/2 and Akt pathways in the cilium and via the Na+/H+ exchange protein, NHE1. Directional cell migration and chemotaxis in response to PDGF-AA is blocked in mutant Tg737orpk MEFs that have no or very short cilia. SEM reveals that wt MEF primary cilia extend from a ciliary pocket positioned at the apical cell surface above and close to the nucleus. In migrating cells the cilium orients towards the leading edge and parallel to the path of migration, where NHE1 at the leading edge alkalinizes the cytoplasm resulting in assembly of the actin cytoskeleton. Consequently, specific inhibitors of Akt, Mek1/2 or NHE1 destroy PDGF-AA-mediated directional cell migration. Preliminary evidence has indicated that NHE1 is present in cytoplasmic vesicles before stimulation and that localization at the leading edge is blocked by Akt inhibition. This implies that the ciliary $PDGFR_{\alpha}$ signaling cascade coordinates the trafficking of NHE1-containing vesicles through the cell to the forming leading edge for directional migration. To visualize NHE1 transport directly, we have stably transfected GFP-NHE1 into wt MEFs that form primary cilia. Fluorescent NHE1 is seen in the Golgi and in small vesicles. Video imaging shows that vesicular trafficking of NHE1 is occurring as the cell moves. We suggest that NHE1 vesicle transport will occur in a direction determined by a PDGF-AA gradient to help establish actin-rich lamellopodia at the leading edge of migrating cells when primary cilia are present.

1446

The Primary Cilium is Regulated By and Plays a Critical Role in Epithelial-Myofibroblast Transition.

M. Rozycki[1], J. Lam[1], A. Kapus[1]; [1]Surgery, University of Toronto, Li Ka Shing Knowledge Institute, St. Michael's Hospital, Toronto, ON, Canada

Epithelial-myofibroblast transition (EMyT), a key process in fibrogenesis, involves the activation of a myogenic program (-smooth muscle actin (SMA) expression) in the injured epithelium. EMyT is an important pathologic feature of polycystic kidney disease, the prototypic ciliopathy. However, the impact of EMyT on the cilium or conversely the role of the cilium in EMyT remains largely unknown. Previously we have developed a two-hit model of EMyT, wherein the injury (uncoupling) of adherens junctions (AJs) induced by scratch wounding or low calcium medium (LCM) and the presence of the fibrogenic cytokine TGFß are both necessary to induce SMA expression in kidney tubular (LLC-PK1) cells. These inputs activate myocardin-related transcription factor (MRTF) and Smad3 respectively, the interplay of which elicits SMA expression. In this study we followed ciliary changes in this two-hit EMyT model and tested the effect of deciliaition on SMA expression. We show that EMyT is associated with a biphasic change in the primary cilium, characterized by initial growth followed by dramatic ciliary loss. Specifically, LCM-induced AJ uncoupling or siRNA-mediated downregulation of E-cadherin triggered a 2-fold growth in ciliary length at 24 h. TGFß alone had little effect on the cilium, while complete EMyT, induced by LCM and TGFß, led to significant ciliary lengthening at early times (6-24 h), followed by dramatic deciliation at 48 h (< 10% ciliated cells vs. 80% in the control). The loss of the cilium is Smad3-dependent since downregulation of Smad3 suppressed the LCM+TGFß-provoked deciliation. While the emergence of myofibroblasts is eventually associated with ciliary loss, the primary cilium itself is not dispensable for EMyT. Deciliation prior to induction of EmyT by Chloral Hydrate or the Hedgehog Pathway Inhibitor-4 (HPI-4) abolished the TGFß+LCM-triggered SMA-promoter activation and SMA protein expression. These deciliating agents caused substantial reduction in MRTF and Smad3 protein levels (or immunoreactivity), concomitant with a robust increase in cytosolic acetylated tubulin. Cyclopamine, a hedgehog pathway inhibitor, which does not affect ciliation, reduced SMA expression and had no effect on MRTF, Smad3 and cytosolic acetylated tubulin. Thus we conclude that the primary cilium is both a target and a mediator of EMyT. The cilium is regulated by AJ integrity and it participates in the regulation of SMA expression via hedgehog pathway-dependent and independent mechanisms. Regarding the latter, cilium integrity seems to control protein acetylation and the expression/stability of MRTF and Smad3.

1447

Targeting of PDGFRα to the primary cilium.

T. A. Andersen[1], S. T. Christensen[1], L. B. Pedersen[1]; [1]Department of Biology, University of Copenhagen, Copenhagen, Denmark

Primary cilia are microtubule-based organelles that extend from the surface of most mammalian cells in growth arrest. The ciliary membrane is continuous with the plasma membrane but contains cilia-specific receptors and ion-channels like polycystin-1 and -2, components from the Hedgehog and Wnt signaling pathway, and the Platelet Derived Growth Factor Receptor (PDGFR)α. PDGFRα is up regulated during growth arrest and localizes to the primary cilium in NIH3T3 cells; this localization is essential for activating the receptor through the ligand PDGF-AA (Schneider et al., Curr Biol, 2005). The molecular mechanism that transports PDGFRα to the primary cilium is unknown.

Studies on other ciliary proteins showed that specific amino acid sequences function as Ciliary Localization Signals (CLSs). Polycystin-2, rhodopsin, somatostatin and serotonin receptors all

contain one or more CLSs, but currently no clear consensus CLS has been found. However CLSs have generally been localized to the cytoplasmic region of the proteins, and some CLSs resemble classic Nuclear Localization Signals (NLSs) that can confer nuclear as well as ciliary targeting, depending on Ran-GTP concentrations (Dishinger et al., Nat Cell Biol, 2010). PDGFRα and PDGFRβ localize to the cilia- and plasma membrane, respectively, suggesting that these closely related receptors contain different targeting signals. PDGFRαand PDGFRβ are almost identical in amino acid sequence (92% identity), except for the last ca. 146 amino acid residues that are localized in the C-terminal tail. Since PDGFRα localizes to primary cilia whereas PDGFRβ does not (Schneider et al. Curr Biol, 2005), the C-terminal tail of PDGFRα likely contains a specific CLS. To test this hypothesis, we cloned the cytoplasmic C-terminal fragment of PDGFRα and PDGFRβ, respectively, into the pEGFP-C1 vector (Clontech), and expressed these fragments in Inner Medullary Collecting Duct (IMCD) 3 cells. The transfected cells were grown to confluence, serum-starved to induce ciliogenesis, and examined by immunofluorescence microscopy with antibodies against acetylated alpha tubulin (cilia marker) and GFP. Interestingly, we found that GFP-tagged, C-terminal PDGFRα localized predominantly to the nucleus whereas GFP-tagged C-terminal PDGFRβ was localized to the cytosol. Furthermore, we observed that in a few cells the C-terminal PDGFRα fusion protein also localized to the primary cilium. We are currently trying to further define the CLS of PDGFRα by mutagenesis of full-length GFP-PDGFRα, and are also investigating the potential role of known cilia vesicle transport proteins (Arf4, IFT20, Rab8) in targeting of PDGFRα to the ciliary membrane.

1448

A role of the primary cilium in regulating TGFβ signaling in cell cycle control and differentiation.

C. A. Clement[1], K. D. Ajbro[2], M. L. Vestergaard[2], M. P. de Jesus[1], L. B. Pedersen[1], L. A. Larsen[2], S. T. Christensen[1]; [1]Department of Biology, University of Copenhagen, Copenhagen, Denmark, [2]Wilhelm Johannsen Centre for Functional Genome Research, University of Copenhagen, Copenhagen, Denmark

The transforming growth factor (TGF)-β signaling pathway plays a critical role in cell cycle control, migration and differentiation and when aberrantly regulated leads to developmental defects and cancer. TGFβ signaling is regulated through the endocytosis and internalization of TGFβ receptor (TGF$\tilde{\beta}$R) via clathrin-coated pits (CCPs) and vesicles (CCVs) at which the receptor activates transcription factors, Smad2/3 and modulates the downstream signaling pathways, PI3K-Akt and Mek1/2-Erk1/2. Here we investigated the relationship between regulation of TGFβ signaling and primary cilia, which are major sensory organelles in developmental processes and in tissue homeostasis. In many cell types a large fraction of the cilium is localized deep in the cytoplasm within an invagination of the plasma membrane known as the ciliary pocket, which is an endocytic domain for CCV formation.

Initially we used cultures of fibroblasts to show that TGFβ signaling components (TGFβ-RI/RII and Smad2/3/4/7) localize at the base and/or along the lower region of the primary cilium in hFF and MEF cells. TGFβ stimulation induced phosphorylation of Akt, Mek1/2, Erk1/2 and Smad2/3 and increased the localization of TGFβ-RI and phospho-Smad2/3 at the base and lower part of the primary cilium, which had high numbers of CCVs and early endosomes. These events were associated with phosphorylation of Retinoblastoma protein (Rb) marking G_1/S-phase transition and cell cycle entry. In cilia deficient MEFs, *Tg737^{orpk}*, there was a major reduction in TGFβ-induced Smad2/3 and Rb phosphorylation and formation of CCVs at the base of stumpy cilia. These results indicate that the primary cilium coordinates TGFβ signaling and partly through the ciliary pocket via CCV formation to control cell cycle entry in fibroblasts. Similar results were

observed during the differentiation of EC P19.CL6 stem cells and human embryonic stem cells (hESC) into cardiomyocytes. During the early stages of differentiation, TGFβ-R and Smad2/3/4 were highly up-regulated at both mRNA and protein levels. Localization of TGFβ-RI and p-Smad2/3 was highly increased at the ciliary base during differentiation, which was accelerated with TGFβ-R agonist, TGFβı, and blocked in the presence of antagonists. Further, knockdown of IFT20 required for transport of Golgi-derived vesicles to the ciliary base blocked TGFβ signaling and differentiation of P19.CL6 cells. Our results support the conclusion that TGFβ signaling is regulated by primary cilia, via the ciliary pocket to regulate cell cycle control and differentiation.

1449

A Role for the Primary Cilium in Notch Signaling and Epidermal Differentiation During Skin Development.

E. Ezratty[1], N. Stokes[1], S. Chai[1], A. Shah[1], S. Williams[1], E. Fuchs[1]; [1]Department of Mammalian Cell Biology and Development, The Rockefeller University, New York, NY

Ciliogenesis precedes lineage-determining signaling in skin development. To understand why, we performed shRNA-mediated knockdown of seven intraflagellar-transport-proteins (IFTs), and conditional ablation of Ift-88 and Kif3a during embryogenesis. In cultured keratinocytes and embryonic epidermis, all eliminated cilia and many (not Kif3a) caused hyperproliferation. Surprisingly and independent of proliferation, ciliary-mutants displayed defects in Notch-signaling and in commitment of progenitors to differentiate. Notch-receptors and Notch-processing-enzymes colocalized with cilia in wild-type epidermal cells. Moreover, differentiation defects in ciliary-mutants were cell-autonomous and rescued by transgenic expression of activated Notch (NICD). In contrast, Shh-signaling was neither operative nor required for epidermal ciliogenesis, Notch-signaling or differentiation. Rather Shh-signaling defects in ciliary-mutants occurred later, arresting HF morphogenesis in the skin. These findings unveil temporally and spatially distinct functions for primary cilia at the nexus of signaling, proliferation and differentiation: a novel, early role in epidermis, whose morphogenesis relies upon Notch-signaling; and a later role in HFs, reliant upon Shh-signaling.

1450

Primary Cilia in Appetite and Satiety.

N. F. Berbari[1], R. C. Pasek[1], E. B. Malarkey[1], S. M. Yazdi[1], A. D. McNair[1], R. A. Kesterson[2], T. R. Nagy[3], B. K. Yoder[1]; [1]Cell Biology, University of Alabama at Birmingham, Birmingham, AL, [2]Genetics, University of Alabama at Birmingham, Birmingham, AL, [3]Nutrition Sciences, University of Alabama at Birmingham, Birmingham, AL

Primary cilia are required to regulate certain signaling pathways during mammalian development. In adult tissues, cilia are also important as evidenced by the spectrum of phenotypes observed in mouse models and human patients with ciliary defects (ciliopathies); however, their roles in tissue physiology and homeostasis are poorly understood and the mechanisms underlying the ciliopathies remain enigmatic. We are addressing this issue using conditional tissue-specific cilia mouse mutants and show that disruption of cilia in the hypothalamus results in hyperphagia and obesity. A similar obesity phenotype was reported in mouse models of Bardet-Biedl Syndrome (BBS). BBS mutants have defects in cilia receptor localization and are thought to be unable to properly localize the receptor for the anorexigenic peptide leptin. Here we assess the leptin signaling axis in cilia mutants and demonstrate they are sensitive to leptin prior to becoming obese, are leptin insensitive when obese, and then regain leptin sensitivity after caloric restriction to bring mutants back to wild type body weight. Thus leptin resistance is a secondary consequence of the obesity and not causal, indicating that

pathways other than the leptin-melanocortin axis are involved. Data indicate that one of these pathways could be the melanin concentrating hormone (MCH) axis. Previous data indicate that MCH receptor localizes in the cilium of control but not of BBS mutants. Further, we show that MCH binds MCHR1 in the cilium and that in the absence of the cilium, the MCH signaling pathway is altered. Pharmacological and genetic studies are being conducted to assess whether defects in MCH signaling are directly associated with the obesity phenotype in cilia mutants. This work will provide novel insights into how dysfunction of the cilium contributes to the onset of obesity and more generally the importance of the cilium in regulating normal neuronal activity and energy balance.

1451

Ciliary trafficking of polycystin-1 is regulated by distinct components of the BBSome.

X. Su[1], K. Driscoll[1], G. Yao[1], J. Zhou[1]; [1]Harvard Center for PKD Research, Brigham and Women's Hospital and Harvard Medical School, Boston, MA

Polycystin-1 (PC1), whose deficiency causes autosomal dominant polycystic kidney disease, localizes to the primary cilia of renal epithelial cells where it mediates mechanosensation and signaling through several pathways. It remains elusive, however, how PC1 is targeted to cilia. We generated an N-terminal YFP-tagged full-length PC1 expression construct (YFP-PC1), which successfully traffics to primary cilia in IMCD3 cells. Removal of the entire C¨Cterminal cytoplasmic tail (C-tail, ~198 aa) abolishes this ciliary trafficking, however. Further deletion analyses of the PC1 C-tail narrowed the region responsible for ciliary trafficking to the middle 100 amino acid of the C-tail spanning the coiled-coil (CC) motif. Notably, deletion of the most C¨Cterminal fragment of PC1 containing the VxPx motif, which has recently been reported to bind ARF4 and is required for the ciliary trafficking of a mini-PC1 construct, does not have any effect on the targeting of full-length PC1 to the primary cilia. Through a yeast two-hybrid screen, we identified that BBS8, a gene mutated in Bardet Biedl Syndrome (BBS), interacts with PC1. Disruption of the CC motif in the PC1 C¨Ctail abolishes this interaction. We also tested the interaction of PC1 with 7 other BBS proteins and found that PC1 interacts with distinct BBS proteins. shRNA depletion of BBS1 but not BBS8 is sufficient to reduce PC1 trafficking to the primary cilia. Furthermore, we found that PC1 is able to interact with the wild type, dominant negative, and constitutively active Rab8 with similar affinities, but the ciliary localization of PC1 relies on functional Rab8. Taken together, these data suggest that the ciliary trafficking of PC1 is subject to the control of the BBSomal pathway.

1452

CRMP-2 in non-neuronal cells: Identification of a novel cilium targeting signal.

Y. Ou[1], Y. Zhang[1], M. Cheng[1], I. Dobrinski[1], J. Rattner[1], F. van der Hoorn[1]; [1]University of Calgary, Calgary, AB, Canada

The primary cilium is a microtubule-based structure. Previously, we showed that lithium induces cilium elongation in a number of cell types. Lithium inhibits several protein kinases, including GSK-3beta. To identify protein components that are involved in lithium and GSK-3beta-related cilium length regulation, we focused on collapsin response mediator protein-2 (CRMP-2). CRMP-2 binds tubulin dimers and microtubules, promoting microtubule assembly. In neuronal cells, CRMP-2 plays a key role in axonal development by regulating microtubule dynamics. GSK-3beta phosphorylates CRMP-2, subsequently regulating axon elongation. In addition, inhibition of GSK-3beta, or expression of the nonphosphorylated form of CRMP-2, induces the formation of multiple axon-like neurites in hippocampal neurons. In non-neuronal cells, CRMP-2 has been found to play a role in regulating trafficking of endocytic components. However,

whether CRMP-2 in non-neuronal cells participates in any microtubule-based functions remains unclear.

In this study, we show that CRMP-2 is a centrosomal protein in cycling cells, with prominent expression at the centrosomes of early interphase cells. In cilium-expressing cells, CRMP-2 shows enhanced association with the basal body and is also present at the primary cilia, although at a barely-detectable level. Lithium treatment of cultured cells could increase CRMP-2 levels at the cilium. Preliminary knockdown of CRMP-2 by shRNA expression interfered with cilium elongation. Expression of CRMP-2-GFP fusion protein confirms that CRMP-2 is expressed at the primary cilia. Deletion analysis of CRMP-2 indicated that CRMP-2 is targeted to the cilia via a small domain close to the C-terminus of CRMP-2. Intriguingly, this domain is a major site of GSK-3beta phosphorylation and contains two VxPx motifs which were shown to be cilium targeting signals found in some cilium proteins. Mutation of the GSK-3beta phosphorylation sites abolished the targeting of the fusion protein to the cilia. However, mutation of both VxPx motifs had no evident effect, suggesting that CRMP-2 contains a novel cilium targeting signal. At present, we are pursuing which protein(s) interacts with this novel cilium target signal to bring CRMP-2 to the primary cilia.

1453

A transition zone complex of Meckel and Joubert syndrome proteins is required for ciliary assembly and trafficking.

F. Garcia-Gonzalo[1], K. Corbit[1], M. Sirerol-Piquer[2], G. Ramaswami[3], E. Otto[3], T. Noriega[4], A. Seol[4], C. Bennett[5], J. Robinson[5], D. Josifova[6], J. García-Verdugo[2], N. Katsanis[5], F. Hildebrandt[3], J. Reiter[1]; [1]University of California at San Francisco, San Francisco, CA, [2]University of Valencia (Spain), Valencia, Spain, [3]University of Michigan, [4]University of California at San Francisco, [5]Duke University, [6]Guy's Hospital (London, UK), London, United Kingdom

Primary cilia are cellular antennae that receive and transduce signals critical for embryonic development and adult tissue homeostasis, and whose malfunction leads to a group of human diseases known as ciliopathies. Many ciliopathy proteins localize to a region of the ciliary base known as the transition zone, but the functions of this ciliary compartment remain poorly understood. Here, we found that Tectonic1 (Tctn1), a regulator of mouse Sonic Hedgehog (Shh) signaling, physically interacts with a number of proteins involved in Meckel and Joubert syndromes, two human ciliopathies. Furthermore, we demonstrate that these proteins are part of a large molecular weight complex that localizes to the transition zone. Interestingly, mice lacking components of this complex fail to form cilia in some tissues, but not in others. In the tissues where ciliogenesis is not affected, ciliary membranes display compositional and functional anomalies, as evidenced by the absence of proteins involved in ciliary signal transduction, including the calcium channel Pkd2, Adenylyl Cyclase III, Inositol 5-phosphatase-E and the Shh signaling regulators Smoothened and Arl13b. Taken together, our data reveal a dual role for the transition zone in ciliary assembly and trafficking, and suggest that transition zone dysfunction underlies Meckel and Joubert syndromes. Consistent with this, we have identified a TCTN1 mutation that causes Joubert syndrome in human patients.

1454

Primary Cilia Loss Occurs Early in Prostate Cancer Progression.

N. Hassounah[1], R. Nagle[2], K. McDermott[2]; [1]University of Arizona, Tucson, AZ

Prostate cancer is the most prominently diagnosed cancer and the second leading cause of cancer related deaths in men in the U.S. Little is known about the role of primary cilia in prostate cancer progression. Primary cilia are microtubule based organelles present on many mammalian cell types and help the cell sense the extracellular environment. Various signaling pathways important in development involve primary cilia, such as the Hedgehog (Hh) and Wingless/Int (Wnt) pathways, and these pathways are also known to be abrogated in prostate cancer. Dysfunction of primary cilia is the cause of numerous ciliopathies, such as polycystic kidney disease and Bardet-Biedl syndrome, and has been linked to cancers including basal cell carcinoma and medullablastoma. We hypothesize that primary cilia loss promotes prostate cancer by altering cell signaling pathways like Hh and Wnt. We looked in human prostate cancers at cilia, Hh and Wnt signaling. Human prostate tissue from 75 prostate cancer patients was stained with antibodies that recognize acetylated and ¦Ã-tubulin to visualize primary cilia. The expression of these proteins was analyzed and compared between adjacent normal, hyperplastic, prostatic intraepithelial neoplasia (PIN), malignant and perineural invasion areas of each patient's tissue. As a control, normal prostate tissue from 10 patients with bladder cancer (but no prostate cancer) was used. A decrease in the percentage of ciliated cells in cancer (median=1.85%) and PIN (median= 5.67%) was observed compared to normal prostate tissue (median =8.88%). Higher grade cancer (Gleason sum ¡Ý7) also had fewer cilia (median=1.42%) than lower grade (Gleason sum = 6) (median = 2.16%).We are currently investigating Hh and Wnt signaling activity in these tissues by staining serial sections to look for the expected increase (Wnt) and decreased (Hh) as a result of loss of cilia. These results indicate that cilia are lost early in the progression of cancer and that severe cilia loss is increased in the most aggressive forms of prostate cancer. Based on these results, we propose that primary cilia play a role in promoting prostate cancer progression.

1455

Primary cilia are decreased during breast cancer progression.

I. Menzl[1], L. LeBeau[2], K. M. McDermott[1]; [1]Department of Cell Biology and Anatomy, University of Arizona, Arizona Cancer Center, Tucson, AZ, [2]Department of Pathology, University of Arizona

Primary cilia are microtubule-based organelles that protrude from the cell surface. A primary cilium consists of a centriole-based basal body and an axoneme nucleating from the basal body. Intensive research within the last decade demonstrates that the primary cilium plays crucial roles in development and disease through regulation of signaling pathways such as the Hedgehog (Hh), Wingless/Int (Wnt) and platelet-derived growth factor (PDGF) pathways. Recent studies have also linked ciliary dysfunction to cancer. The goal of the present study is to investigate the role of primary cilia in breast cancer progression. To accomplish this goal, we examined the expression of cilia in tissues from 85 breast cancer patients by counting and measuring cilia in four different cell types: the basal and luminal epithelial cells, stromal cells and also cancer cells associated with pre-malignant and malignant lesions. In addition, we examined histologically normal cells that are found adjacent to breast cancer lesions. In order to examine the occurrence of primary cilia in these patients, the tissue was stained with anti-ã tubulin (basal body) and anti-acetylated tubulin (axoneme) antibodies. Cilia were visualized using a Leica Confocal Microscope and the median number and length of the detected cilia was determined. We observed a decrease in the percentage of ciliated cells on pre-malignant lesions (grades 1&2: 0.92%, grade 3: 0.18%) as well as in invasive cancers (grades 1 & 2:

0.16% and grade 3: 0.00%) when compared to basal cells of adjacent normal tissue (22.33%). It is possible that cilia are lost on cancer cells due to their highly proliferative state. However, in cancer cells stained with Ki67 we found no correlation between decreased cilia and high Ki67. Interestingly, the percentage of ciliated stromal cells was decreased in both pre-malignant lesions (grades 1&2: 4.1%, grade 3: 5.9 %) and invasive cancers (grades 1&2: 4.8%, grade 3: 1.4 %) when compared to stromal cells associated with normal adjacent tissue (11.8%). This data suggests that primary cilia are lost very early in breast cancer progression. Future research will include the investigation of the Hh and Wnt signaling pathways in serial sections of these tissue samples to determine if loss of cilia is associated with the anticipated misregulation of these pathways. We propose that loss of cilia works through misregulation of Hedgehog and Wnt pathways to promote breast cancer progression.

1456

Smurf1 is involved in cardiac development and congenital heart defects.

K. Koefoed[1,2], K. D. Ajbro[3], C. A. Clement[1], M. L. Vestergaard[2], K. Moellgaard[4], E. Bendsen[5], N. Tommerup[6], S. T. Christensen[1], L. A. Larsen[2]; [1]Department of Biologi, University of Copenhagen, Copenhagen, Denmark, [2]Wilhelm Johannsen Centre for Functional Genome Research, University of Copenhagen, Copenhagen, Denmark, [3]Johannsen Centre for Functional Genome Research, University of Copenhagen, Copenhagen, Denmark, [4]Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark, [5]University of Odense, [6]University of Copenhagen

The transforming growth factor β (TGF-β) superfamily controls important events in heart development, including cell migration, cardiomyocyte proliferation, chamber formation, endocardial cushion formation, development of smooth muscles and vessel stabilization. The concentration and expression of TGF-β components are tightly controlled with respect to tissue, concentration and time during normal heart development. Congenital heart defects (CHDs) are characterized by a large spectrum of structural anomalies of the heart, and since TGF-β is highly implicated in cardiogenesis, the different TGF-β components are candidate genes for CHDs.

An arrayCGH screening identified a 486 kbp de novo duplication of 7q22.1 in a patient with coarctation of the aorta. This region contains three genes; *TMEM130*, *TRRAP* and *SMURF1*. Smurf1 is an E3 ubiquitin ligase involved in targeting TGF-β components for degradation. SMURF1 interacts with six known heart proteins and is highly expressed in human embryonic and fetal heart. Immunohistochemical analysis of human embryonic and fetal hearts revealed that the SMURF1 protein has a spatially and temporally restricted expression pattern during cardiogenesis, which suggests that SMURF1 plays a specific role in chamber formation. *Smurf1* expression is up regulated during differentiation of P19.CL6 mouse stem cells into mature beating cardiomyocytes, and the expression peaks at day seven post differentiation induction. The same pattern is observed on protein level. Knockdown of Smurf1 results in a delay in differentiation of P19.CL6. Surprisingly, knockdown of Smurf1 with subsequent TGF-β stimulation had a negative effect on the TGFβ/BMP pathway, visualized by decreased phosphorylation of Smad2, which localizes to the base of primary cilia and. In the same knockdown study it was shown that the overall level of Smad2 seemed to be unaffected, indicating an effect upstream of Smad2 phosphorylation. During differentiation, the localization of Smurf1 shifts from being nuclear to cytosolic – a pattern similar to Smad7 localization – suggesting an interplay between these two proteins in regulation of the TGF-β pathway. Since TGF-β receptors localize to primary cilia of P19.CL6 cells to control Smad2 phosphorylation during cardiomyocyte differentiation, it is possible that Smurf1 may act as a positive regulator of ciliary TGF-β signalling in P19.CL6 cells.

Our results suggest that SMURF1 has important functions during heart development, specifically during cardiomyogenesis and chamber formation and potentially through interaction with TGF-β signaling at the primary cilium.

Mitotic Spindle and Kinetochores

1457

Identification of a TPX2-like protein in Drosophila.

G. Goshima[1]; [1]Nagoya Univ, Nagoya, Japan

TPX2 is highly conserved and is one of the best studied spindle microtubule-associated proteins. Characteristic intracellular dynamics and several molecular activities have been reported for this protein, such as nuclear localisation during interphase, poleward movement in the metaphase spindle, microtubule nucleation, microtubule stabilisation, Aurora A activation, kinesin-5 binding, and kinesin-12 recruitment. This protein has been shown to be essential for spindle formation in every cell type analysed so far. However, Drosophila homologues of TPX2 have not yet been identified. In this study, I identified DPX2, a Drosophila protein that has limited but significant homology to TPX2. Sequence conservation was found to be limited to the putative spindle microtubule-associated region of TPX2, and direct binding of DPX2 to microtubules was seen in vitro. Intriguingly, DPX2 lacks the Aurora A- and kinesin-5-binding domains; these domains are highly conserved in other animal and plant species, including many insects such as ants and bees. The contribution of DPX2 to spindle assembly seems to be minor and differs in this regard from other systems. Live cell imaging of microtubules and chromosomes after RNAi knockdown of DPX2 in S2 cells showed significant delay in chromosome congression in only 18% of the cells. Thus, the Drosophilidae family does possess this conserved spindle protein but also possesses other mechanisms that largely compensate for its function.

1458

CENP-T proteins are conserved KMN-independent centromere receptors of the Ndc80 complex.

S. Westermann[1], A. Schleiffer[1], M. Maier[1], G. Litos[1], P. Hornung[1], K. Mechtler[1]; [1]Res Inst Molec Pathol, IMP, Vienna, Austria

Transmission of genetic information in eukaryotes depends on kinetochores which drive chromosome segregation by providing a dynamic link between centromeres and spindle microtubules. All kinetochores contain multiple copies of the four-protein Ndc80 complex whose microtubule binding activity is essential for chromosome segregation in all systems tested. A fundamental question is therefore how this complex is anchored to centromeres. Here we show that the conserved histone-fold protein Cnn1^{CENP-T} is a direct centromere receptor of the Ndc80 complex. Using bioinformatic, proteomic and biochemical reconstitution approaches we demonstrate that centromere-binding proteins are highly conserved between yeast and humans. We identify the novel budding yeast protein Wip1 as a CENP-W homolog that interacts with the CENP-T-like protein Cnn1. The N-terminus of Cnn1 contains a conserved peptide motif that mediates stoichiometric binding to the Spc24-25 globular domain of the Ndc80 complex. Cnn1 and the Mtw1 complex are mutually exclusive binding partners of Spc24-25, demonstrating the presence of distinct Ndc80 populations at yeast kinetochores. Artificial tethering of Cnn1 but not of the Ndc80 complex itself is sufficient to promote acentric mini-chromosome segregation depending on the Ndc80 interaction motif. Our results reveal the conserved molecular function

of CENP-T proteins and identify a kinetochore attachment fiber that combines microtubule-binding with DNA-binding activities.

1459

Structural cell biochemistry of a novel histone fold vertebrate kinetochore complex: CENP-TW and CENP-SX form a heterotetramer.

T. Nishino[1], K. Takeuchi[1], K. E. Gascoigne[2], A. Suzuki[1], T. Hori[1], T. Oyama[3], K. Morikawa[4], I. M. Cheeseman[2], T. Fukagawa[1]; [1]National Institute of Genetics, Mishima, Shizuoka, Japan, [2]MIT, [3]Inst. of Prot. Res., Osaka Univ., [4]IIAS

Kinetochore is a conserved multi-protein structure required for segregation of sister chromatids during mitosis. It functions as an interface with spindle microtubule. Without a functional kinetochore, the cell fails to segregate chromosomes and this results in aneuploidy or even cancer. Recent proteomic analyses have identified components of the Kinetochore ensures proper segregation of the replicated sister chromatids during mitosis. It connects the sister chromatids and the spindle microtubules emanating from the two daughter centrosomes. With the progress of proteomic analyses, we now know that the vertebrate kinetochore complex comprises of more than 80 proteins and the numbers are still increasing. On the other hand, structural and functional analyses are progressing at a much slower rate.
To elucidate the structure-function relationships of the vertebrate kinetochore components, we are taking two approaches: high-speed atomic force microscopy (AFM) and X-ray crystallography. High speed AFM enables direct visualization of the protein architecture such as globular, flexible or coiled- coil regions at nanometer resolution and its solution dynamics in millisecond intervals. On the other hand, crystal structure reveals the details of protein ultrastructure at atomic resolution. Following these structural analyses, we can perform various biochemical and cell biological analyses.
We have measured the high-speed AFM movies and determined the crystal structures of CENP-T/W and CENP-S/X complexes. Both were histone fold and they formed dimer and tetramer, respectively. The structures were similar between each other. Surprisingly, mixture of the two complexes resulted in a new complex that formed a heterotetramer. Biochemistry and cell biology suggest that the complex formation is required for functional kinetochore.

1460

Using Electron Tomography to Understand the Organization of the Microtubules in the *Xenopus laevis* Spindle.

E. Tranfield[1], X. Heiligenstein[1], C. Antony[1]; [1]The European Molecular Biology Laboratory, Heidelberg, Germany

Understanding the organization (polarity, length and spacing) of the microtubules (MTs) in the vertebrate spindle is important for extending our understanding of the spindle functionality including chromosome segregation. Light microscopy studies done on spindles formed in the *Xenopus laevis* egg extract system propose a complex array of MTs with different dynamics that are cross-linked and focused during bipolar spindle assembly. However, the fundamental three-dimensional (3D) organization of the vertebrate spindle at electron microscopy resolution is still unknown and many questions remain about the detailed organization of the MTs in the spindle. This work aims to address those knowledge gaps. We are using the *Xenopus laevis* egg extract system to assemble cycled meiotic spindles. The spindles are assessed using light microscopy and well-formed, isolated spindles are high-pressure frozen, freeze substituted and processed into plastic for electron tomography. Samples are then aligned relative to the long axis of the spindle, serial sectioned, post-stained and screened on a transmission electron microscope. For spindles that are properly oriented, high magnification montage tilt series are acquired on a FEI

Tecnai F30 transmission electron microscope, and reconstructed into tomograms. Serial tomograms are then stacked together into a large 3D volume before structures of interest are modeled. To date, a partial volume of the spindle midzone has been acquired, reconstructed, stacked and partially modeled. We are currently trying to overcome acquisition challenges that are limiting our x,y resolution for such a large area. We will present our current model of spindle subzones. Furthermore, we will discuss the technical approach we are now taking, and the lessons we have learned while acquiring the largest sample yet to be attempted by our laboratory.

1461

Determining the nanoscale distribution of kinetochore proteins around the microtubule tip.

B. Wood[1], J. Lawrimore[2], K. Gurunathan[1], A. Joglekar[1]; [1]Cell & Developmental Biology, University of Michigan, Ann Arbor, MI, [2]Biology, University of North Carolina

Chromosome segregation during cell division relies on the activity of the kinetochore as a microtubule (MT) plus-end tracking motor. As a macromolecular complex, the kinetochore executes highly sophisticated plus-end driven motility that cannot be entirely explained from the relatively simple biochemical properties of the MT-binding kinetochore proteins Ndc80, Spc105/KNL-1, and Dam1 (in fungi). This emergent behavior of the kinetochore results from the combined activity of multiple copies of each of these proteins cooperating in a specific geometry with respect to the MT plus-end. Although much is known about the biochemical and structural properties of Ndc80, Spc105/KNL-1, and Dam1, the nanoscale geometry relative to the plus-end in which they operate remains virtually unknown. We have developed a systematic approach for determining the nanoscale distributions of kinetochore proteins using live-cell fluorescence microscopy. By establishing the correspondence between FRET efficiency (using donor quenching and fluorescence lifetime methods) and sensitized emission measurements, we can exploit the sensitivity of a fluorescence microscope for indirect, but accurate FRET efficiency measurements. We also incorporate fluorescence polarization data to ensure that the assumption of isotropic rotation of the fluorophores is valid. Using this approach, we are measuring the average separation of adjacent Ndc80 molecules within a kinetochore-MT attachment. Our data reveals that the N-terminal MT-binding domains on adjacent molecules are in close proximity to each other, while the centromeric side of the complex is further apart on average. We are also measuring the position of various Dam1 complex subunits with respect to the MT lattice, each other, and the Ndc80 complex. This work will reveal whether the Dam1 complex forms oligomeric rings in vivo.

1463

The Ska1 and Ndc80 complexes form an integrated kinetochore-microtubule interface.

J. C. Schmidt[1], N. Dashkevich[2], N. Monnier[3], M. Bathe[3], E. Grishchuk[2], I. M. Cheeseman[1]; [1]MIT, Whitehead Institute for Biomedical Research, Cambridge, MA, [2]University of Pennsylvania, [3]MIT

The macromolecular kinetochore connects the mitotic spindle with chromosomes to facilitate faithful chromosome segregation in mitosis. Force generated by microtubule depolymerization drives chromosome movements and generates tension across sister kinetochores. How the kinetochore couples chromosome movements to microtubule depolymerization remains poorly understood. The Ndc80 complex and the Ska1 complex have both been individually implicated in this process. In the absence of either complex, robust kinetochore-microtubule attachments fail to form. Using biochemical, single-molecule, and cell biological approaches, we demonstrate that the Ndc80 complex and the Ska1 complex bind to microtubules cooperatively, an activity conserved from human to C. elegans. This synergy is required to produce tension across sister

kinetochores. In vitro, the Ska1 and Ndc80 complexes readily diffuse on microtubules and couple bead movement to microtubule depolymerization. We propose that the combined activities of the Ndc80 and Ska1 complexes allow the kinetochore to utilize the energy of microtubule depolymerization to generate tension across sister kinetochores and drive chromosome movement.

1464

Kinetochore-microtubule attachments slip dependent on the phosphorylation of Ndc80.

P-H. Hsu[1,2], E. Marco[3], K. Jaqaman[3], P. Sorger[3], G. Danuser[1]; [1]Cell Biology, Harvard Medical School, Boston, MA, [2]Cell Biology, The Scripps Research Institute, La Jolla, CA, [3]Systems Biology, Harvard Medical School

Accurate segregation of mitotic chromosomes is a prerequisite for the maintenance of genomic integrity. To prevent aneuploidy, the interaction between kinetochore and kinetochore-microtubules (kMTs) has to be regulated to ensure the timely correction of erroneous attachments. Although most of the kinetochore components interfacing with kMTs have been identified, very little is known about the actual mechanics of their interactions. To address this question, we have expanded previous single-chromosome tracking and modeling methods in budding yeast to differentiate the effects of kMT-interfacing kinetochore components on transient kinetochore-kMT binding versus on regulation of kMT dynamics. Here we report the construction of yeast strains with symmetrically-tagged Chromosome IV, where the fluorescent signal accurately represents the location of centromeric DNA (CEN), and tagged spindle pole body (SPB). We propose that the dynamics of CEN relative to SPB can be subdivided into two components: (1) the global extension and shortening of the CEN-SPB distance are controlled by the growth and shrinkage of kMT, respectively; whereas (2) the local adjustment of the distance between CEN and kMT plus end is fine-tuned by kinetochore and can be quantified by using the previously published framework of autoregressive-moving-average (ARMA) models. Attempts to reproduce experimentally observed ARMA models of chromosome dynamics with simulation of kMT dynamics strongly suggest that the kinetochore constantly slides about the kMT end, defining an interface of transient bindings and releases. To further investigate the origin of this slippage we began to analyze the changes in the dynamics induced by ndc80 phosphorylation site mutants (kindly provided by Dr. Biggins). We find that ndc80 mutants with un-phosphorylatable N-terminal domains exhibit dampened dynamics between CEN and kMT plus end, indicating the crucial role of ndc80 in fine-tuning the kinetochore-kMT interaction.

1465

Importin beta regulates the RANBP2/RANGAP1 complex at mitotic kinetochores.

E. Roscioli[1], M. Giubettini[1], L. Di Francesco[2], A. Bolognesi[1], A. Ruggiero[1], A. Harel[3], M. Schinina[2], P. Lavia[1]; [1]Institute of Molecular Biology and Pathology, CNR National Research Council, c/o Sapienza University of Rome, Italy, Rome, Italy, [2]Department of Biochemical Sciences, Sapienza University of Rome, Italy, [3]Department of Biology, Technion-Israel Institute of Technology, Haifa, Israel

The GTPase Ran regulates nuclear transport in interphase and plays important roles in mitosis. The underlying mechanism in both processes is based on RanGTP ability to bind importin beta, the major nuclear transport vector, thereby releasing importin beta cargoes in a free active form. We previously investigated how the system operates in mitosis, when nuclear transport ceases, and found that Ran and importin beta co-localize at mitotic spindle poles and microtubules. Inducing an imbalance between Ran and importin beta yields the formation of abnormal spindles that drive chromosome mis-segregation.

To further investigate how importin beta acts in human mitotic cells, we have combined deletion mapping, functional assays, and proteomic analysis of importin beta mitotic partners. We find that importin beta functional domains regulate diverse aspects of mitosis via different classes of target proteins. The C-terminal domain (interacting with importin alpha and hence nuclear cargoes in interphase) regulates spindle pole organization in early mitosis. The central domain, harboring nucleoporin binding sites, regulates microtubule dynamic functions and interactions with kinetochores. Importin beta interacts through this region with NUP358/RANBP2 and SUMO-conjugated RanGAP1 even after nuclear pore disassembly. We found that this interaction is required to regulate RanGAP1 localization on microtubule-attached kinetochores and hence the local hydrolysis of RanGTP after microtubule attachment.
Together these data reveal a novel interplay between importin beta and RanBP2 at KTs and, more generally, indicate that importin beta domains regulate distinct temporal and spatial aspects of mitosis in a highly regulated manner. Overall, our results highlight the role of importin beta as a master regulator of mitotic progression.

1466

The human Ndc80 complex is a microtubule rescue factor regulated by Aurora B kinase.

D. Gestaut[1], N. Umbreit[1], J. Tien[1], B. Vollmar[1], T. Gonen[1], C. Asbury[2], T. Davis[1]; [1]Biochemistry, University of Washington, Seattle, WA, [2]Department of Physiology and Biophysics, University of Washington, Seattle, WA

During mitosis, kinetochores couple chromosomes to the dynamic tips of spindle microtubules. Since microtubule dynamics are stochastic in nature, the precise movement of chromosomes is dependent on the regulation of these dynamics. Several accessory factors, regulated by the Aurora B kinase, localize to the kinetochore and can affect microtubule dynamics. However, the role of core kinetochore components is not well understood. Using electron microscopy and single-molecule biophysical techniques, we show that the human Ndc80 complex directly modifies microtubule dynamics by stabilizing the tips of disassembling microtubules and promoting microtubule rescue (the transition from microtubule shortening to growth). Mutations in the Ndc80 complex that mimic its phosphorylation by Aurora B inhibit the ability of the complex to influence microtubule dynamics, but do not prevent the complex from forming stable attachments to disassembling microtubule tips. Our results indicate that Aurora B can regulate microtubule dynamics through phosphorylation of the Ndc80 complex, a conserved and essential microtubule-binding component of the kinetochore.

1467

Autoactivation of Aurora B Kinase Can Generate a Mobile Phosphorylation Switch in Mitotic Cells.

R. S. Stamatov[1,2], M. A. Lampson[3], F. I. Ataullakhanov[4], E. L. Grishchuk[2]; [1]School of Engineering and Applied Science, University of Pennsylvania, Philadelphia, PA, [2]Physiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, [3]Department of Biology, University of Pennsylvania, Philadelphia, PA, [4]Center for Theoretical Problems of Physicochemical Pharmacology, Russian Academy of Sciences, Moscow, Russia

Aurora B kinase is one of the major regulators of proper chromosome segregation during cell division. Its critical role is to phosphorylate kinetochore proteins, thereby changing their affinity to the microtubules. When Aurora B kinase activity is inhibited, the inappropriate, merotelic kinetochore-microtubule attachments become stabilized, leading to lagging chromosomes in Anaphase. Current views of the kinetochore bi-orientation and error-correction imply that the activity of Aurora B kinase is differentially distributed across the kinetochore. Strikingly, Aurora B kinase is concentrated not at the kinetochore but in the centromeric chromatin. It is thought that

the active kinase propagates spatially via diffusion to reach its targets at the outer kinetochore plate, which is located hundreds of nanometers away. However, the molecular mechanisms that determine the precise positioning and shape of this phosphorylation gradient are still unknown. Here, we consider a mathematical model in which Aurora B kinase is present as centromere-bound and soluble pools. Within each pool there are two forms of the kinase with different activities; a partially active form can be activated by trans-phosphorylation giving rise to a fully active form. This auto-activation creates a positive feedback loop, which is counteracted by a cytoplasmic phosphatase. We show that such previously unexplored, coupled kinase-phosphatase system exhibits a highly non-linear behavior and can generate a variety of complex spatio-temporal regimes, including bi-stability, propagation of autowaves and generation of stable long-range gradients. We test the predictions of this in silico model by visualizing in real time the spatial phosphorylation gradients in mitotic HeLa cells using a FRET-based phosphorylation sensor. By varying the concentration of a kinase inhibitor, we observed that sensor phosphorylation changes in a highly non-linear, step-wise manner with slight hysteresis. Furthermore, we observed the constant rate of propagation of phosphorylation waves, which arise following the removal of kinase inhibitor, implying that these waves are self-sustained. Together, these results support a model in which a vitally important long-range pattern of Aurora B activity at the kinetochore is established via the formation of a stable dissipative structure, which arises dynamically around the centromeric region where the binding sites for Aurora B kinase are clustered.

1468

The Microtubule-Associated Protein TPX2 contributes to interspecies spindle scaling in *Xenopus.*

K. Helmke[1], R. Heald[1]; [1]University of California Berkeley, Berkeley, CA

The mitotic spindle is a dynamic macromolecular assembly comprised mainly of microtubules (MT) and microtubule associated proteins (MAPs) that must react to cell size in order to properly organize and separate chromosomes during cell division. However, physiological determinants of spindle size control are poorly understood. Taking advantage of spindles formed *in vitro* in egg extracts from the frog *Xenopus laevis* and its smaller relative *Xenopus tropicalis*, we are investigating the role of spindle assembly pathways that likely contribute to the observed cytoplasmic, dose-dependent regulation of spindle size. Spindle assembly in *X. laevis* egg extracts relies heavily on RanGTP, which is locally generated by its nucleotide exchange factor RCC1 bound to chromatin, creating a spatial gradient of active Spindle Assembly Factors (SAFs) released from the cargo carrying proteins importin α/β. SAFs regulate aspects of MT organization and dynamics that could contribute to spindle size, including nucleation and bundling. Interestingly, whereas adding hydrolysis-deficient Ran(Q69L)GTP caused MT spontaneous nucleation and formation of self-organizing bipolar structures in *X. laevis* egg extracts, MTs formed asters but not bipolar structures in *X. tropicalis* extracts under the same conditions. Adding the dominant-negative RanT24N, which inhibits RCC1, resulted in strong spindle disruption in *X. laevis*, with mislocalization of SAFs including the spindle MT-associated protein (MAP) TPX2 (Targeting Protein for Xklp2). In contrast, *X. tropicalis* extracts formed bipolar spindles even at 20-fold higher RanT24N concentrations, and strong TPX2 staining persisted. Furthermore, TPX2 levels appeared approximately three-fold higher in X. tropicalis egg extracts by Western blot, whereas importin α levels are three-fold lower. These results suggest that *X. tropicalis* depends less on the Ran pathway for spindle assembly and that TPX2 is a candidate spindle scaling factor. Consistent with this model, addition of TPX2 to *X. laevis* reduced spindle length. Experiments are underway to test whether TPX2 levels affect the activity of the kinesin-5 spindle motor Eg5 in egg extracts, thereby modulating the outward sliding of antiparallel MTs and steady state spindle length.

1469

Regulation of Kif2a by Importin α Contributes to Spindle Size Scaling during *Xenopus* Development.

E. Whitehead[1], R. Heald[1], J. Wilbur[1]; [1]University of California, Berkeley, Berkeley, CA

During the cleavage divisions of *Xenopus laevis* embryos, mitotic spindle size must adjust to decreasing cell size to ensure proper segregation of replicated chromosomes to daughter cells, but mechanisms underlying changes in spindle size and morphology during development are not understood. We observed increased recruitment of the microtubule depolymerizing kinesin-13 Kif2a to the spindle later in development, a phenomenon that could be recapitulated *in vitro* with spindles assembled in embryo extracts prepared from stage 8 embryos (~4000 cells) compared to those in stage 3 (4 cells). Whereas inhibiting Kif2a in stage 3 reactions did not significantly affect spindle size, stage 8 spindles increased in area by 34 +/- 5%, appearing wider and lantern-shaped due to an increase in microtubules. Interestingly, although Kif2a localizes to centrosomes and not the nucleus during interphase in human cells, it contains a canonical Nuclear Localization Signal (NLS) in its motor domain, suggesting regulation by importins, and we detected importin α (impα) in Kif2a immunoprecipitates. Although Kif2a levels do not change significantly during *X. laevis* early development, impα levels drop 50% by stage 8, and addition of excess impα increased the size of stage 8 spindles. We hypothesize that impα sequesters Kif2a in early stage embryos thereby increasing steady state spindle size. In support of this model, we have found that impα inhibits Kif2A microtubule depolymerization activity *in vitro*. Experiments are underway to test direct binding of the two proteins and its dependence on the Kif2a NLS, and to evaluate the effects on spindle size of altering Kif2a and impα *in vivo* during *Xenopus* development.

1470

Microtubule Destabilizing Activities Scale Spindle Size in Xenopus.

J. Wilbur[1], R. Loughlin[1], F. McNally[2], F. Nedelec[3], R. Heald[1]; [1]Molecular and Cell Biology, UC Berkeley, Berkeley, CA, [2]Molecular and Cellular Biology, UC Davis, [3]Cell Biology and Biophysics Unit, EMBL

Bipolar spindles must separate chromosomes the appropriate distance during cell division, but mechanisms determining spindle size are poorly understood. Using two Xenopus-based systems to study physiological mechanisms of spindle scaling, we have identified microtubule (MT) destabilization as a major spindle size controlling activity. Based on predictions from a 2-D meiotic spindle simulation, we identified katanin-dependent MT severing as an activity reduced in egg extracts from X. laevis compared to the smaller frog X. tropicalis, which forms smaller spindles in vitro. Interestingly, X. tropicalis lacks an inhibitory Aurora B phosphorylation site in the p60 catalytic subunit of katanin found in X. laevis at Ser131. P60 depletion increased spindle length and disrupted spindle structure in X. tropicalis, as kinetochore fibers protruded through spindle poles. Spindle morphology and size defects were reversed by addition of a recombinant X. laevis p60Ser 131Ala mutant that cannot be phosphorylated, but not by the phosphomimetic mutant Ser131Glu. Thus, phosphoregulation of p60 dependent MT destabilization scales meiotic spindle size between closely related species and coordinates stability of multiple MT populations in order to generate a robust steady state structure. MT destabilization also correlated with mitotic spindle size changes during X. laevis embryogenesis. By establishing an embryo extract system to examine intrinsic spindle scaling during development, we could compare extracts from stage 3 to stage 8 embryos that contain 4 large or thousands of small cells and exhibit a ~2.5 fold difference in spindle size. We observed increased MT catastrophe frequency from centrosomal MTs, a shift away from chromatin mediated spindle assembly, and increased recruitment of both p60 katanin and the MT

destabilizing protein kif2a in stage 8 spindles. Thus, in both systems appropriate spindle size appears to depend on defined levels of tightly regulated MT destabilizing activity, establishing this mechanism as a physiologically utilized means of spindle scaling.

1471

IFT88 and Ciliary IFT B Complex Members in Mitosis.

A. Bright[1], S. Doxsey[1]; [1]Program in Molecular Medicine, University of Massachusetts Medical School, Worcester, MA

Intraflagellar transport (IFT) is a bidirectional transport system required for the generation and maintenance of primary and motile cilia in noncycling cells. IFT proteins form multimeric complexes, A and B, which transport ciliary components from the cell body to the ciliary tip, and back to the base, while riding on microtubule motors. Cilia protein disruption results in multiple disorders collectively termed ciliopathies. Interestingly, IFT88, a conserved IFT component required for ciliogenesis, also localizes to mitotic centrosomes/spindle poles where it functions in spindle orientation and astral microtubule organization (Delaval et al, Nature Cell Biology, 20ll). Like in cilia, where IFT complexes carry pre-assembled ciliary components along the microtubule axoneme, mitotic IFT88 carries peripheral microtubule bundles containing spindle pole proteins along microtubules to spindle poles. However, it is currently unknown if IFT88 functions in combination with the ciliary IFT B complex during mitosis, as it does within cilia. To answer this question we characterized two additional IFT proteins: IFT57 and IFT20. Like IFT88, these proteins are members of the ~14 protein IFT B complex that localize to mitotic spindle poles. As with IFT88, IFT57 and IFT20 depletion led to disrupted spindle poles and an increased mitotic index. Furthermore, IFT57 and IFT20 co-fractionated with IFT88 in mitotic lysate, suggesting that like in cilia, some or all IFT B complex members may form a mitotic complex. Consistent with this model, IFT20 depletion partially mislocalized IFT88 from spindle poles, demonstrating interdependence amongst IFTs for spindle pole localization. Together our data suggest that like in cilia, IFT88 functions along with additional IFT B complex members during mitosis. It also raises the important possibility that mitotic defects induced by mutations in IFT proteins could contribute to the phenotypes associated with ciliopathies. In this regard, it may be the centrosome, an integral cilia and spindle pole component, which is the underlying source of ciliopathies.

An inducible RNAi screening system reveals augmin-mediated spindle microtubule generation in plant cells.

T. Miki[1], Y. Nakaoka[1], R. Fujioka[1], R. Uehara[1], A. Tomioka[1], C. Obuse[2], M. Kubo[3,4], Y. Hiwatashi[4,5], G. Goshima[1]; [1]Graduate School of Science, Nagoya University, Nagoya, Japan, [2]Graduate School of Life Science, Hokkaido University, [3]ERATO, Japan, [4]National Institute for Basic Biology, Japan, [5]School of Life Science, The Graduate University for Advanced Studies

The moss *Physcomitrella patens* is an emerging land plant model to which several key molecular techniques, such as homologous recombination or RNA interference (RNAi), can be applied. The caulonemal cells in the protonemata (a filamentous structure arising from spore germination) have stem cell characteristics and less interference by autofluorescence, and therefore are suitable for live imaging with fluorescent protein-tagged markers. Recently, it was reported that the γ-tubulin ring complex (γ-TuRC) and augmin (an 8-subunit protein complex) are required for centrosome-independent microtubule generation within the mitotic spindle in fly and human cells possessing centrosomes. However, the contribution of augmin to spindle microtubule generation in cells that naturally lack centrosomes has not been elucidated. In this study, we developed an inducible RNAi system in *P. patens* to evaluate the mitotic phenotype

after augmin knockdown in caulonemal cells that naturally lack centrosomes. After RNAi, ~50% longer bipolar spindles were initially formed with reduced microtubule intensities and misaligned chromosomes, and were eventually collapsed during prolonged mitosis. Cytokinesis was also incomplete owing to failure in phragmoplast expansion. Furthermore, fluorescence recovery after photobleaching analysis for green fluorescent protein (GFP)-tubulin revealed that the recovery of GFP intensity within the spindle is significantly delayed. Indistinguishable phenotypes were observed after RNAi of γ-TuRC subunits. These results show that γ-TuRC and augmin play a critical role in spindle microtubule generation during metaphase and cytokinesis in *P. patens* caulonemata. We also found unanticipated dynamics during caulonemal mitosis, such as asymmetric spindle formation in prometaphase or midzone accumulation of γ-tubulin, augmin, and EB1 in anaphase, which may represent the unique mechanism of non-centrosomal cell division developed by land plants.

The Nucleotide-Binding State of Microtubules Modulates Kinesin Processivity and Tau's Ability to Inhibit Kinesin Mediated Transport.

D. P. McVicker[1,2], L. R. Chrin[1], C. L. Berger[1]; [1]Molecular Physiology and Biophysics, University of Vermont, Burlingtin, VT, [2]Cell and Molecular Biology, University of Vermont, Burlington, VT

Tau's ability to act as a potent inhibitor of kinesin motility in vitro suggests it may actively participate in the regulation of axonal transport in vivo. However, it remains unclear how kinesin-based transport could then proceed effectively in neurons, where tau is expressed at high levels. One potential explanation is that tau, a conformationally dynamic protein, has multiple modes of interaction with the microtubule, not all of which are inhibitory for kinesin motility. Thus, if tau can bind microtubules in distinct conformations or at unique binding sites that no longer inhibit kinesin, transport would proceed unhindered along the axon. Previous studies support the hypothesis that tau has at least two modes of interaction with microtubules, but the mechanisms by which tau adopts these different conformations and their functional consequences have not previously been investigated. In the present study we have used single molecule imaging techniques to demonstrate that tau inhibits kinesin motility in an isoform dependent manner on GDP-microtubules stabilized with either paclitaxel or glycerol, but not GMPCPP-stabilized microtubules. Furthermore, the order of tau addition to microtubules before or after polymerization has no effect on tau's ability to modulate kinesin motility regardless of the stabilizing agent used. Finally, the processive run length of kinesin is reduced on GMPCPP-microtubules relative to GDP-microtubules, and kinesin's velocity is enhanced in the presence of 4RL-tau but not the 3RS-isoform. These results shed new light on tau's potential role in the regulation of axonal transport, which is more complex than previously recognized.

1474

The length of the neck linker domain controls processivity across diverse N-terminal kinesin families.

W. O. Hancock[1], S. Shastry[1]; [1]Bioenginering, Penn State University, University Park, PA

Consistent with their diverse intracellular roles, the processivity of N-terminal kinesin motors varies considerably between different families. Gating mechanisms that control kinesin processivity involve inter-head tension that must be transmitted through the neck linker domains of each head. The objective of this study is to determine the degree to which unloaded

processivity is controlled by the length of the neck linker, as opposed to kinetic differences in the core motor domains. The motor and neck linker domains of Kinesin-2, 3, 5 and 7 were fused to the neck-coil and rod domains of Kinesin-1 and run lengths of GFP-tagged motors visualized by total internal fluorescence microscopy. When the neck linkers were shortened to the 14 amino acids found in Kinesin-1, all motors had similar run lengths, and when the neck linkers were extended the run lengths fell. These results suggest that inter-head tension, which is regulated by the mechanical properties of the neck linker, controls processivity in a conserved manner across diverse kinesins. Monte Carlo modeling of the kinesin hydrolysis cycle conclude that the results can be quantitatively accounted for by differences in either front head or rear head gating.

1475

The loop 5 element structurally and kinetically coordinates dimers of the human kinesin-5, Eg5.

J. Waitzman[1], A. Larson[2], J. Cochran[3], N. Naber[2], R. Cooke[2], E. Pate[4], S. Rice[1]; [1]Cell and Molecular Biology, Northwestern University, Chicago, IL, [2]Biochemistry and Biophysics, University of California--San Francisco, [3]Chemistry, Dartmouth College, [4]Chemical Engineering and Bioengineering, Washington State University

Eg5 is a homotetrameric kinesin-5 motor that generates outward force on the overlapping, antiparallel microtubules (MTs) of the mitotic spindle. Upon binding a MT, an Eg5 dimer releases one ADP molecule, undergoes a slow (~0.5 s-1) isomerization, and finally releases a second ADP, adopting a tightly MT-bound, nucleotide-free conformation. This conformation precedes ATP binding and stepping. We have used mutagenesis, steady-state and presteady-state kinetics, motility assays, and electron paramagnetic resonance (EPR) spectroscopy to examine Eg5 monomers and dimers as they bind MTs and initiate stepping. We found that a critical element of Eg5, loop 5 (L5), accelerates both basal and MT-stimulated ADP release and ATPase rates. Furthermore, L5 mediates the slow isomerization by preventing Eg5 dimer heads from binding the MT until they release ADP. Structurally, the slow isomerization is a transition of the forward head from an ADP-bound, MT-unbound state into an APO, MT-bound state having an undocked neck-linker. Taken together, these properties of L5 completely explain the kinetic effects of L5-directed inhibition on Eg5 activity and may direct further interventions targeting Eg5 activity.

1476

Measuring the cytosolic drag experienced by molecular motors *in vivo.*

C. Leidel[1], G. T. Shubeita[1]; [1]Center for Nonlinear Dynamics, Department of Physics, The University of Texas at Austin, Austin, TX

Molecular motors are responsible for facilitating many vital cellular processes. By generating forces to haul various cargo to their destinations over the necessary time scales, these motor proteins help achieve the complex yet organized net distributions of vesicles and organelles that are essential for the cell's functionality and survival. Motors such as kinesin-1 and cytoplasmic dynein have been extensively studied *in vitro* where viscous drag has negligible effects on the motion of cargos. However, the issue of whether cytosolic drag *in vivo* is large enough to significantly slow cargo motion has remained controversial. To probe the importance of viscous drag on cargo motion, we tracked lipid droplets being hauled by kinesin motors in *Drosophila* embryos. An optical trap was used to apply a force on these cargos sufficient to make them stall and then fall back to the trap center. The magnitude of the cytosolic drag force determines how quickly the lipid droplets recoil back to the trap center. We use high speed detection to study the details of the recoil and its dependence on the size of the cargo and cytoskeletal content. Our

data enable us to estimate the drag force experienced by the motors and relate it to the how multiple motors cooperate in hauling cargos.

1477

Role of kinesin-mediated transport of VEGFR2 to the cell surface in mediating angiogenesis.

K. Yamada[1], G-F. Chen[2], H. Gong[1], Y. Komarova[1], M. Ushio-Fukai[1], K. Wary[1], A. Malik[1]; [1]Pharmacology, University of Illinois at Chicago, Chicago, IL, [2]Pharmacology and Medicine, University of Illinois at Chicago, Chicago, IL

Although VEGF/VEGFR2 ligand-receptor system is known to play a central role in angiogenesis, the underlying mechanism(s) regulating transport of VEGFR2 to the cell surface is not well understood. The pan-inhibitor of kinesins and dyneins, Rose Bengal lactone, prevented VEGF-mediated migration of human umbilical vein endothelial cells (HUVECs) and tube formation in Matrigel. Based on an RNAi screen, we focused on investigating the role of the molecular motor KIF13B/GAKIN (guanylate kinase-associated kinesin) in mediating VEGF-induced angiogenesis. KIF13B is known as a PIP3 transporter in neurons. In our studies, KIF13B-knockdown inhibited VEGF-mediated migration of HUVECs, as well as tube formation in Matrigel in vitro, and in Matrigel plugs in mice. PIP3 and VEGFR2 were co-localized in VEGF-stimulated endothelial cells, and interestingly, accumulated at the leading edge of migrating cells. These responses were abolished by KIF13B depletion. To address whether KIF13B mediates transport of VEGFR2, we detected KIF13B-VEGFR2 complex by co-immunoprecipitation. After VEGF stimulation, VEGFR2 is known to internalize, which mediates angiogenic signaling from the intracellular signaling compartment. VEGF also induces de novo synthesis and translocation of VEGFR2 from intracellular pool to the cell surface to receive second peak of receptor phosphorylation subsequent to VEGF binding to VEGFR2. We observed that KIF13B-knockdown inhibited translocation of VEGFR2 from intracellular pool to the cell surface and second peak of phosphorylation. These data demonstrate the crucial role of KIF13B as a VEGFR2 transporter to the endothelial membrane and in thereby mediating angiogenesis.

1478

Probing Molecular Motor Coordination via Thermal Fluctuation Analysis.

R. A. Longoria Casasa[1,2], T. F. Bartsch[1,2], E-L. Florin[1,2], G. T. Shubeita[1,2]; [1]Physics Department, University of Texas at Austin, Austin, TX, [2]Center for Nonlinear Dynamics, University of Texas at Austin, Austin, TX

Lipid droplets in *Drosophila* embryos are transported along microtubules by kinesins and cytoplasmic dyneins, each of which moves mainly unidirectionally along the track. Lipid droplets exhibit local bidirectional motion while globally moving in one direction or the other. The mechanism of direction switching is largely unknown. Here we present an *in vitro* study of the dynamics along the microtubule of endogenous cargo-motor complexes, i.e. lipid droplets purified from *Drosophila* embryos. In contrast to their transport characteristics *in vivo*, the majority of purified lipid droplets exhibit short-range transport. We combine Thermal Fluctuation Analysis via Photonic Force Microscopy, fluorescence and bright field microscopy to study the interaction of opposite-polarity motors bound to the same cargo near an immobilized microtubule. Using this approach, we can resolve individual motor binding events and motor run-lengths that would otherwise be masked by Brownian motion.

1479

Mechanical Tug-of-war Models Explain In Vitro Unidirectional but not In Vivo Bidirectional Multiple Kinesin-Dynein Transport.

A. Kunwar[1], S. Tripathy[2], J. Xu[3], M. Mattson[3], P. Anand[3], R. Sigua[3], M. Vershinin[4], R. McKenney[5], C. Yu[2], A. Mogilner[1], S. Gross[3]; [1]Department of Neurobiology, Physiology and Behavior, University of California Davis, Davis, CA, [2]Department of Physics and Astronomy, University of California Irvine, Irvine, CA, [3]Department of Developmental and Cell Biology, University of California Irvine, Irvine, CA, [4]Department of Physics and Astronomy, University of Utah, Salt Lake City, UT, [5]Department of Pathology and Cell Biology, Columbia University, New York, NY

Intra-cellular transport via the microtubule motors kinesin and dynein plays an important role in maintaining cell structure and function. Often, multiple kinesin or dynein motors move the same cargo. Because their collective function depends critically on the detachment kinetics of motors under load, we experimentally measure these kinetics for both kinesin and dynein. This experimental constraint—combined with other experimentally determined parameters—is then incorporated into theoretical stochastic and mean-field models. Comparison of modeling results and in vitro data shows good agreement for the stochastic, but not mean-field, model. In many cases, both kinesin and dynein function on the same cargo, which then moves bi-directionally, frequently reversing course. One popular hypothesis explaining this behavior is that opposite polarity motors engage in unregulated stochastic tug-of-wars and that the properties of cargo motion are determined entirely by the outcome of these opposite-motor competitions. We use fully calibrated stochastic and mean-field models to test the tug-of-war hypothesis. Neither model agrees well with our in vivo data, so we conclude that such models are not consistent with the experiments, suggesting that in addition to inevitable tug-of-wars between opposite motors, there is an additional level of regulation not included in the models.

1480

Microtubule Motor Traffic Jams.

L. Conway[1], D. Wood[2], K. E. Daly[3], A. M. O' Neill[3], E. Tuzel[3], J. Ross[2]; [1]Molecular and Cellular Biology, University of Massachusetts Amherst, Amherst, MA, [2]Physics, University of Massachusetts Amherst, Amherst, MA, [3]Physics, Worcester Polytechnic Institute, Worcester, MA

Microtubules are polarized filaments that function as transport tracks for motor proteins. These filaments are arranged such that their plus ends reach towards the cell periphery. Kinesin-1 is a motor protein that walks towards the plus ends of these filaments, carrying cargoes to the cell periphery. Numerous studies have revealed that cargo transport is often achieved through the cooperation of multiple motors carrying a single cargo. However, these studies are often carried out in a dilute environment, where factors such as crowding along the microtubule and motor exchange on a single cargo are eliminated. The objective of this study is to better understand how crowded conditions along the microtubule and motor exchange on cargoes affects cargo transport. We use quantum dots (Qdots) to create self-assembled cargoes. Qdots are known to non-specifically bind kinesin-1. When Qdot cargoes encounter excess motile kinesin-1 on the microtubule, they self-assemble cargoes with many motors, creating a system that allows for an exchange of motors on a single cargo. We used Total Internal Reflection Fluorescence (TIRF) microscopy to track individual self-assembled cargoes in varying degrees of crowded conditions. We found that while the velocity of cargoes decreased as conditions became more crowded, the run length and total association time of cargoes increased. We also found that cargoes paused more frequently in more crowded conditions. Interestingly, we observed cargo reversal events during runs, which were more likely to occur in crowded conditions. We believe

that these reversals occur when a cargo bound to multiple motors is blocked from moving forward, resulting in the release of the front kinesin. When this occurs, a kinesin in the back will most likely bind the microtubule, resulting in a rock backwards. Using statistical mechanics simulations, we can recapitulate velocity reduction, longer run lengths, increased pausing, and reversals *in silico*. From this study, we conclude that transport of self-assembled cargoes is affected by levels of crowding along the microtubule.

1481

Experimental and theoretical analyses of the mechanism and function of Kinesin-1-dependent cytoplasmic flows.

L. Williams[1], S. Ganguly[2], R. Goldstein[2], I. Palacios[1]; [1]Zoology, University of Cambridge, Cambridge, United Kingdom, [2]DAMTP, University of Cambridge, United Kingdom

We study two types of motion that depend on the motor protein Kinesin-1: the transport of material along microtubules and cytoplasmic streaming. One context in which streaming occurs is the establishment of Drosophila body axes, when Kinesin-1 transports the axes determinants and drives ooplasmic streaming. Although Khc is essential for flows, neither the mechanism by which Khc induces streaming nor the impact of these flows on transport are known.

Using an interdisciplinary approach we are deciphering the biophysical behavior of streaming as the oocyte polarizes. Firstly, we have succeeded in the quantitative measurement of the statistical properties of streaming by Particle Image Velocimetry (PIV, a method used in fluid dynamics), allowing us to understand the link between the motivate force of streaming and its macroscopic consequences. Secondly, we have determined the rheological properties of the ooplasm. Since Khc drives flows measured viscous energy dissipation can be related to the number of motors contributing to fluid deformation. Calculation of the viscous energy dissipation requires knowledge of the flow at all points in space (by PIV), and the fluid viscosity which we have measured using microrheology (by injecting beads into khc mutant oocytes that lack flows and tracking their Brownian motion). The calculated viscosity (1 Pa.s, 1000 x water) makes the cytoplasm a low Reynolds number fluid, meaning that the energy required to deform fluid equals the energy dissipated by Khc. Using a value of 10 kBT per motor step, and an stepping rate of 10Hz, then the number of Kinesins contributing to flow is ~ 2500.

To analyze the impact of flows on motor function, we are currently correlating the flow rate with the flux of oskar RNP (a Khc cargo). With these parameters and theoretical analysis of the impact of streaming on transport, we aim to learn whether streaming assists or hinders the asymmetric distribution of cargoes. Ultimately, we would like to reconstitute streaming in vitro in controlled geometries.

In addition, a functional/structural study of Khc has shown that the tail of Khc is not required for streaming, since a tailless Khc supports flows in oocytes that lack endogenous Khc. This truncated motor is able to localize Dynein to the posterior of the oocyte, another function of Khc. These findings suggest that Khc has domain-specific functions, which is further supported by the fact that the tail is essential for oskar RNA localization but only partially contributes to the Khc-dependent positioning of the oocyte nucleus

1482

Binding studies of the TRAK/kinesin-1 trafficking complex.

T. S. Randall[1], C. Moores[2], A. Stephenson[1]; [1]School of Pharmacy, University of London, London, England, [2]Birkbeck College, University of London, United Kingdom

Little is known regarding the molecular interactions between kinesin motor proteins and kinesin adaptor proteins. Trafficking kinesin proteins (TRAK) are a family of kinesin adaptor proteins that facilitate transport of cargoes in neurons via the microtubule network. There are two TRAKs

in vertebrates, TRAK1 and TRAK2. TRAKs bind to kinesin-1 molecular motors and to their cargoes. The best characterised cargo transported by TRAKs is mitochondria. Mitochondrial transport occurs via the binding of TRAKs to the mitochondrial outer membrane protein, Miro. In vitro experiments using the kinesin-1, KIF5C, showed that TRAK proteins bind to the motor via the C-terminal cargo binding domain. However, in the brain, TRAK2 associates predominantly with the kinesin-1, KIF5A. In this study we have designed experiments to refine further the TRAK binding site within the cargo domain of KIF5A. A series of KIF5A C-terminal truncations were generated. The cargo binding domains of the kinesin-1 family share an overall ~ 85% amino acid identity but KIF5A has an additional 75 C-terminal amino acids compared to KIF5B and KIF5C. The KIF5A C-terminal deletions were designed to exploit similarities and differences between the members of the kinesin-1 sub-family. Wild-type KIF5A (1-1032) and nine KIF5A truncations (including KIF5A (1-825) that contains the motor and stalk domains only), were each co-expressed in parallel with FLAG-tagged TRAK2 in mammalian cells. The binding of KIF5A truncations to TRAK2 was determined by quantitative immunoblotting following immunoprecipitation. Similarly to KIF5C, TRAK2 was shown to bind to the KIF5A cargo binding domain. Deletion of the KIF5A C-terminal tail appeared to enhance the binding of TRAK2. Further truncations resulted in a reduction in KIF5A immunoreactivity in immune pellets. These studies yield new insights into kinesin/kinesin adaptor interactions which may impact in the future on a better understanding of neurodegenerative diseases such as amyotrophic lateral sclerosis and Alzheimer's disease which have both been linked to deficiencies in neuronal transport mechanisms of mitochondria.

1483

Probing CENP-E function in central spindle plasticity using chemical inhibitor syntelin.

Y. Yao[1], X. Ding[2], F. Yan[3], Y. Huang[3], J. Zhang[4], X. Gao[4], D. Wang[3], Z. Dou[4], X. Yao[1,5];
[1]Physiology, Morehouse School of Medicine, Atlanta, GA, [2]Beijing University of Chinese medicine, Beijing, China, [3]Morehouse School of Medicine, [4]Anhui Laboratory for Cellular Dynamics and Chemical Biology, [5]Anhui Laboratory for Cellular Dynamics and Chemical Biology, Hefei, China

Mitotic kinesin CENP-E plays key roles in chromosome congression, spindle checkpoint satisfaction and central spindle plasticity. We have identified and characterized syntelin, a novel selective CENP-E inhibitor (Ding et al., 2010. Cell Res. 20, 1386-1390). Cells treated with syntelin progress through interphase, enter mitosis normally with a bipolar spindle and lagging chromosomes around the poles. Chromosomes in syntelin-treated cells frequently have both sister kinetochores attached to spindle microtubules from the same pole (syntelic attachment). Our biochemical study shows that syntelin is an allosteric inhibitor which tightens CENP-E-microtubule interaction by slowing inorganic phosphate release. Given the spatiotemporal dynamics of CENP-E localization to the central spindle during anaphase onset and accurate inhibition of CENP-E with syntelin, we probe for a role of CENP-E in the organization of interpolar microtubules into an organized central spindle. Inhibition of metaphase synchronized cells does not perturb interpolar microtubule assembly but abrogates the anti-parallel microtubule bundle formation. Inhibition of CENP-E motor activity leads to an aberrant localization of PRC1 and CLASP1 to the central spindle. Real-time image shows that CENP-E inhibited cells undergo central spindle splitting and exhibits chromosome instability phenotypes. These findings reveal a previously uncharacterized role of CENP-E in orchestrating central spindle plasticity essential for the initiation and execution of cytokinesis.

1484

A tethering mechanism controls the processivity and kinetochore-microtubule plus-end enrichment of the kinesin-8 Kif18A.

Y. Du[1], J. Stumpff[2], C. English[1], Z. Maliga[3], M. Wagenbach[2], C. Asbury[2], L. Wordeman[2], R. Ohi[1]; [1]Department of Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN, [2]Department of Physiology and Biophysics, University of Washington, Seattle, WA, [3]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

The alignment of chromosomes at the metaphase plate prior to segregation is an essential step towards ensuring genomic stability. This alignment process critically depends on the activity of Kif18A, a kinesin-8 motor that shows a graded distribution along K-MTs, peaking at their plus-ends where it suppresses their dynamics. The significance of this graded enrichment to the control of chromosome movements is not understood. By engineering Kif18A mutants that retain the ability to suppress MT dynamics but fail to become enriched at K-MT plus-ends, we identify a mechanism that allows Kif18A to concentrate at K-MT plus ends to a level required to suppress chromosome movements. The graded localization of Kif18A along K-MTs depends on the activity of its C-terminal tail domain, while the ability of Kif18A to suppress MT growth is an intrinsic activity of the motor. Kif18A's C-terminal tail contains a second MT-binding domain that makes diffusive movements along the MT lattice, suggesting that it effectively acts as a tether to prevent motor dissociation from the MT track. In support of this idea, the tail significantly enhances the processivity of single Kif18A molecules and is crucial for Kif18A to accumulate at K-MT plus-ends in cells. These data support a model in which the Kif18A tail confers unusually high processivity to the motor via a tether-like activity. This increased processive movement, in turn, promotes concentration of the Kif18A motor at K-MT plus-ends, where it suppresses their dynamics to control chromosome movements.

1485

Regulation of *C. elegans* MCAK by Aurora Kinase Phosphorylation.

X. Han[1], K. Cheung[2], M. Srayko[2]; [1]Biological Sciences, University of Alberta, Edmonton, AB, Canada

Microtubules are required for multiple cellular processes including mitosis, cytokinesis, and vesicle transportation. Factors that regulate microtubule dynamics in the cell help determine the final form and precise cellular role of many cytoskeletal structures. Among the known modulators of microtubule dynamics, we are specifically interested in the microtubule-depolymerizing kinesins of the kinesin-13 family, such as KLP-7 (CeMCAK).
In *C. elegans*, KLP-7 locates to the kinetochore and the centrosome. It has been implicated in regulating microtubule outgrowth at the centrosome (Srayko *et al.*, 2005, Schlaitz *et al.*, 2007). Extensive work on the vertebrate homologues of KLP-7 indicates that they are negatively regulated through phosphorylation by the Aurora kinases (Andrews *et al.*, 2004, Lan *et al.*, 2004, Ohi *et al.*, 2004, Schlaitz *et al.*, 2007, Zhang *et al.*, 2007 and 2008). In order to understand how KLP-7 is regulated in the cell, we tested the possibility that Aurora kinases are directly involved. 2D gel-electrophoresis revealed an alteration in the ratio of potential KLP-7 phosphorylation variants in lysates from either Aurora A-depleted or Aurora B-depleted embryos, compared to wild type. Furthermore, we found that both Aurora A and B kinases phosphorylated KLP-7 *in vitro*. We used a combination of *in vitro* kinase assays, similarity to data on the vertebrate homologues, and an Aurora kinase phospho-site prediction algorithm to identify potential in vivo phosphorylation sites within KLP-7 (Zhou *et al.*, 2004). We are currently performing a structure-function analysis to determine which putative Aurora sites are required for KLP-7's intracellular location and/or its depolymerase activity at the centrosome. Results obtained thus far indicate that mutating one of the C-terminal Aurora sites from serine to

glutamic acid (to mimic constitutive phosphorylation) or to alanine (to mimic non-phosphorylation) interferes with KLP-7 function but not its ability to target to centrosomes or kinetochores.

1486

In Vitro and In Vivo Single-Molecule Imaging Experiments Provide Mechanistic Insight into the Role of the Arabidopsis FRA1 Kinesin in Cell Wall Assembly.

C. Zhu[1], R. Dixit[1]; [1]Washington University in St. Louis, St. Louis, MO

The interphase microtubule cytoskeleton at the cortex of plant cells drives directional cell expansion by regulating the assembly of the cellulosic wall. Genetic analysis has indicated that the *Arabidopsis* FRA1 kinesin, a member of the kinesin-4 family, mediates the cytoskeletal control of cellulose patterning. To understand the mechanism of FRA1 function, we analyzed the motor properties of FRA1 both in vitro and in vivo using single-molecule imaging. We found that recombinant GFP-tagged FRA1 consisting of the motor and coiled-coil domains moves towards the microtubule plus-end as a dimer. Notably, the processivity of FRA1 is at least twice the processivity of conventional kinesin in vitro, making FRA1 the most processive kinesin to date. To study the motility of full-length FRA1 in vivo, we introduced a full-length FRA1-3GFP construct, driven by the native *FRA1* promoter, into a *fra1* null mutant. The FRA1-3GFP construct fully complemented the *fra1* mutant phenotype indicating that the encoded protein is functional. We used highly inclined and laminated optical sheet (HILO) microscopy for single-molecule imaging of FRA1-3GFP in living *Arabidopsis* seedlings. We found that FRA1-3GFP localizes to the cell cortex as discrete particles that bind to cortical microtubules. A subset of the cortical microtubule-bound FRA1-3GFP particles move highly processively while others dissociate quickly and do not show processive movement. Interestingly, the motile fraction of FRA1-3GFP correlates with the cell expansion rate. These observations reveal that FRA1 motility is tightly regulated in cells and probably contributes to altering the cell wall composition and/or structure during cell expansion. Pharmacological experiments showed that FRA1 motility is independent of cellulose synthesis. In addition, the velocity of full-length FRA1 in vivo is at least 60-fold greater than the velocity of the plasma-membrane-embedded cellulose synthase complexes, which synthesize and extrude cellulose microfibrils in the extracellular space. Therefore, FRA1 is unlikely to regulate cellulose patterning by guiding the directional movement of cellulose synthase complexes. Instead, FRA1 may transport vesicles containing cell wall matrix polysaccharides along cortical microtubules. Together, our data provide new insights into how the FRA1 kinesin mediates the cytoskeletal control of cell wall assembly.

1487

Mechanisms of Fast Axonal Transport of Prion Protein Vesicles and Infectious Prions.

S. Encalada[1], L. Szpankowski[2], X. Chun-hong[3], L. Goldstein[2]; [1]Molecular and Experimental Medicine and Cell Biology, The Scripps Research Institute, The Scripps Research Institute Department of Molec, Ca, [2]University of California San Diego, [3]University of California Berkeley

Movement and positioning of vesicles inside axons is accomplished by the regulated active transport of kinesin and dynein motor proteins, which move along microtubules in anterograde and retrograde directions, respectively. The normal mammalian prion protein (PrPC) is a GPI-anchored protein that follows the secretory pathway inside vesicles toward the cell surface by an unknown mechanism. Once at the cell surface, PrPC is thought to interact with a number of ligands, including infectious scrapie (PrPSc), if present. Thus, trafficking of PrPC to the plasma membrane via an intact transport system might be a relevant mechanism for initiation of neurodegenerative conditions. Using imaging, biochemical, and genetic approaches, we show differential transport of the prion protein along axons by Kinesin-1 and cytoplasmic dynein. We

show that anterograde and retrograde motors associate to PrPC vesicles regardless of directionality or speed of movement, suggesting that the activity of these motors is uncoupled from their association to these vesicles and that regulatory factors instead of structural changes to motor-vesicle associations dictate the transport mechanics of these vesicles in axons. Furthermore, we show evidence for the fast axonal transport of infectious prions, and how prion infection might lead to the poisoning of an intact transport system in axons.

1488

A kinesin-mediated linkage between centrosomes and the nuclear envelope.

I. Tikhonenko[1], V. Magidson[1], R. Gräf[2], A. Khodjakov[1], M. Koonce[1]; [1]Wadsworth Center, Albany, NY, [2]University at Potsdam

Interphase centrosomes in Dictyostelium cells are located in the cytoplasm, adjacent to and tightly connected with the nucleus (hence the name, nuclear-associated bodies). Deletion of the M-type kinesin isoform, Kif9, disrupts the centrosome-nuclear linkage and enables the centrosome to move in the cytoplasm independent of the nucleus. This disruption leads to an accumulation of supernumerary centrosomes and produces multiple mitotic defects. Kif9 null cells are viable but they accumulate in suspension at an exceedingly slow rate, indicating that a physical association between these two organelles is required for normal cell growth. Kif9 contains a C-terminal transmembrane/tail domain that appears to function as a nuclear envelope anchor. Kif9 localization reveals that the motor is restricted to a perinuclear region close to the centrosome position. Removal of the C-terminal domain distributes the truncated motor into the cytosol, whereas a Kif9 fragment containing only the C-terminal tail is nuclear envelope localized similar to the wild type protein. The solubilities of expressed full length and truncated polypeptides are consistent with the localization data. These results indicate that the C-terminus of Kif9 contains an important nuclear targeting motif. Dual labeling of Kif9 and the nuclear envelope linker protein, Sun1, demonstrate significant overlap in polypeptide distribution. Similar to Kif9, Sun1 staining is enriched on the side of the nucleus facing the centrosome. Interestingly, in the absence of Kif9, Sun1 distribution is more uniform over the nuclear surface. Kif9 also shows ATP sensitive binding to microtubules. Taken together, we postulate that Kif9 functions as a KASH protein, and directly couples Sun1 to cytoplasmic microtubules that are, in turn, anchored to the Dictyostelium centrosome. If Kif9 functions as a microtubule depolymerase activity similar to other M-type kinesins, it would draw the centrosome toward the nucleus and thus act to maintain the normal tight association between these two organelles. A close proximity between these two organelles likely facilitates centrosome insertion into the nuclear envelope for division and minimizes multiple centrosome-nuclear interactions in multinucleated cells. We are currently testing this hypothesis.

1489

Functional Interaction between phosphatidylinositol 4-phosphate 5-kinase α and KIF2A in Neurite Remodeling.

Y. Noda[1], S. Niwa[2], N. Homma[2], H. Fukuda[3], S. Imajoh-Ohmi[3], N. Hirokawa[2]; [1]Jichi Medical University, [2]Univ Tokyo, Sch Med, Tokyo, Japan, [3]Univ Tokyo, Institute of Medical Science

Neuronal morphology is regulated by the cytoskeleton. Kinesin superfamily protein 2A (KIF2A) depolymerizes microtubules (MTs) at growth cones and regulates axon pathfinding. The factors regulating KIF2A in neurite remodeling remain elusive. Here, using immunoprecipitation with an antibody specific to KIF2A, we identified phosphatidylinositol 4-phosphate 5-kinase (PIPK) as a candidate membrane protein that regulates the activity of KIF2A. Yeast two-hybrid and biochemical assays demonstrated direct binding between KIF2A and PIPKα. Partial colocalization of the clusters of punctate signals for these two molecules was detected by

confocal microscopy and photoactivated localization microscopy. Additionally, the MT-depolymerizing activity of KIF2A was enhanced in the presence of PIPK in vitro and in vivo, suggesting a novel PIPK-mediated mechanism controlling MT dynamics in neurite remodeling.

1490

Preferential binding of a kinesin-1 motor to GTP-tubulin-rich microtubules underlies polarized vesicle transport.

T. Nakata[1], S. Niwa[2], Y. Okada[2], F. Perez[3], N. Hirokawa[2]; [1]Cell Biology, Tokyo Medical & Dental University, Yushima, Japan, [2]Cell Biology and Anatomy, Tokyo University Graduate School of Medicine, Tokyo, Japan, [3]Institut Curie

Polarized transport in neurons is fundamental for the formation of neuronal circuitry. A motor domain-containing truncated KIF5 (a kinesin-1) recognizes axonal microtubules, which are enriched in EB1 binding sites, and selectively accumulates at the tips of axons. However, it remains unknown what cue KIF5 recognizes to result in this selective accumulation. We found that axonal microtubules were preferentially stained by the anti-GTP–tubulin antibody hMB11. Super resolution microscopy combined with EM immunocytochemistry revealed that hMB11 was localized at KIF5 attachment sites. In addition, EB1, which binds preferentially to GMPCPP(guanylyl-methylene-diphosphate)-microtubules in vitro, recognized hMB11 binding sites on axonal microtubules. Further, expression of hMB11 antibody in neurons disrupted the selective accumulation of truncated KIF5 in the axon tips. In vitro studies revealed approximately three times stronger binding of KIF5 motor head to GMPCPP-microtubules than to GDP-microtubules. Collectively, these data suggest that the abundance of GTP-tubulin in axonal microtubules may underlie selective KIF5 localization and polarized axonal vesicular transport.

1491

Transgenic mice study of cargo binding domain mutants of KIF17 reveals a mechanism for NMDA receptor transport regulation in synaptic plasticity and spatial memory in vivo.

X. Feng[1], X. Yin[1], Y. Takei[1], N. Hirokawa[1]; [1]Tokyo University, Tokyo, Japan

CaMKII phosphorylates the tail domain of KIF17 to control NR2B transport by modulating the interaction between KIF17 and Mint1 *in vitro*. However, the mechanism of regulation of NR2B transport *in vivo* has been largely unknown. Here, we generated transgenic mice of cargo binding domain mutants of KIF17, and show that altering KIF17–Mint1 binding leads to a disturbance of neuronal plasticity and memory formation *in vivo*. KIF17 with the S1029A mutation does not release cargo and KIF17 with the S1029D mutation does not bind cargo. Consequently, *TgA/kif17-/-* and *TgD/kif17-/-* mice showed significant reductions in the amounts of synaptic NMDA receptors. Accordingly, hippocampal LTP, CREB activation and spatial memory were severely impaired. These results suggest that not only binding of NR2B to KIF17 but also release of NR2B from KIF17 is a critical step for NR2B transport and regulation of learning and memory *in vivo*.

1492

Kinesin Motor Eg5 Functions during Protein Synthesis to Promote Ribosome Transit.

K. Bartoli[1], J. Jakovljevic[2], J. Woolford[2], W. Saunders[1]; [1]Biological Sciences, University of Pittsburgh, Pittsburgh, PA, [2]Biological Sciences, Carnegie Mellon, Pittsburgh, PA

Kinesin microtubule motors are important for the transport of specific intracellular cargoes along microtubules and are critical for cell division. Eg5 is a plus-end directed motor essential for spindle assembly during mitosis. Eg5 is believed to function exclusively in mitosis and as such

is an anti-cancer drug target. Inhibitors to Eg5 are currently undergoing stage I and stage II clinical trials and new clinical trials of Eg5 inhibitors are ongoing. However, unlike some other mitotic proteins, mitotic motors can be detected throughout the cell cycle and anti-Eg5 antibodies robustly label interphase cells. Such constitutive expression led us to investigate potential interphase functions for Eg5. We performed sucrose gradient fractionation of mature ribosomes and immunoprecipitation of RPE1 cell lysates and determined that during interphase Eg5 predominantly associates with mature ribosomes in the cytoplasm. In vitro microtubule binding assays demonstrated that the 80S ribosome association with microtubules requires Eg5. In addition, inhibition of Eg5 function, by knockdown or small molecule inhibition, resulted in a marked ~40% decrease in nascent protein synthesis in multiple human cell lines. This decrease in protein synthesis was reversible and was not due to mitotic arrest or apoptotic cell death. In order to identify which step in translation Eg5 could be participating in, polysome profiling was completed to observe the distribution of ribosomes within cells. After Eg5 inhibition by monastrol, S-Trityl-L-cysteine, or dimethylenastron, inhibitors of the ATPase activity of Eg5, a reduction in the 80S ribosomes and an increase in polysomes were observed, typical for an elongation/termination defect phenotype. Eg5 function in translation elongation/termination was corroborated by completing ribosome transit time assays, which measures the time it takes one ribosome to traverse a single mRNA. After Eg5 inhibition, a ~2.5-fold increase was observed in the transit rate demonstrating the requirement of Eg5 for elongation/termination. When Eg5 was knocked-down, polysome profiling analysis demonstrated an increase in 80S ribosomes and Eg5 function was more essential for translation of longer polypeptides than shorter polypeptides. Therefore, we propose that Eg5 links 80S ribosomes to microtubules during translation and is required for optimal efficiency of the elongation step of translation. The ribosomes processivity, the distance the ribosome can travel on the mRNA, appears to be enhanced by its association with microtubules through Eg5. This suggests a novel role for the mitotic microtubule motor Eg5 and the microtubule cytoskeleton as processivity factors for protein synthesis.

1493

Dissecting the cellular functions of *Drosophila* kinesin 5 using STLC-sensitive KLP61F chimeras.

H. Y. Caro-Gonzalez[1], L. Tao[1], I. Brust-Mascher[1], V. I. Gelfand[2], J. M. Scholey[1]; [1]Department of Molecular and Cellular Biology, University of California, Davis, Davis, CA, [2]Department of Cell and Molecular Biology, Northwestern University Feinberg School of Medicine

The *Drosophila* kinesin 5, KLP61F, is a homotetrameric motor that slides apart interpolar microtubules within mitotic spindles, thereby driving poleward flux and controlling mitotic spindle length by opposing Ncd and other force generators that pull the spindle poles together. Since KLP61F is not inhibited by known chemical inhibitors of kinesin 5, most of our findings have relied on the microinjection of function-blocking antibodies into embryos. Here, we created KLP61F chimeras containing an engineered S-trityl-L-cysteine (STLC) binding site similar to that found in the human kinesin 5, Eg5, and expressed it in *Drosophila* Schneider S2 cells and flies. We find that mitosis proceeds normally in cells expressing the chimeric motors, but is severely impaired in the prescience of STLC. Low concentrations of STLC cause a significant decrease in metaphase spindle length. The results so far are highly concordant with our published antibody inhibition results. We are analyzing the effects of STLC in syncytial embryos from transgenic flies. The ability to use the small molecule inhibitor, STLC will greatly facilitate the study of loss of kinesin-5 function on multiple aspects of mitosis and other processes, such as neuronal cell function.

1494

Molecular mechanism of kinesin-1 activation by Alcadeinα.

M. Araseki[1], T. Kawano[1], Y. Araki[2], M. Kinjo[3], T. Yamamoto[1], T. Suzuki[1]; [1]Laboratory of Neuroscience, Graduate School of Pharmaceutical Sciences, Hokkaido Universiity, Sapporo, Japan, [2]Department of Neuroscience, Howard Hughes Medical Institute, Johns Hopkins University School of Medicine, [3]Laboratory of Molecular Cell Dynamics, Faculty of Advanced Life Science, Hokkaido University, Japan

Objectives: We previously reported that Alcadeinα (Alcα) functions a novel cargo to kinesin-1, which comprises two heavy (KHC) and two light (KLC) chains (*EMBO J*. [2007] 26, 1475-1486). Association of Alcα to KLC evoked the vesicle association of functional kinesin-1 resulting in the fast anterograde transport of Alcα-vesicles, while the kinesin-1 was inactive with an autoinhibition state in the absence of Alcα. We dissected the function of WD motif which is the region required for binding to the tetratricopeptide repeats (TPR) region of KLC1, and determined whether the binding itself to KLC is required for activation of kinesin-1. It is known that KLC binds to C-terminal 11-amino-acids of c-Jun N-terminal kinase-interacting protein 1 (JIP1C11) and KHC associates with fasciculation and elongation protein ζ 1 (FEZ1). Those interactions activates kinesin-1 in vesicular transport (*J. Cell Biol*. [2007] 176, 11-17). Herein we analyzed the regulatory mechanism of kinesin-1 activation by WD motif of Alcα in comparison with known mechanism.
Methods: Artificial membrane proteins possessing a WD-motif of Alcα were expressed in a mouse CNS catecholaminergic cell line CAD cells with EGFP-KLC1 in the presence or absence of EGFP-KHC, and CAD cells were subjected to differentiation by serum depletion. Vesicular formation and anterograde transport of EGFP-KLC1 and EGFP-KHC were examined using a total internal reflectance fluorescence (TIRF) microscopy system.
Results: Artificial membrane proteins possessing a single WD-motif, which is enough to bind KLC1, could induce vesicle association of EGFP-KLC1 and EGFP-KHC, and these vesicles were transported anterogradely. The 1st and the 6th tetratricopeptide repeats of KLC1 are dispensable for WD motif-dependent kinesin-1 activation *in vivo*. The C-terminal 11-amino-acid sequence of JIP1 can recruit KLC1 to vesicles, but does not activate kinesin-1 for vesicular transport.
Conclusion: Our previous and current studies indicate that either of two WD motifs in Alcα cytoplasmic region is necessary and sufficient to initiate kinesin-1 activation. Moreover, Alcα may initiate the activation of kinesin-1 on its own, that differs from a manner by JIP1 which required for an assistance of FEZ1 binding to KHC.

1495

Kinesin-1 and dynein transport Dense Core Vesicles in axons.

A. Lim[1], W. M. Saxton[2]; [1]Univ California-Santa Cruz, Santa Cruz, CA, [2]MCDB, Univ California-Santa Cruz

Microtubule based transport is essential for proper cellular function, particularly in neurons, which have a highly asymmetric structure. In the neuron, there is a constant flux of newly synthesized material from the cell body toward the axon terminal (anterograde) while excess material and endocytic organelles are returned toward the cell body (retrograde). Anterograde axonal transport is carried out mainly by kinesins 1-3, while retrograde transport is achieved by cytoplasmic dynein. To understand how multiple types of motor proteins contribute to the intracellular distribution of organelles, we are studying Dense Core Vesicles (DCV) loaded with the neuropeptide ANF::GFP in the axons of Drosophila. Using this system our lab previously found that mutations in unc104, which encodes for kinesin-3, inhibit DCV flux, run velocity and run length in both directions. To test for contributions by other motors , we are doing live

imaging of DCV transport in intact kinesin-1 (Khc) and dynein (Dhc64C) mutant larvae. Hypomorphic Khc mutations cause a 4 fold reduction in anterograde and a 10-fold reduction in retrograde DCV flux. Anterograde vesicles have reduced net velocity, reduced run length and they have increased pause time. Hypomorphic Dhc64Cmutations also cause ~4- and 10-fold reductions respectively in anterograde and retrograde flux, slower run velocities, shorter run lengths and spent more time paused compared to DCVs from the control animals. Anterograde DCVs in the Dhc64C mutants have shorter run lengths and mildly reduced net velocity compared to those from the control animals. These results show that:
1) cytoplasmic dynein is the retrograde DCV motor, 2) kinesins-1 and -3 both are important anterograde motors for DCV and 3) anterograde transport by one or both kinesins is somehow dependent on dynein. These findings suggest important coordination and interdependence for the three vesicle motors. To gain insight into the cooperative mechanisms, we are pursuing further genetic and biochemical tests.

Growth Cone Traction Forces in Regenerating *Aplysia* Neurons.

C. Hyland[1], A. F. Mertz[2], Y. Xu[3], E. R. Dufresne[2,4], P. Forscher[5]; [1]Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, [2]Department of Physics, Yale University, [3]Engineering and Applied Science, Yale University, [4]Department of Mechanical Engineering and Materials Science, Yale University

The structure and dynamics of the growth cone cytoskeleton is central to developement and regeneration of neurons. The present study addresses the mechanical engagement between the growth cone cytoskeleton and the extracellular environment. We have used laminin-coated flexible PDMS (polydimethyl siloxane) substrates to measure traction force and strain energy in regenerating *Aplysia* bag cell growth cones. Traction force vectors are oriented perpendicular to the leading edge and parallel to the direction of retrograde flow. Traction force measurements also give insight into the mechanical organization of the neuron. Integrating force vectors over the growth cone reveals a net nano-Newton scale force in the direction of the axon shaft, implying a mechanical connection between the growth cone and other parts of the cell. Highest forces were measured in the transition zone coincident with previously reported myosin II localization. Growth cone traction is myosin II dependent: treatment with myosin II inhibitor significantly reduced total growth cone strain energy.

1497

The Axonal Translation of Cortactin Contributes to the Formation of Axonal Filopodia and Collateral Branches.

M. Spillane[1], A. Ketschek[1], C. Donnelly[2], J. Twiss[3], G. Gallo[1]; [1]Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA, [2]Neurology, The Johns Hopkins University School of Medicine, Baltimore, [3]Biology, Drexel University College of Arts and Sciences, Philadelphia, PA

Axon collateral branches allow individual neurons to make connections with multiple targets. In vitro and in vivo collateral branches arise through the maturation of transient axonal filopodia. In turn, axonal filopodia emerge from axonal patches of actin filaments. The formation of axonal actin patches requires the actin nucleation Arp2/3 complex. Cortactin is a multifunctional protein that can regulate the stability of Arp2/3 nucleated actin filaments and promote complex activity.

We investigated the role of cortactin in the formation of axonal filopodia and branches using chicken sensory neurons. As determined by immunocytochemistry and live imaging of RFP-cortactin and eGFP-actin, cortactin is recruited to actin patches. In vivo and in vitro over-expression of cortactin increased the number of axonal filopodia and branches along sensory axons in the spinal cord. In vitro over-expression of cortactin increased the duration of actin patches and the frequency of the emergence of filopodia from patches, but did not affect the rate of patch formation. Expression of the NTA fragment, which prevents cortactin binding to Arp2/3, decreased the duration of patches but did not affect filopodial emergence. These data indicate that cortactin regulates the duration of actin patches through Arp2/3 but promotes formation of filopodia in an Arp2/3 independent manner. Treatment with nerve growth factor (NGF) promotes branching and increases the rate of formation of axonal filopodia and patches without affecting the rate of filopodial emergence from patches. In the absence, but not presence, of NGF over-expression of cortactin increased filopodial formation. Cortactin and Arp2 mRNAs have been previously reported in axons, and using a purified axonal preparation we have detected cortactin mRNA in axons. NGF induced a cycloheximide sensitive increase in the levels of cortactin and Arp2 in axons severed from the cell body, suggesting cortactin and Arp2 are locally translated in axons. Cycloheximide also blocked the NGF-induced increase in filopodia and patch formation. Collectively, the data indicate that the promotion of axonal filopodia by NGF requires the intra-axonal translation of cortactin, which acts to promote the emergence of filopodia from actin patches in the context of the NGF-induced increase in the rate of patch formation.

1498

Mitotic motors co-regulate microtubule patterns in axons and dendrites.

S. Lin[1], O. Mozgova[1], M. Liu[2], W. Yu[1], P. Baas[1]; [1]Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA, [2]Jiangsu Key Laboratory of Neuroregeneration, Nantong University, Nantong, China

Vertebrate neurons extend two distinct types of processes, axons and dendrites, which differ in morphology, composition and function due, in part, to distinct patterns of microtubule (MT) polarity orientation. MTs in the axon are nearly uniformly oriented with their plus end distal to the cell body, whereas MTs in the dendrites are non-uniformly oriented. Studies to date suggest a scenario for establishing these MT patterns whereby MTs are transported into the axon and nascent dendrites with plus-ends-leading, and then additional MTs of the opposite orientation are transported into developing dendrites. If this is correct, molecular motor proteins with assigned roles would presumably tightly regulate these MT transport events. Kinesin-6 (also called CHO1/MKLP1), a molecular motor best known for its role in mitosis, is present in cell bodies and dendrites but is absent from the axon. We found that depletion of kinesin-6 by siRNA from cultures of rat neurons significantly reduces the number of processes with dendritic characteristics, which is accordant with our previous work in neurons using antisense oligonucleotides. Those processes that did display some dendritic characteristics were nevertheless longer than control dendrites, and thinner in their more proximal regions. In addition, such processes displayed a higher proportion of plus-end-distal MTs than control dendrites, as indicated by live-cell imaging with GFP-tagged EB3. Interestingly, there was no effect of kinesin-6 depletion on axonal branch formation or growth cone turning, which is consistent with the motor protein being absent from axons. Surprisingly, however, depletion of kinesin-6 caused axons to grow faster, and there was a notable increase in the frequency of transport of short MTs compared to control axons. These effects on axonal length and MT transport are similar to those observed in previous studies in which we depleted either kinesin-5 or kinesin-12, two other molecular motors mainly known for their roles in mitosis. Based on these observations, we propose that all three of these mitotic motors act within the cell body to

attenuate the transport of plus-end-distal MTs into the axon while driving the transport of minus-end-distal MTs into dendrites. In this manner, we speculate that mitotic motors co-regulate MT polarity patterns in axons and dendrites.

1499

Kinesin-6, a motor protein essential for cytokinesis, plays a key role in neuronal migration.

A. Falnikar[1], E. O'Toole[2], M. Morphew[2], A. Hoenger[2], P. Baas[1]; [1]Department of Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA, [2]Department of Molecular, Cellular, and Developmental Biology, University of Colorado, Boulder, Boulder, CO

The development of the mammalian brain requires the orderly migration of neurons from their sites of origin to their final destinations. Neuronal migration is critically dependent upon both microtubules (MTs) and actin-based motility. Here we focused on a potential role in neuronal migration of kinesin-6 (also called CHO1/MKLP1), a molecular motor protein best known for its role in mitosis. We recently published that migratory neurons maintain their bipolar morphology when depleted of kinesin-5 (another mitotic motor protein, also called Eg5), but migrate notably faster than controls. Here we found that neurons depleted of kinesin-6 were typically multi-polar, and displayed continuous alterations in their direction of movement, resulting in no net movement. Interestingly, kinesin-6-depleted neurons displayed numerous outgrowths along their processes, which were reminiscent of the actin-rich protrusions that often appear on developing axons. Such outgrowths were rarely observed in control migrating neurons or migrating neurons depleted of kinesin-5. This observation is particularly intriguing as kinesin-6 has two splice variants, one of which has an actin-binding domain not found in kinesin-5. Consistent with our previous report using fluorescence microscopy, we have now obtained results with electron tomography demonstrating that not all of the MTs in the migratory neuron converge on the centrosome. These studies reveal the presence of a sub-population of MTs that extend into the leading process but have free minus ends posterior to the centrosome. Such MTs intermingle with MTs of the opposite orientation, resulting in regions of antiparallel organization behind the centrosome, ideally suited to interact with molecular motors such as kinesins 5 and 6. The very different phenotypes obtained from depleting each of these motors indicates, however, that the unique functions of each motor are not explicable entirely on the basis of interactions with antiparallel MTs. In mitotic cells, kinesin-6 signals to the actin cytoskeleton while interacting with MTs in the spindle midzone, to concentrate cortical movements to the cleavage furrow during cytokinesis. We hypothesize that kinesin-6 functions analogously in migrating neurons to constrain process number and restrict protrusive activity to the tip of a single leading process. Together, these two effects result in a bipolar neuron able to move in a concerted fashion.

1500

Glutamate-Induced Incorporation of Cofilin into Rods Depends on Disulfide Inter-molecular Bonds: Implications for Actin Regulation and Neurodegenerative Disease.

B. W. Bernstein[1], A. E. Shaw[2], L. S. Minamide[2], C. Pak[3], J. R. Bamburg[2]; [1]Biochemistry & Molecular Biology, Colorado State University, Fort Collins, CO, [2]Biochemistry & Molecular Biology, Colorado State University, [3]University of Texas Southwestern Medical Center

Rod-shaped aggregates (“rods”), containing equimolar actin and the actin dynamizing protein cofilin appear in neurons following a wide variety of potentially oxidative stress: simulated microischemia, cofilin overexpression, and exposure to excess glutamate, peroxide, or the dimer/trimer forms of amyloid beta peptide (Aβd/t), the most synaptotoxic species. These rods are initially reversible and neuroprotective, but if they persist in neurites, the synapses

degenerate without neurons dying. Herein we report that rod formation depends on the generation of inter-molecular disulfide bonds in cofilin. Of four Cys-to-Ala cofilin mutations expressed in rat E18 hippocampal neurons, only the mutant incapable of forming inter-molecular bonds (CC39,147AA) has significantly reduced ability to incorporate into rods. Rod regions show unusually high oxidation levels, and rods can be reversed by treating cells with reducing agent. Rods, isolated from stressed neurons, contain dithiothreitol-sensitive multimeric forms of cofilin. Oligomerization of cofilin in cells represents one more mechanism for regulating cofilin's actin dynamizing activity and probably underlies synaptic loss.
Supported in part by NIH grant NS40371.

1501

A new model for cofilin's action in morphological plasticity in dendritic spines of neurons.

B. Calabrese[1], J-M. Saffin[1], S. Halpain[1]; [1]Division of Biological Sciences, UC San Diego, La Jolla, CA

Long-term depression (LTD) is a form of plasticity at excitatory synapses characterized by decreased synaptic strength and shrinkage of dendritic spines. A widely cited model has proposed that cofilin becomes activated during LTD and mediates spine shrinkage by severing and depolymerizing actin filaments. However, we observed, using fluorescence resonance energy transfer, that the interaction between F-actin and cofilin actually decreases in spines following LTD, and that the concentration of free barbed ends of actin filaments also decreases. These results are therefore inconsistent with an LTD-induced increase in cofilin activity. Furthermore, enhancing endogenous cofilin activity by overexpressing the protein phosphatases chronophin or slingshot not only attenuated the LTD-induced decrease in cofilin-actin binding, but also inhibited LTD-induced spine shrinkage. Sequestration by PIP2, reduced cofilin concentration and an increase in the fraction of phospho-cofilin within the spine all may contribute to the LTD-induced inhibition of cofilin activity. These results suggest that constitutive F-actin severing by cofilin is essential for normal spine maintenance, and that a decrease in cofilin activity, not an increase, significantly contributes to a net loss of F-actin and consequent spine shrinkage during this form of synaptic plasticity.

1502

Myosin-X and its Motorless Isoform Differentially Regulate the Formation of Dendritic Filopodia and Spines, which are Actin-rich Structures in Neurons that Resemble Leading Edge Protrusions in Migrating Cells.

W-H. Lin[1], M. Da Silva[1], J. T. Hurley[1], A. N. Raines[2], R. Cheney[2], D. J. Webb[1,3]; [1]Biological Sciences, Vanderbilt University, Nashville, TN, [2]Cell and Molecular Physiology, University of North Carolina, Chapel Hill, NC, [3]Cancer Biology, Vanderbilt University

Filopodia are dynamic, finger-like protrusions that are thought to guide directed cell migration and to promote cell motility. Similar protrusive structures known as dendritic filopodia are found in neurons and later mature into dendritic spines, which comprise the postsynaptic sites of excitatory synapses. Alterations in spine formation are mediated by actin rearrangement and are crucial for cognitive functions such as learning and memory; however, the roles of actin-based motors in this process are not well understood. Myosin-X (Myo 10), an unconventional myosin motor, promotes the formation of filopodia in non-neuronal cells, leading us to hypothesize that it regulates dendritic filopodia dynamics and spine development in neurons. Here, we use cultured hippocampal neurons to show that full-length Myo 10 and its motorless isoform (headless Myo10) play important, but distinct, roles in regulating the formation of dendritic spines and their precursors, dendritic filopodia. Full-length Myo10 localizes to the tips

of dendritic filopodia; in contrast, headless Myo10 is enriched at the heads of dendritic spines. While most headless Myo10 puncta co-localize with presynaptic terminals, the majority of full-length Myo10 puncta do not make stable contacts. Interestingly, dendritic filopodia in full-length Myo10 expressing neurons exhibit robust movement. Elevated expression of full-length Myo10 results in a significant increase in the density and length of dendritic filopodia and a decrease in the density of spines and synapses. Importantly, knockdown of full-length Myo10 also reduces the number of spines and synapses, suggesting that full-length Myo10 is required for spine formation via the regulation of dendritic filopodia. Expression of headless Myo10, unlike the full-length form of this protein, does not affect the formation of dendritic filopodia, but does induce the expansion of spine heads. Collectively, our data indicate that full-length and headless Myo10 differentially modulate the formation and maturation of dendritic spines.

1503

The Rac and Cdc42 Guanine Nucleotide Exchange Factor Asef2 Mediates Dendritic Spine Formation in Cultured Hippocampal Neurons.

C. Evans[1], D. J. Webb[1,2]; [1]Biological Sciences, Vanderbilt University, Nashville, TN, [2]Cancer Biology, Vanderbilt University

The formation of dendritic spines, actin-rich protrusions from dendrites that form synapses with presynaptic axons, is dependent upon the activity of molecular switches, such as the Rho family of small GTPases. Once activated, these proteins are thought to play vital roles in regulating actin cytoskeleton dynamics within dendritic spines; however, the function of upstream activator proteins, known as guanine nucleotide exchange factors (GEFs), in spine formation is not well understood. Here, we show that the Rac and Cdc42 GEF Asef2 is critical for the development of dendritic spines in hippocampal neurons. Expression of EGFP-tagged Asef2 causes a significant increase in the density of spines and synapses, while knockdown of Asef2, using an siRNA approach, leads to a loss of dendritic spines and synapses. To determine if the GEF activity of Asef2 is critical for mediating its effects on spine formation, point mutations that disrupt GTPase activation were generated in the DH domain. Abrogation of Asef2's GEF activity results in a decrease in mature spines as well as an increase in filopodia-like protrusions, which are thought to be the precursors of dendritic spines. Collectively, our data suggest that Asef2 utilizes its GEF activity to regulate the development of dendritic spines. This underscores the need for precise control of GTPase activation, which is necessary to properly modulate the actin cytoskeleton in order to promote spine formation.

1504

Functional analysis of Dysbindin, a schizophrenia risk factor, in dendritic spine formation.

H. Ito[1], R. Morishita[1], Y. Nishimura[1], T. Shinoda[1], I. Iwamoto[1], K-I. Nagata[1]; [1]Institute for Developmental Research, Aichi Human Service Center, Kasugai, Japan

Dysbindin (dystrobrevin-binding protein, DTNBP) is a multi-functional adaptor protein thought to be involved in cell growth, neuronal apoptosis, intracellular vesicle traffic and neurotransmitter release. Genetic variations in dysbindin are one of the most commonly reported variations associated with schizophrenia. Since schizophrenia could be regarded as a neurodevelopmental disorder resulting from abnormalities of synaptic connectivity, we attempted to clarify the function of dysbindin in neuronal development. We examined the developmental change of dysbindin in rat brain by Western blotting and found that a 50 kDa isoform is highly expressed during the embryonic stage while a 40 kDa one is detected at postnatal day 11 and increased thereafter. Immunofluorescent analyses revealed that dysbindin is enriched at the spine-like structure of primary cultured rat hippocampal neurons. Knockdown

of dysbindin led to the generation of abnormally elongated immature dendritic protrusions. To elucidate dysbindin function at the molecular level, we screened dysbindin-binding proteins, and consequently identified an actin cytoskeleton regulator, WAVE2, and an adaptor protein, Abi-1. Abi-1 is known to associate with WAVE2 and be involved in spine morphogenesis. Interestingly, dysbindin promoted the binding of WAVE2 to Abi-1, and the phenotype of dysbindin-knockdown was rescued by overexpression of Abi-1. Collectively, the present results indicate possible function of dysbindin at the postsynapse in the regulation of dendritic spine morphogenesis through the interaction with WAVE2 and Abi-1. These results also support the "neurodevelopmetal hypothesis" for the mechanism of schizophrenia symptoms.

Microtubule and Protein Kinase A Interaction is Important for Neurite Morphogenesis.

Y-A. Huang[1], D. T-H. Tseng[2], E. Hwang[1,2,3]; [1]Institute of Bioinformatics and Systems Biology, National Chiao Tung Univ, Hsin-Chu, Taiwan, [2]Institute of Molecular Medicine and Bioengineering, National Chiao Tung Univ, Hsin-Chu, Taiwan, [3]Department of Biological Science and Technology, National Chiao Tung Univ, Hsin-Chu, Taiwan

Neurite morphogenesis is a process through which neurons generate their widespread axon and dendrites. During neurite morphogenesis, the microtubule cytoskeleton plays a crucial role. Our proteomic study indicated that the amount of protein kinase A (PKA) on microtubules significantly increased after neuronal differentiation and neurite morphogenesis. PKA has been show to play essential roles in various cellular processes. However, its function on microtubule organization during neurite morphogenesis remains elusive. Since PKA is essential for various cellular functions, knocking down PKA genes will causes a plethora of phenotypes unrelated to neurite morphogenesis. As a result, we developed two different methods to alter the amount of PKA on microtubules without changing the overall PKA level. This allows us to determine the specific function of PKA on microtubule.

MAP2c, a neuron-specific microtubule-associated protein, is also a PKA anchoring protein in neurons. It has been shown that overexpressing MAP2c can produce cellular protrusion in non-neuronal cells. A MAP2c deletion construct (MAP2c-ΔRII) is generated in which the PKA binding domain is removed; this allows us to reduce PKA localization on microtubules without changing the overall PKA level. Here we show that overexpressing MAP2c-ΔRII in P19 cells resulted in shorter protrusions than overexpressing MAP2c. In addition, overexpressing MAP2c-EEE in mouse primary hippocampal neurons resulted in shorter neurite length than MAP2c-EEE-ΔRII. These results indicated that PKA's association with microtubules is important for generating cellular protrusions and neurites.

Another approach to investigate the function of PKA on neuronal microtubules is by using an artificial protein-protein interaction method. In this method, we can force the PKA complex from the microtubule cytoskeleton onto the actin cytoskeleton. Currently, we have proved that our method is feasible by diverting a fluorescent cytoplasmic protein onto the cell membrane.

Pro- and mature neurotrophins differentially regulate neuronal morphology.

K. Deinhardt[1], F. Jeanneteau[1], B. Hempstead[2], M. Chao[1]; [1]Mol. Neurobiology, Skirball Institute, NYU SoM, New York, NY, [2]Weill Cornell Medical College

The establishment and refinement of neural circuits during development depends upon a dynamic process of outgrowth and branching of axons and dendrites that leads to synapse

formation and connectivity. However, the mechanisms that translate extracellular signals into axonal branch formation are incompletely understood, as are the mechanisms that negatively regulate the arborization of processes. The neurotrophin BDNF plays an essential role in the outgrowth and activity-dependent remodeling of axonal arbors in vivo. We recently reported that the MAP kinase phosphatase-1 (MKP-1) controls BDNF-dependent axon branching. MKP-1 expression induced by BDNF signaling exerts spatio-temporal deactivation of JNK, which negatively regulates the phosphorylation of JNK substrates that impinge upon microtubule destabilization. Indeed, neurons from mkp-1 null mice were unable to produce axon branches in response to BDNF. On the other hand, dendritic growth is affected negatively by the BDNF precursor, proBDNF. Mice impaired in proBDNF processing display markedly reduced dendritic complexity in vivo, suggesting that proneurotrophins negatively influence neuronal morphology. Both proBDNF and proNGF acutely cause collapse of growth cones in vitro, a retraction that is mediated by two discrete signaling pathways: Inactivation of the actin-bundling protein fascin and dissociation of the Rac activator Trio from p75NTR, resulting in decreased activation of Rac. These results identify a bifunctional signaling mechanism through which proneurotrophins and their mature forms differentially modulate neuronal morphology in the nervous system.

Tropomyosins induce neurite formation in B35 neuroblastoma cells and control neurite branching.

N. Curthoys[1], H. Freittag[1], A. Connor[2], M. Desouza[1], E. Hardeman[1], P. Gunning[1], G. Schevzov[1], T. Fath[1]; [1]School of Medical Sciences, University of New South Wales, Sydney, Australia

Fundamental mechanisms of neuronal differentiation and neurite formation are controlled through the actin cytoskeleton. Dynamic and structural properties of the actin cytoskeleton are regulated by a large pool of actin-associated proteins including tropomyosins, a family of actin-associated proteins controlling actin filaments stiffness in an isoform dependent manner. In neurons products from three tropomyosin genes are found (α-, γ- and δ-tropomyosin). The current study aims to understand the role of α- (TmBr1, TmBr2, TmBr3) and δ-tropomyosin (Tm4) gene products in early neuronal development.
Using B35 neuroblastoma cells overexpressing individual tropomyosin isoforms we investigated the impact of the actin cytoskeleton on neuronal morphology and early stages of neuritogenesis. We show that the overexpression of tropomyosins is sufficient to induce the formation of neurites which is associated with an upregulation of markers of neuronal differentiation including MAP2c.
Tropomyosins differentially control the branching of neurites in db cAMP stimulated B35 cells. While we observed no changes in the neurite branching in TmBr2 overexpressing B35 cells, overexpression of TmBr1 attenuated and overexpression of TmBr3 and Tm4 increased the degree of branching. This was associated with an isoform dependent change in growth cone size and number of filopodia along these neurites. Overexpression of TmBr3 and Tm4 resulted in larger growth cones and increased number of filopodia while TmBr1 led to smaller growth cones and no change in filopodia number as compared to control B35 cells.
Our data suggest a central role for the actin-associated protein tropomyosin in neuronal differentiation and establishing of complex neuronal networks.

1508

Kinesin-5 regulates microtubule organization in dendrites.

V. Sharma[1], O. Mozgova[1], W. Yu[1], P. Baas[1]; [1]Neurobiology and Anatomy, Drexel Univ Coll Med, Philadelphia, PA

Kinesin-5 (also termed kif11 or Eg5) is a homotetrameric motor protein that plays an essential role in mitosis. Its best recognized mode of function is to generate forces between oppositely oriented microtubules (MTs). We reported previously that kinesin-5 is expressed robustly in developing neurons, and that it plays key roles in axonal elongation and turning of the growth cone. These effects are explicable, at least in part, by kinesin-5 acting as a kind of "brake" on the transport and sliding of MTs relative to each other. The precise mechanism by which this occurs remains mysterious, however, because nearly all of the microtubules in the axon have the same plus-end-distal orientation. By contrast, dendritic MTs are non-uniformly oriented, and hence would presumably be better suited for interacting with kinesin-5. We have now endeavored to determine whether kinesin-5 plays an important role in regulating the dendritic MT array. Treatment of cultured rat sympathetic neurons with monastrol, a potent and specific inhibitor of kinesin-5, resulted in dendrites that were thinner and longer than control dendrites, and which contained far fewer minus-end-distal MTs (as assessed by live-cell imaging with GFP-tagged EB3). Thus, the dendrites were much more similar to axons with regard to both morphology and MT polarity orientation. Immunostain analyses indicate a relatively uniform distribution of total kinesin-5 in axons and dendrites, but an enrichment in dendrites of a variant of kinesin-5 phosphorylated at a site required for it to interact with MTs. Additional studies revealed that kinesin-5 binds more avidly to tyrosinated MTs than detyrosinated MTs, which is provocative in light of the fact that dendritic MTs are known to be less detyrosinated than axonal MTs. Partial knockdown of tubulin tyrosine ligase resulted in an elevation of detyrosinated MTs in dendrites, a more homogeneous distribution of phospho-kinesin-5 in axons and dendrites, and morphological changes akin to those observed with monastrol treatment. Collectively, these results suggest that kinesin-5 is an important factor in establishing the distinct MT polarity pattern and morphology of the dendrite, and that kinesin-5's localization and functions are regulated in part by its phosphorylation and in part by its preference for tyrosinated rather than detyrosinated MTs.

1509

Phosphorylation by GSK-3β and subcellular Localization of Stathmin 3/SCLIP in Neurons.

S. Devaux[1,2], F. E. Poulain[1,2], V. Devignot[1,2], S. Lachkar[1,2], T. Irinopoulou[1,2], A. Sobel[1,2]; [1]U839, Institut du Fer a Moulin, INSERM, Paris, France, [2]Université Pierre et Marie Curie, Paris, France

During development of the nervous system, neuronal growth, migration and functional morphogenesis rely on the appropriate control of the subcellular cytoskeleton. Among the numerous proteins involved in the control of microtubule dynamics, stathmin family proteins are involved in the control of diverse stages of neuronal differentiation, including axonal growth and branching, or dendritic development. An important issue is the deciphering of differences and specificities in the likely complementary roles of the various members of the stathmin family, as well as their underlying molecular and regulatory features. We have shown previously that stathmins 2 (SCG10) and 3 (SCLIP) fulfill distinct, independent and complementary regulatory roles in axonal morphogenesis. Although the two proteins have been proposed to display the characteristic four conserved phosphorylation sites originally identified in stathmin 1, we show that they possess distinct phosphorylation sites within their specific proline-rich domains (PRDs) which are differentially regulated by phosphorylation by proline-directed kinases involved in the control of neuronal differentiation. ERK2 or CDK5 display different site specificities for the two

proteins and, in contrast to stathmin 2, stathmin 3 is a substrate for GSK-3β which phosphorylates its serine 60 both in vitro and in vivo. Moreover, serine 60 phosphorylated stathmin 3 displays a specific subcellular localization at neuritic tips and within the actin-rich peripheral zone of the growth cone of differentiating hippocampal neurons in culture. Finally, pharmacological inhibition of GSK-3β induces a redistribution of stathmin 3, but not stathmin 2, from the periphery towards the Golgi region of neurons. Stathmin proteins can thus be either regulated locally or locally targeted by specific phosphorylation, each phosphoprotein of the stathmin family fulfilling distinct and specific roles in the control of neuronal differentiation.

1510

GSK3β activity and CNS axonal regeneration: insights from in vivo studies.

M. Liz[1], H. I. Pimentel[1], A. Marques[1], F. M. Mar[1], V. Sousa[1], F. Cerciello[2], B. Wollscheid[2], M. M. Sousa[1]; [1]Nerve Regeneration, IBMC, Porto, Portugal, [2]ETH Zurich

The central nervous system (CNS) regenerates under certain conditions such as following a conditioning lesion (CL): the central branch of a dorsal root ganglia (DRG) neuron is capable of growing within the CNS inhibitory environment after its peripheral branch has been previously injured. We aimed at disclosing intrinsic mechanisms enabling CNS axonal regeneration using the CL as a model and used two proteomic approaches, iTRAQ and phosphoproteomic arrays. From the proteins identified in the DRG as differentially regulated following CL in comparison with spinal cord injury (SCI), the Glycogen synthase kinase 3β (GSK3β) pathway, involved in the regulation of microtubule dynamics, emerged as a key player. GSK3β activity was downregulated following CL. Significantly, despite the focus on the inhibition of GSK3β through Ser9 phosphorylation, our data shows that a decreased phosphorylation of Tyr216, the activator of kinase activity, both in DRG and in the spinal cord injury site is the regulatory event leading to gain of regenerative capacity following CL. Preliminary results suggested that Fyn kinase is a candidate for the modulation of Tyr216 phosphorylation. In the spinal cord injury site the levels of phosphorylated CRMP2 (GSK3β substrate negatively regulated by the kinase) were decreased, while MAP1B (GSK3β substrate positively regulated by the kinase) phosphorylation levels were increased after CL. Concerning the role of GSK3β Ser9 phosphorylation, we observed that DRG neurons from transgenic mice expressing the GSK3β mutant Ser9Ala (GSK3βS9A knockin mice) have increased neurite outgrowth in vitro following CL. Moreover, in vivo retrograde tracing with cholera toxin B of dorsal column axons confirmed the conditioning effect of GSK3βS9A knockin mice thus showing that modulation of GSK3β activity through Ser9 is not needed to induce axonal growth. Further studies to clarify the role of GSK3β in axonal growth in vivo are currently being performed.

1511

Role of GSK3 in regulation of growth cone microtubule dynamics.

P. Nicovich[1], E. Hur[1], F. Zhou[1,2]; [1]Orthopaedic Surgery, Johns Hopkins University, Baltimore, MD, [2]Department of Neuroscience, Johns Hopkins University, Baltimore, MD

Emerging evidence indicates that glycogen-synthase kinase 3 (GSK3) proteins are fundamental components in neurodevelopmental processes including neurogenesis, neuronal migration, neuronal polarization, and axon outgrowth. Previous studies, including ours, have revealed that GSK3 signaling regulates neuronal polarization and axon growth via controlling reorganization of neuronal microtubules. However, how GSK3 controls the dynamics of neuronal microtubules remains unknown largely due to lack of technology that allows high-resolution live-cell imaging of microtubule dynamics in mammalian neurons. Leading advances in live cell imaging techniques and computer-based image analysis have now provided an opportunity to solve this problem, thus allowing us to perform more detailed investigation of the role of GSK3 in neuronal

microtubule dynamics. By using a newly developed approach that analyzes microtubule dynamics through detecting microtubule plus-end tracking proteins (+TIPs), we studied how GSK3 and its downstream microtubule regulatory proteins, such as APC and CLASP, control microtubule dynamics in nerve growth cones. Results show a surprising spatial difference in microtubule dynamics between distal axon shaft and the growth cones, consistent with the spatial distribution of GSK3 activities. We are now investigating if modulation of GSK3 activity or the function of APC and CLASP can affect such spatial distribution of microtubule dynamics. The results will reveal the molecular mechanism by which GSK3 regulate neuronal microtubules and its role in controlling neuronal function.

1512

The F-BAR protein CIP4 inhibits neurite formation by producing lamellipodial protrusions.

W. Saengsawang[1], C. Viesselmann[1], K. Mitok[1], L. Pietila[1], D. Lumbard[1], S. Corey[2], E. Dent[1]; [1]Neuroscience, University of Wisconsin-Madison, Madison, WI, [2]Pediatrics and Cellular and Molecular Biology and Robert H. Lurie Comprehensive Cancer Center, Northwestern University, Chicago, IL

F-BAR proteins are a large family of proteins that function in sensing and inducing membrane curvature. Cdc42-interacting protein 4 (CIP4), a member of the F-BAR family of proteins, regulates endocytosis in a variety of cell types. However, there is little data on how CIP4 may be functioning in neurons. Here we show that CIP4 plays a novel role in neuronal development by inhibiting neurite formation. Remarkably, CIP4 exerts its effects, not through endocytosis, but by producing lamellipodial protrusions. In primary cortical neurons, CIP4 does not localize to endosomes, but instead is concentrated at the tips of extending lamellipodia and filopodia. Overexpression of CIP4 results in lamellipodial protrusions around the cell body, resulting in delayed neurite formation and enlarged growth cones. Conversely, cortical neurons from CIP4-null mice initiate neurites nearly twice as fast as controls. These data demonstrate CIP4 is one of few proteins whose expression inhibits neurite formation. Moreover, it is the first to demonstrate that an F-BAR protein functions differently in neuronal vs. non-neuronal cells and induces lamellipodial protrusions instead of invaginations.

1513

Evidence for end-to-end annealing and breakage of neurofilaments in cultured neurons.

A. Uchida[1], G. Colakoglu[2], L. Wang[1], A. Brown[3]; [1]Department of Neuroscience, The Ohio State University, Columbus, OH, [2]Sanford-Burnham Medical Research Institute, La Jolla, CA

We have shown previously that neurofilaments expressed in heterologous non-neuronal cell lines can lengthen by end-to-end annealing (Colakoglu & Brown, *J. Cell Biol.* 185:769-777, 2009). To test if this also occurs in neurons, we transfected cultured rat cortical neurons with neurofilament protein M fused to the photoconvertible fluorescent protein mEos2 (mEos2-NFM), or we co-transfected with neurofilament protein M fused to photoactivatable GFP (PAGFP-NFM) and neurofilament protein L fused to mCherry (NFL-mCherry). These fusion proteins all co-assembled with endogenous neurofilament proteins throughout the neurons. To test for end-to-end annealing, we used mEos2-NFM photoconversion, or we combined PAGFP-NFM photoactivation with NFL-mCherry photobleaching, to create distinct populations of red and green fluorescent neurofilaments within the cell bodies or axons. Over time, the red and green fluorescent filaments intermixed due to their rapid intermittent movement by axonal transport. After several hours, we observed the appearance of chimeric filaments consisting of alternating red and green segments, which is indicative of end-to-end annealing of red and green filaments. Time-lapse imaging of the axonal transport and Brownian motion of these chimeric filaments

demonstrated that the red and green segments were part of the same filament. Thus neurofilaments can lengthen by end-to-end annealing of preexisting filaments in cultured neurons. In addition to this evidence for end-to-end annealing, we also observed gradual shortening of the photoconverted or photoactivated filaments, suggesting that there are also mechanisms in nerve cells that can break or sever neurofilaments. In two rare instances, we were able to capture an annealing and a severing event "on camera" in time-lapse movies. We propose that the length of neurofilaments in nerve cells is regulated by a dynamic cycle of annealing and severing, and we speculate that this may also influence their transport within axons.

1514

Dynamic microtubules protect dendrites from degeneration triggered by poly-Q proteins or reduced levels of an axon transport motor.

L. Chen[1], J. Tao[2], M. Rolls[2]; [1]Pennsylvania State Univ, University Park, PA

Dendrites and axons differ not only in their morphology and function, but also in their responses to injury. Using Drosophila dendritic arborization neurons as a model system, we previously showed that microtubule dynamics are up-regulated in response to axon, but not dendrite, severing (Stone et al. MBC, 2010).

We now show that similar increases in the number of growing microtubules are triggered by reducing levels of unc-104/imac, a kinesin-3 motor protein involved in synaptic vesicle trafficking in axons. This observation led us to hypothesize that increased microtubule dynamics are a general response to axon stress. In support of this hypothesis, expression of expanded poly-Q proteins that cause neurodegeneration, including SCA3tr-Q78 (Q78), increased the number of growing microtubules. Thus in addition to axotomy, reduced levels of a motor protein or overexpression of disease proteins can increase microtubule dynamics.

In a candidate screen to identify proteins required for the increased dynamics, we found that reducing the level of gamma-tub23C, the core nucleation protein in drosophila, suppressed dynamics induced by poly-Q proteins. Reducing levels of microtubule severing proteins did not have a strong effect. We conclude that microtubule nucleation is required to generate large numbers of growing microtubules in stressed neurons.

As the microtubule dynamics is increased throughout the cell, including in dendrites, we hypothesized that persistent microtubule growth in dendrites might help this compartment resist degeneration while the cell attempts axon repair. We first tested whether increased microtubule dynamics can delay short-term degeneration induced by injury. At 18h post dendrite severing, only 5% of the control neurons failed to remove the dendrites, whereas 30% and 60% remained in the presence of unc-104 RNAi and Q78, respectively. This supports the hypothesis that microtubule dynamics might be part of a protective response.

To test whether microtubule dynamics protects dendrites from longer term degeneration, Q78 was co-expressed with gamma-tub23C RNAi or a control RNAi, and dendrite morphology was monitored for four days. More dendrite degeneration was observed in neurons with reduced nucleation than in the control, supporting the idea that increased microtubule growth is a protective mechanism to combat dendrite degeneration.

In summary, elevation of microtubule dynamics represents a novel neuroprotective pathway that is intrinsically activated by a variety of axon stresses. Enhancing this protective pathway could be a strategy to prevent dendrite loss in neurodegenerative diseases.

1515

The microtubule severing protein spastin is required for regeneration after axon injury.

M. Stone[1], S. Kim[1], J. Tao[1], S. Coven[1], K. Gheres[1], C. La Rochelle[1], C. Folker[1], N. Sherwood[2], M. Rolls[1]; [1]Penn State University, University Park, PA, [2]Duke University

Most neurons are irreplaceable, yet they are susceptible to many types of injury ranging from trauma and disease to stroke and immune attack. Neurons typically have many dendrites and a single axon. This axon often extends long distances from the cell body and is especially vulnerable to injury. Axon injury induces a number of cytoskeletal changes thought to be involved in the degeneration of the distal region and subsequent regeneration. Using live imaging of whole Drosophila larvae and cell type-specific RNAi, we found that *spastin* is required for regeneration following axon injury. Mutations in the gene that encodes *spastin*, a microtubule severing protein containing a transmembrane domain, have been shown to be a primary cause of hereditary spastic paraplegia in humans. In many cases, loss of a single copy of *spastin* will result in this degenerative disease. To determine whether axon regeneration is sensitive to *spastin* gene dosage, we assayed axon regeneration in animals heterozygous for a *spastin* null allele. Surprisingly we found that axon regeneration, following both distal and proximal axotomy, is extremely sensitive to *spastin* dosage. In control neurons, axons extended an average of 250 microns from dendrites after proximal axotomy. This number was reduced to 50 microns in *spastin* heterozygotes. After distal axotomy, 100% of control neurons initiated axon regrowth from the stump, but only 50% regrew in *spastin* heterozygotes. To test whether this represented a general requirement for *spastin* in neurite growth, we assayed developmental outgrowth of photoreceptor and mushroom body axons and dendrite regrowth after pruning. Both of these types of neurite growth were normal in *spastin* heterozygotes. We conclude that *spastin* plays a crucial role in axon regeneration and that this function of *spastin* is sensitive to *spastin* dosage, while other types of neurite growth are not.

1516

Myelin-derived inhibitors suppresses axon regeneration by PIR-B/SHP-mediated inhibition of Trk activation.

Y. Fujita[1], T. Yamashita[1]; [1]Molecular Neuroscience, Osaka University, Osaka, Japan

Paired immunoglobulin-like receptor B (PIR-B) mediates certain regeneration-inhibiting effects of the myelin-derived proteins-Nogo, myelin-associated glycoprotein (MAG), and oligodendrocyte-myelin glycoprotein (OMgp). Here, we report that inhibition of the PIR-B enhanced axon regeneration in the central nervous system (CNS). Binding of MAG to PIR-B led to the association of PIR-B with tropomyosin-receptor kinase (Trk) neurotrophin receptors, which were known to promote neurite growth in neurons. Src homology 2-containing protein tyrosine phosphatase (SHP)-1 and SHP-2, which were recruited to PIR-B upon MAG binding, functioned as Trk tyrosine phosphatases. Further, SHP-1 and SHP-2 inhibition reduced MAG-induced dephosphorylation of Trk receptors, and abolished the inhibitory effect of MAG on neurite growth. Thus, PIR-B associated with Trk to downregulate basal and neurotrophin-regulated Trk activity through SHP-1/2 in neurons. Moreover, in vivo transfection of siRNA for SHP-1 or SHP-2 induced axonal regeneration after optic nerve injury in mice. Our results thus provide a new molecular target to enhance the regeneration of the injured CNS.

1517

A specialized tubulin in the nervous system of *C. elegans.*

K. Giardino[1], L. Lamphear[1], D. Hurd[1]; [1]Biology, St. John Fisher College, Rochester, NY

Microtubules are self-assembling tube-shaped polymers composed of heterodimers of the GTP-binding alpha- and beta-tubulin. Microtubules play a fundamental role in multiple cellular structures and processes including cytoplasmic organization, intracellular transport and the mitotic spindle. Multicellular organisms have multiple genes that encode for highly conserved alpha- and beta-tubulins, which only significantly diverge at their C-termini. This raises the question of whether paralogues are redundant or specialized. In many organisms, tubulins are often redundant in the mitotic spindle. In other contexts, mutations in certain tubulins cause specific developmental and neurological conditions. *C. elegans* has nine alpha- and six beta-tubulins. TBA-9 was originally identified as a ciliary/axonemal alpha-tubulin. While it is expressed in multiple ciliated sensory neurons, it is also expressed in certain motor neurons and neuronal support cells that are non-ciliated. Mutations in *tba-9* cause a number of behavioral abnormalities in nematodes including altered locomotion, increased roaming behavior and reduced slowing upon encountering food. The sum of these mutant phenotypes suggests defects in dopamine signaling. A beta-tubulin, BEN-1, was originally identified in a screen for mutations that provide resistance to the microtubule depolymerizing drug benomyl, which causes paralysis in *C. elegans*. It is coexpressed with TBA-9 in a set of motor neurons that also express dopamine receptors. To determine where TBA-9 functions in dopamine signaling and how it might interact with BEN-1 and play a role in locomotion, we have undertaken multiple approaches. First, we have analyzed the structure of motor neurons in single and double mutants for these tubulins. Second, we used behavioral assays to assess the point of disruption of dopamine signaling in *tba-9* mutants. Single mutants show no gross abnormalities in the structure of the nervous system, and the defect in dopamine signaling appears to be during synthesis, transport or secretion as opposed to reception. These results suggest that TBA-9, a highly specialized tubulin in *C. elegans*, plays a unique role in the nervous system.

1518

Cellular damage in brain of rat with endotoxic shock induced by LPS.

J. J. Martinez-Castillo[1], G. Amaral-Torres[1], S. Sánchez-Rodriguez[1], M. Moreno-Garcia[2], J. Garcia-Estrada[3], E. Meza-Lamas[4], E. López-Robles[1]; [1]Cellular Biology, Universidad Autónoma de Zacatecas, Zacatecas, Mexico, [2]Cellular and Microbiology-UACB, Universidad Autónoma de Zacatecas, [3]Neurosciences, CIBO-IMSS, Guadalajara, Mexico, [4]Enfermeria, Universidad Autónoma de Zacatecas, Zacatecas, Mexico

Bidirectional communication between the immune system and brain allow a regulation in response to infections. Endotoxic shock is caused by lipopolysaccharides (LPS) of gram-negative bacteria, followed by overproduction of diverse molecules that cause damage on diverse tissues; such molecules modify neuroimmune functions. Enolase and GFAP are cellular damage markers in brain. We studied brain cell damage in rats with endotoxic shock induced by LPS (*E. coli* 0111:B4). Windstar adult males were used, five animals/group received intraperitoneal injections as follows: (i) Control, 500 µl of normal saline. The remaining groups were inoculated with 12 mg/Kg of LPS dissolved in 500 µl of distiller water. Brains were obtained at: (ii) Group, 60 min after LPS. (iii) Group 120 min after LPS. (iv) Group 240 min after LPS. The brain was cut at 4µm. In each cut antibody anti-GFAP, anti-enolase and anti-TNFa were added for 30', washed down with PBS and added anti-IgG conjugate fluorescein for 30', washed again and observed under a microscope. Our results show that **Enolasa** in (ii), there are fluorescent deposits in the periphery of the cell, increased in (iii), in (iv) decreased slightly. **GFAP** in (ii) dim deposits on the periphery of the cell and dotted deposits in the center of the cell

are seen; in (iii) deposits and number of positive cells increased; in (iv) more dispersed continued increase all over the tissue. **TNF-α**, show faint deposits in (ii). In (iii) more intense deposits, as well as more positive cells, decreased in (iv). In conclusion, the presence of TNFα was the factor that triggered the destruction of neuronal and astrocyte cells, which increased in relation to time elapsed after inoculation.

Mechanotransduction II

1519

The pulsating migration of single breast cancer cells mediated by the collective migration of normal breast epithelial cells.

M. Lee[1,2], D. Wirtz[1,2]; [1]Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, [2]Johns Hopkins Physical Sciences - Oncology Center, Johns Hopkins University, Baltimore, MD

Whether normal epithelia cells actively participate in the early steps of cancer metastasis in epithelial sheets is unclear. A co-culture system of scattered, individual human breast cancer cells surrounded by dense, non-transformed human breast epithelial cells reveals that the non-transformed cells collectively mediate a dramatically enhanced, “pulsating” migratory phenotype of the individual carcinoma cells. Quantitative analysis correlates this enhanced migration with the intermittent crowding of individual cancer cells by the stiff nuclei of normal cells, which induces a cyclic stretch-shrink of the soft nucleus of the cancer cell. Enhanced pulsating migration is absent in single and confluent metastatic cancer cells and in non-metastatic cancer cells surrounded by normal cells. The pulsating migration of individual cancer cells is mediated by the motility of the normal cells and the differential strengths of homotypic and heterotypic cadherin-based cell-cell adhesions: Disruption of cortical actin filament bundles, or depletion of α-catenin in normal cells or the re-expression of E-cadherin in cancer cells all halted the pulsating migration of cancer cells. These results reveal a previously unknown, but critical, role played by normal epithelial cells in the enhanced migration of metastatic carcinoma cells, which might provide new avenues for cancer therapies where, in addition to cancer and stromal cells themselves, normal epithelial cells in the vicinity of a carcinoma tumor are targeted to reduce metastasis.

1520

Constraining Cell Motility Increases Sensitivity to Nocodazole via the Inhibition of Glu-Tubulin Formation.

A. Rape[1], Y-L. Wang[1]; [1]Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA

The production of traction forces – forces generated by the actin-myosin II cytoskeleton and exerted on the substrate – is vital to the proper regulation of many functions of adherent cells including adhesion and differentiation. Traction forces increase upon the depolymerization of microtubules, indicating intricate crosstalks between the actin and microtubule cytoskeletons. In addition, this interaction may be affected by the post-translational de-tyrosination of tubulin, which forms what is termed Glu-tubulin and imparts stability to modified microtubules. Based on the previous observations that Glu-tubulin forms preferentially at the leading edge of wounded monolayers, where cells migrate actively, we hypothesized that migration activities cause cells to form an increasing amount of Glu-tubulin, which may then weaken traction forces and adhesions, causing a positive feedback by decreasing substrate anchorage. To test this hypothesis, we applied time-lapse traction force microscopy to NIH 3T3 fibroblasts and NMuMG

mouse breast epithelial cells on micropatterned polyacrylamide hydrogels before and after the addition of 10 µM nocodazole. We found that 3T3 cells confined to 50x50 µm squares generated significantly higher traction stress and showed stronger responses to nocodazole than cells that were allowed to spread freely. Similar results were obtained using a teardrop-shaped pattern designed to mimic the shape of migrating cells. Immunofluorescence staining showed little or no Glu-tubulin in immobilized cells, but prominent presence of Glu-tubulin in motile 3T3 cells. The difference in nocodazole sensitivity between motile and non-motile cells was eliminated by limited serum starvation, which is known to inhibit the formation of Glu-tubulin while allowing cell migration. As Glu-tubulin has been found to accumulate in invasive cancer cells, we hypothesized that constraining the motility of post-EMT cells may reduce this response. Using NMuMG cells that were engineered to be in a pre- or post-EMT state, we found that constraining the motility of post-EMT cells significantly reduced the amount of Glu-tubulin, while pre-EMT cells showed no accumulation of Glu-tubulin in unconstrained or constrained cells. Thus, contrary to the common notion that genetic aberrations cause cancer phenotypes, we suggest that the stimulation of cell migration by a damaged basal membrane or other factors may be responsible for some of the invasive phenotypes, due to the ability of mesenchymal cells to sense their migration state and regulate their cytoskeletal structures and mechanical output to further enhance the motility.

Megakaryoblastic leukemia-1 influences proliferation and cell migration by transcriptional regulation of tenascin-C and other cancer-relevant genes.

M. Asparuhova[1], J. Ferralli[1], I. Gürbüz[1], R. Chiquet-Ehrismann[1]; [1]Friedrich Miescher Institute for Biomedical Research, Basel, Switzerland

The extracellular matrix protein tenascin-C (TNC) is highly over-expressed in cancer stroma and favors cell migration and invasion. Furthermore, TNC is up-regulated in processes influenced by mechanical stress, such as inflammation, tissue remodeling, wound healing, and tumorigenesis (1). Cyclic strain-induced TNC expression depends on RhoA-actin signaling, the pathway that regulates transcriptional activity of serum response factor (SRF) by its coactivator megakaryoblastic leukemia-1 (MKL1). Therefore, we tested whether MKL1 controls TNC transcription. We found that overexpression of MKL1 strongly induces TNC expression in mouse NIH3T3 fibroblasts and normal HC11 and transformed 4T1 mammary epithelial cells. An MKL1 mutant incapable of binding to SRF still strongly induced TNC, while induction of the SRF target c-fos was abolished. Cyclic strain failed to induce TNC in MKL1-deficient but not in SRF-deficient fibroblasts, and strain-induced TNC expression strongly depended on the SAP domain of MKL1. Promoter-reporter and chromatin immunoprecipitation experiments unraveled a SAP-dependent, SRF-independent interaction of MKL1 with the proximal promoter region of TNC, attributing for the first time a functional role to the SAP domain of MKL1 in regulating gene expression (2). Recent data from the literature have indicated that the stiffness or rigidity of the cancer stroma is a crucial cause for the invasive behavior of cancer cells and e.g. tissue stiffness is a bad prognostic factor in human breast cancer. We postulate that mechanical stimulation of cells induces similar cellular responses as the contact of cells with rigid matrices does. In a stiff microenvironment, the cytoskeleton will contract, actin polymerizes and G-actin levels fall. This will induce signaling by the actin sensor MKL1 and result in the expression of tenascin-C as well as other proteins co-regulated with tenascin-C that we were able to identify in our screen based on the use of cells overexpressing different MKL1 mutants. We could identify groups of transcripts that were specifically induced in cells that exhibited increased proliferation and migration. The expression of these genes was dependent on the presence of the SAP domain of MKL1 pointing to a crucial role for the SAP-domain in the control of proliferation and cell migration.

Substrate stiffness regulates NF-kB expression and activity in cancer cells.

S. Ishihara[1], M. Yasuda[2], T. Mizutani[1], K. Kawabata[1], H. Haga[1]; [1]Transdisciplinary Life Science Course, Graduate School of Life Science, Hokkaido Univ., Sapporo, Japan, [2]Department of Oral Pathobiology, Graduate School of Dental Medicine, Hokkaido Univ.

Tumor tissues are stiffer than normal ones. The stiffer the extracellular environment is, the more invasiveness of cancer cells is induced. Cells can sense stiffness of the surrounding substrate; it is called mechanosensing. However, it is not clear if the cancer malignancy is induced by the mechanosensing process.
In this study, we focused on transcription factor NF-kB, which regulates the expression of many kinds of molecules in the immune system in response to multiple stresses and also induces proliferation and invasion of cancer cells. We make a hypothesis that tissue stiffness enhances NF-kB expression and/or activity in cancer cells, causing malignant transformation.
We cultured A549 lung carcinoma cells and observed the morphology of the cells cultured on stiff or soft substrates. For a stiff substrate, we used a glass or plastic plate coated with type-I collagen. And for a soft substrate, we used a type-I collagen gel (1.6 mg/mL). On the stiff substrate, A549 cells adhered with spreading morphology and showed high migrating activities. On the other hand, on the soft substrate, most of A549 cells adhered with round morphology and showed low migrating activities. Western blotting experiments revealed that expression of NF-kB (p65) on the stiff substrate was greater than that on the soft substrate. Furthermore, A549 cells showed a localization of NF-kB at nucleus sites within 60 minutes after adhering on the stiff substrate. By contrast, on the soft substrate, A549 cells did not show a localization of NF-kB at nucleus sites after adhesion.
These results indicate that cancer cells cultured on a stiff substrate enhance NF-kB expression and activation, which promote inflammatory reaction. Stiffer tumor tissues possibly induce cancer malignancy through the enhancement of NF-kB expression and activity.

Forcing Tumor Cell Invasion: The Role of Extracellular Matrix Mechanics and Topology.

L. Cassereau[1,2], J. Lopez[2], C. Frantz[2], I. Acerbi[2], H. Yu[2], J. Lakins[2], Q. Shi[3], J. Liphardt[3], V. Weaver[2,4]; [1]Bioengineering, University of California Berkeley, Berkeley, CA, [2]Center for Bioengineering and Tissue Regeneration, University of California San Francisco, San Francisco, CA, [3]Biophysics, University of California Berkeley, [4]Surgery and Anatomy, University of California San Francisco

Tumor progression is traditionally linked to the sequential accumulation of genetic mutations. However, we have shown that tumor development is also strongly influenced by physical cues such as extracellular matrix (ECM) organization and stiffness. To understand how ECM mechanics and architecture regulate tumor progression, we conducted a comprehensive analysis of the interplay between ECM tension and topology and tumor development. Second-generation harmonics (SHG) and structured-illumination polarization microscopy (SIM-POL) imaging revealed that ECM stiffening in developing mammary cancers is functionally linked to collagen linearization and cross-linking that generate heterogeneous oriented matrix bundles associated that globally influence tissue architecture. Moreover, AFM mapping of PyMT mammary tumors and human invasive triple-negative breast cancers revealed that the invasive front of these lesions frequently contained tracts of highly rigid oriented ECM. We hypothesize

that this aligned ECM architecture creates a mechanically anisotropic environment, which fosters directed tumor cell invasion. To explore the molecular mechanisms through which anisotropic ECM stiffness regulates tumor cell invasion, we performed experiments using mechanically heterogenous 2D and 3D gel systems. In 2D we demonstrated that ECM tension gradients significantly promote the directional migration, or durotaxis of oncogenically (EGFR, ErbB2, Ha-Ras, V12 Ras) transformed breast cells. To address this issue in 3D we engineered a mechanically anisotropic 3D organotypic gel system. SHG and SIM-POL imaging revealed that our mechanically and topologically heterogeneous (MTH) gels recapitulate the architectural heterogeneity of the ECM at the invasive front of breast tumors *in vivo.* Utilizing our MTH gel system and real time two-photon imaging we could show that the structure and organization of nonmalignant and oncogenically-transformed mammary organoids adjacent to mechanically loaded collagen fibers were consistently disrupted and that cells within the organoids invaded into the ECM along collagen fibers in response to epidermal growth factor (EGF) stimulation. Consistent with results from our 2D assays, we found that in 3D, persistent invasion was favored following oncogene transformation. We also noted that mammary epithelial cells (MECs) in a 3D context demonstrated heightened EGFR-induced Rac activity suggesting that a 3D ECM may potentiate invasion by modifying the growth factor and mechanosignaling behavior of MECs. Studies are now underway using our MTH gel system in combination with transgenic mouse models to explore how dimensionality and ECM architecture in combination with oncogenic transformation could modify MEC signaling to promote invasion. Focal adhesion kinase stabilizes the cytoskeleton.

B. Fabry[1], A. H. Klemm[1], S. Kienle[1], T. E. Schäffer[2], W. H. Goldmann[1]; [1]Biophysics, University of Erlangen-Nuremberg, Germany, Erlangen, Germany, [2]Applied Physics, University of Erlangen-Nuremberg, Germany, Erlangen, Germany

Focal adhesion kinase (FAK) is a central focal adhesion protein that promotes focal adhesion turnover, but the role of FAK for cell mechanical stability is unknown. We measured the mechanical properties of wildtype (FAKwt), FAK-deficient (FAK-/-), FAK-silenced (siFAK), and siControl mouse embryonic fibroblasts by magnetic tweezer, atomic force microscopy, traction microscopy and nanoscale particle tracking microrheology. FAK-deficient cells showed lower cell stiffness, reduced adhesion strength, and increased cytoskeletal dynamics. These observations imply a reduced stability of the cytoskeleton in FAK-deficient cells. We attribute the reduced cytoskeletal stability to a compensatory overexpression of *rho*-kinase (ROCK) in FAK-deficient cells that suppresses the formation of ordered stress fiber bundles, enhances cortical actin distribution, and reduces cell spreading. In agreement with this interpretation is that cell stiffness and cytoskeletal stability in FAK-/- cells are partially restored to wildtype level after ROCK inhibition with Y27632.

1525

Vinculin is required for cell polarization, migration and extracellular matrix remodeling in three-dimensional collagen matrices.

I. Thievessen[1], N. Fakhri[2], S. McIsaac[3], L. Gao[4], B-C. Chen[4], E. Betzig[4], R. Oldenbourg[5], C. M. Waterman[1]; [1]Laboratory of Cell and Tissue Morphodynamics, National Heart, Lung and Blood Institute/NIH, Bethesda, MD, [2]Fakultaet fuer Physik, iii. Physikalisches Institut, Georg August Universitaet Goettinggen, Goettingen, Germany, [3]Lewis-Sigler Institute for Integrative Genomics, Princeton University, [4]Janelia Farm Research Campus, [5]Marine Biological Laboratory

Vinculin is an F-actin binding protein that localizes to integrin-based cell-extracellular matrix (ECM) adhesions. Studies in two-dimensional (2D) tissue culture models have suggested that vinculin is a negative regulator of cell migration via its role in cytoskeleton-ECM coupling to strengthen and stabilize adhesions, as well as in modulating leading edge protrusion dynamics. However, whether vinculin plays a similar role in regulating cell migration in more physiologically relevant 3D environments is not known. To address this question, we analyzed morphodynamics and ECM remodeling of primary murine embryonic fibroblasts (MEF) with cre/loxP-mediated vinculin gene disruption (Vcl-KO) in 3D collagen/fibronectin cultures. By spinning disk confocal and Bessel beam microscopy of plasma membrane or F-actin markers (tdTomato-Farnesyl or tdTomato-Ftractin), we found that control MEF exhibited an elongated morphology with extended, polarized, sheet-like lamellipodial protrusions, while Vcl-KO MEF were less extended and polarized, with lamellipodia being dominated by finger-like protrusions. These protrusions exhibited mEmerald-VASP at their extending tips, confirming them as filopodia. Analysis of protrusion dynamics revealed increased velocity of cell edge protrusion in Vcl-KO compared to control MEF. Thus, vinculin is required for cell polarization, regulating lamellipodial protrusion and suppressing filopodia in 3D ECM, similar to functions described in 2D culture. Surprisingly, long term time-lapse imaging showed that vinculin depletion decreased 3D cell migration velocity of control MEF, opposite to observations in 2D culture. However, Vcl-KO MEF showed an increased cell shape persistence compared to control MEF, demonstrating that vinculin may be important for effectively converting edge protrusion into cell shape change, and thus forward motion in 3D collagen. This suggested that vinculin may be required for effective interaction with 3D ECM. To test this further, we examined the ability of cells to remodel ECM. In a macroscopic gel contraction assay, Vcl-KO MEF exhibited decreased contraction of 3D collagen gels compared to control MEF. Consistent with this, live-cell polarization microscopy of collagen gels containing MEF revealed that while control cells induced a highly homogeneous, highly aligned collagen matrix, gels containing Vcl-KO cells displayed a more heterogeneous fiber orientation and a lower degree of fiber alignment, indicating defects in ECM organization. Our results suggest that vinculin promotes cell migration and matrix remodeling by effectively coupling cell morphodynamics to the ECM in complex 3D extracellular environments.

1526

Spatial distribution of protrusion, contraction and adhesion determines cell migration strategy in 3D matrices: a computational study.

J. Zhu[1], S. Pulford[2], A. Mogilner[1]; [1]Mathematics, UC Davis, Davis, CA, [2]Mechanical & Aerospace Engineering, UC Davis

Cell migration on a two-dimensional flat surface has been extensively studied and is generally characterized by a front-protrusion-rear-contraction process. In a 3D environment, on the other hand, cells adopt multiple, not well understood, migration strategies depending on the cell type and the properties of the extracellular matrix (ECM). By using mathematical modeling and

computer simulations, we find that these migration strategies in 3D can be classified by various spatial arrangements of actin-based protrusion, contraction and actin-ECM adhesion. We show that when the ECM undergoes proteolysis, a cell can move by using a broad protrusion at the front followed by transient actin-ECM adhesions at the side and a strongly contracting actin-myosin network at the rear. The cell can also be pulled along thin protrusive extensions if there are transient adhesions near the tip and a contractive actin network along the extension. In the absence of proteolysis, the cell switches to an amoebae-like motion to squeeze through pores in the ECM. We propose that these migration strategies are triggered by mechanical sensing of ECM through cell signaling pathways.

1527

The actomyosin linkage and integrin-ligand interaction regulate adhesion dynamics and cell migration.

L. Chen[1], M. Vicente-Manzanares[2], L. Potvin-Trottier[3], P. Wiseman[3], R. Horwitz[1]; [1]Cell Biology, University of Virginia, Charlottesville, VA, [2]Universidad Autonoma de Madrid, [3]McGill University

The adhesive and migratory behavior of a cell depends on its type, its adhesion receptor repertoire and the substrate to which they are attached. Previous observations show the different MII isoforms and the level of phosphorylated RLC (pRLC) regulate adhesion maturation and turnover, protrusion rates, and polarity for cells migrating on fibronectin or vitronectin. We have asked whether adhesion and migration are similarly regulated in cells using other two other integrin receptors, α6β1 and αLβ2. We find that CHO.B2 cells expressing either α6β1 or αLβ2 integrins migrate and protrude faster on laminin or ICAM-1, respectively, than CHO.B2 cells expressing α5β1 migrate on fibronectin. However, changing the levels of MIIA, MIIB or pRLC do not have the large effects on migration, adhesion, and protrusion that are seen in α5β1-expressing cells on fibronectin. Despite the presence of large adhesions, the force on the substrate was also reduced in regions of protrusions in the α6- vs α5-expressing cells, and they showed robust tyrosine phosphorylation. Surprisingly, we observed a rapid retrograde flux of paxillin and integrin in the elongated adhesions in the protrusions of α6β1-expressing cells on laminin or αLβ2-expressing cells on ICAM-1, but not with α5β1-expressing cells on fibronectin. However, activation of α6β1, using Mn^{2+} inhibits this flux, as well as the cell migration and protrusion rates. Finally, we show that the migratory behavior of fast migrating leukocytes on Fn or ICAM-1 is largely independent of myosin II. Our data suggest the integrin-ligand interaction differs among integrin-ligand pairs and affects traction forces, signaling, adhesion, protrusion and cell migration.

1528

Septins are required for efficient epithelial cell-ECM adhesion and protrusion.

L. Dolat[1], E. T. Spiliotis[1]; [1]Biology, Drexel University, Philadelphia, PA

Septins comprise an evolutionarily conserved family of guanine nucleotide-binding proteins that assemble into oligomeric filaments. Abnormal septin expression has been implicated in several disease states including cancer. Overexpression of septins has been shown to promote cell migration and invasion. In previous studies, pharmacological targeting and knock down of septins have resulted in attenuation of cell motility. Septins associate with the actomyosin and microtubule networks and effectors of Rho signaling, but the precise role of septins in cell motility is unknown. Since motility relies upon a dynamic interplay between membrane protrusion and adhesion to the extracellular matrix, we explored a role for septins relative to components of both processes. Here, we show that in epithelial cells (MDCK, HeLa), septin 2 (SEPT2) colocalizes with actomyosin stress fibers and microtubules, but also forms peripheral filaments and rings that localize at lamella, near sites of enlarging focal adhesions. Using an

alternative fixation technique, which extracts cytoplasmic proteins before paraformaldehyde fixation, we show that peripheral septins are associated with the cortical membrane. Knockdown of SEPT2 in HeLa cells resulted in smaller, more peripherally localized focal adhesions compared to control cells. Since focal adhesion enlargement is a force-driven process dependent upon myosin II-generated contraction, we examined myosin activity by staining for the phosphorylation of its regulatory light chain. More diffuse and reduced levels of phosphorylated myosin were observed in SEPT2-depleted cells compared to the control, suggesting that septins play a role in the mechanotransductive properties that regulate growth of focal adhesions. Additionally, preliminary data show that SEPT2 depletion decreases the width of cortactin-enriched lamellipodia, suggesting a role for septins in lamellipodial generation and/or maintenance. Our results indicate that septins are essential for the mechanochemical and protrusive activities that underlie cell motility. On-going studies aim at defining the molecular relationship between septins and actin in the leading lamellae and at the cortical membrane.

1529

Conformational Switch of Vinculin: a Prerequisite for Mechanical Force Transmission.

V. Auernheimer[1], G. Diez[1], B. Fabry[1], W. Goldmann[1]; [1]Center for Medical Physics and Technology, Biophysics Group, University of Erlangen-Nuremberg, Erlangen, Germany

Mechanical coupling of the actin cytoskeleton to the extracellular matrix via the integrin-focal adhesion (FA) link is crucial for proper cellular function. Within the focal adhesion complex, the mechano-coupling protein vinculin plays a fundamental role in transmitting cellular forces. Vinculin consists of a head and a tail domain and displays a bi-stable behavior, operating either in a closed auto-inhibited, or an open active state. In the open conformation, the head and tail dissociate, exposing numerous binding sites for different proteins. We developed a constitutively open vinculin mutant by inserting 3 point-mutations in the head domain (E28, 29, 31 → R). This mutant was compared to a constitutively closed vinculin (A50 → I). FRAP experiments revealed a decreased recovery time of constitutively open vinculin, suggesting that vinculin in the active (open) conformation inserts more stably into the focal adhesion complex. We next tested whether cell mechanical properties are also affected by vinculin head-tail interactions. Vinculin in the closed state displayed lower stiffness and reduced tractions compared to vinculin in the open state. Interestingly, cell stiffness and traction forces were even further reduced in a VinΔex20 mutant where vinculin was in the open (active) form but devoid of actin binding sites. Together, these data suggest that a conformational switch of vinculin strongly affects cellular mechanics through a concurrent modulation of force transmission to actin and to focal adhesion proteins.

1530

Mechanical Stimulation Induces an Actin Cytoskeletal Response and Recruitment of Zyxin, Mena/VASP and α-Actinin.

L. M. Hoffman[1], C. Jensen[1], M. Yoshigi[1], M. Beckerle[1]; [1]Huntsman Cancer Institute, University of Utah, Salt Lake City, UT

Mechanotransduction occurs in organs that experience regular mechanical stress, such as lung, bladder, uterus and the vasculature. Stretch stimulation of cells in culture induces dramatic alignment and reinforcement of the actin cytoskeleton, visualized by phalloidin staining and fluorescence microscopy. To investigate mechanotransduction at the cellular and molecular level, we applied uniaxial cyclic stretch to fibroblasts expressing wild-type and mutant proteins then evaluated the stretch response. Indirect immunofluorescence microscopy studies showed that zyxin, α-actinin, and Mena/VASP proteins mobilized from focal adhesions to stretch-

stimulated actin stress fibers while canonical focal adhesion markers such as vinculin and tyrosine-phosphorylated proteins remained at focal adhesions. The actin cytoskeletal response was abrogated in zyxin-null cells, and was rescued by adding back wild-type zyxin, implicating zyxin in mechanotransduction. Furthermore, zyxin proteins mutated to disrupt binding partner interactions (e.g. for α-actinin and Mena/VASP) retained their mechanosensitive localization to stretch-induced stress fibers but the resulting actin failed to thicken normally. These results revealed that zyxin plays a key role in recruiting actin regulatory proteins to sites of dynamic actin remodeling. Interestingly, immunoblot analysis of a survey of mouse tissues detected the highest zyxin expression in lung. Subsequent immunohistochemistry detected zyxin in lung alveoli, sites of greatest inspiration induced tissue expansion. To test if zyxin activity is required for maintaining barrier function integrity, we compared lungs from wild-type and zyxin-null mice. Measurement of lung/body ratios and bronchoalveolar lavage for protein leak did not detect a zyxin-dependent difference. We conclude that in unstressed conditions, zyxin is dispensable for normal lung physiology. In future work it will be interesting to assess the impact that zyxin, α-actinin, and Mena/VASP have on actin dynamics that occur in lungs challenged by mechanical stress or pharmaceutical agents.

1531

Oscillatory Coupling between the Extracellular Matrix and the Actin Cytoskeleton is Essential for Cell Mechanosensing and Durotaxis.

S. V. Plotnikov[1], A. Pasapera[1], B. Sabass[2], U. Schwarz[2], C. M. Waterman[1]; [1]National Heart, Lung and Blood Institute, Bethesda, MD, [2]University of Heidelberg, Germany

The ability of cells to sense mechanical properties of the extracellular matrix (ECM) and to exhibit durotaxis (directed migration toward stiffer environments) is thought to underlie many biological processes including angiogenesis, neurogenesis and cancer metastasis. Although it has been shown that both structural and signaling components of focal adhesions (FAs) are crucial to translate mechanical cues into cell behavior, the molecular mechanism of mechanosensing remains unknown. Here we demonstrate that the ‘molecular clutch’, an ensemble of links between the actin cytoskeleton and ECM-engaged integrins, is mechanoresponsive. We identify a functional module, composed of FAK, paxillin and vinculin, that is essential to enable mechanoresponsive behavior of the FA molecular clutch and is required for durotaxis over a wide range of ECM compliances.

By high-resolution traction force microscopy on polyacrylamide hydrogels of varying stiffness, we visualized traction distribution along individual FAs in migrating mouse embryonic fibroblasts. We revealed two distinct patterns of traction dynamics within individual FAs: static and oscillating over time. FAs with static traction exerted low traction stress, which did not change over time. FAs with oscillating traction were identified as exerting higher traction stress on average, but exhibited periodic centripetal movement of the peak position of traction within an individual FA from the distal tip of the FA towards the FA center, which was accompanied by a transient increase of traction magnitude. As ECM rigidity was increased, the traction peak movement was suppressed, signifying mechanoresponsiveness of traction oscillations. We found that perturbing paxillin phosphorylation by expressing Y31/118E- or Y31/118F-paxillin mutants, inhibiting FAK, or expressing a paxillin point mutant defective in vinculin binding declined traction stress in FAs, abrogated traction oscillations on soft ECM and switched adhesions to the non-mechanoresponsive static regime of traction dynamics. However, mechanoresponsive traction oscillations could be rescued by further decreasing either ECM stiffness or myosin II contractility, suggesting a shift in the ECM stiffness range in which FAs are mechanoresponsive. This finding allowed us to suppress either oscillating or static regimes of traction dynamics and to reveal the physiological importance of traction oscillations. We demonstrated that traction oscillations are essential for stiffness-dependent FA maturation and

durotaxis. Random cell migration and chemotaxis, assessed by a Boyden chamber assay, occurred independently of the dynamic state of FA traction. Our results suggest that not a certain protein within a FA, but the entire 'molecular clutch' may act as a mechanosensor in FAs, and that a FAK-Paxillin-vinculin module regulates the dynamic range of cell mechanosensing to guide durotaxis.

1532

Cellular Traction Forces are Regulated by the Cell Spread Area not Substrate Stiffness.

P. Oakes[1,2], M. Gardel[1,2]; [1]Institute for Biophysical Dynamics, University of Chicago, Chicago, IL, [2]Physics Deparment, University of Chicago, Chicago, IL

Extracellular Matrix stiffness has been shown to impact numerous aspects of cell physiology including cell migration, proliferation and differentiation. Such cellular mechanosensation is thought to be driven by stiffness-dependent perturbations to actomyosin contractility and subsequent mechanotransduction pathways. However ECM stiffness simultaneously drives changes in cell spread area, lamellar actin organization and the magnitude of traction forces on the ECM, making it difficult to identify causal relationships. Here we focus on the traction forces exerted by the cell and explicitly investigate how changes in these forces vary with changes in cell spread area and lamellar actin organization on ECM of varied stiffness. To measure the actin organization we developed a novel quantitative Fourier image analysis technique. This technique measures the local direction and magnitude of alignment within the cytoskeleton and calculates an order parameter based on comparison with adjacent regions. Surprisingly, we found no correlation between the organization of the lamellar actin into bundles with the magnitude of cellular traction forces exerted on the ECM. Instead, we find that the total cellular force is directly proportional to the cell's spread area, with the slope defining a cellular contractile stress. This relationship is robustly observed among several different cell types, with each cell type exhibiting a unique level of contractile stress. Additionally, this contractile stress can be varied by titration of the pharmacological inhibitor of myosin II ATPase activity, blebbistatin. Quite unexpectedly, however, we find that the contractile stress is independent of substrate stiffness, despite large perturbations to the cell spread area. Cells that spread on soft substrates are able to generate equivalent amounts of force to similarly spread cells on stiff substrates. These results indicate that cellular contractile stress is not directly regulated by substrate stiffness, but rather indirectly impacted through the cell's spread area. Thus, these data suggest stiffness sensing occurs during the early spreading phase and is not a product of whole cell contractility.

1533

Spaceflight alters the migratory ability of stem cell derived keratinocytes resulting in decreased wound healing potential.

H. Finkelstein[1], E. Blaber[1,2], N. Dvorochkin[1], R. K. Globus[1], B. P. Burns[2], E. A. Almeida[1,3]; [1]Space Biosci Div., NASA Ames Research Center, Moffett Field, CA, [2]School of Biotechnology and Biomolecular Sciences, UNSW, Sydney, Australia, [3]Dept. Cell Tissue Biol., UCSF

Spaceflight can cause degenerative conditions in multiple tissues including incomplete or delayed wound closure. We hypothesize that somatic stem cells responsible for tissue regeneration require mechanical stimulation from gravity to regenerate tissues at normal rates and that spaceflight conditions, specifically microgravity, may interfere with their proliferation and differentiation. Previous experiments conducted in microgravity on shuttle mission STS-131 using stem cell derived embryoid bodies, resulted in many genes involved in stem cell pluripotency failing to turn off, and in the normal up-regulation of germ-layer markers being inhibited. Additionally, results from hypergravity experiments show an increase in proliferation of

mouse embryonic stem (mES) cells, suggesting gravity mechanical stimulation may regulate various stages of stem cell-based tissue regeneration. Here we specifically hypothesize that mechanical unloading in microgravity may alter the ability of mES cells to differentiate into keratinocytes. To test this hypothesis we induced keratinocyte differentiation from mES cells in microgravity through the addition of BMP4, retinoic acid and calcium to culture medium for 48 hrs prior to spaceflight. Cells were transferred to keratinocyte low serum medium and flown on the space shuttle STS-135 mission in the Cell Culture Module hardware using hollow fiber bioreactors. After 13 days orbital flight, cells were either fixed in-orbit for gene expression analysis, or returned to Earth for live wound closure assays. Keratinocytes isolated from bioreactors were allowed to attach to a collagen matrix before exposure to a migration exclusion zone. After a 48 hr period, 5.2% of cells exposed to microgravity had migrated into the exclusion zone whilst 9.3% of cells differentiated at 1g had migrated ($p=0.048$) indicating that spaceflight strongly inhibits their migratory ability. However, spaceflight did not affect the ability of keratinocytes to adhere to, and spread on a collagen matrix, with 37.3% of cells from ground controls and 34.7% of cells differentiated in microgravity attached and spread to a diameter >100 µm. These initial results suggest that exposure of keratinocyte progenitors to microgravity may alter their differentiation and reduce their ability to regenerate epidermal tissue during wound closure. Signaling Networks Governing Cell Migration II

1534

Live *in vivo* imaging of active RhoGTPase and cell behavior during neural crest EMT reveals a role for Rho in promoting EMT.

M. Clay[1], M. Halloran[1]; [1]Cellular and Molecular Biology Program, Dept. of Zoology, Dept. of Neuroscience, University of Wisconsin-Madison, Madison, WI

Objective: Epithelial to mesenchymal transition (EMT) is a process in which epithelial cells become motile. EMTs are critical events in normal development and are co-opted during pathological processes such as carcinoma invasion. To understand mechanisms controlling EMT, it is critical to establish *in vivo* models to study cells undergoing EMT in their natural environment. RhoGTPase has been implicated in EMT, although its precise function is controversial. We are investigating mechanisms of EMT using zebrafish neural crest cell (NCC) EMT as an *in vivo* model. We imaged the distribution of endogenous active Rho during cell behaviors associated with NCC EMT and tested how disruption of Rho signaling affects these behaviors.

Methods: We imaged endogenous active Rho distribution with a biosensor containing the Rho binding domain of Rhotekin fused to GFP driven by a NCC specific promoter. We expressed the biosensor in individual NCCs along with a volume marker, and performed ratiometric imaging to identify subcellular localizations of endogenous active Rho during EMT *in vivo*. We used small molecule inhibitors to disrupt Rho/ROCK signaling and examined the effects on NCC behaviors.

Results: Premigratory NCCs have an elongated morphology similar to other neuroepithelial cells, spanning from the apical midline to the basal surface of the neuroepithelium (NE). During EMT, the apical attachment retracts and NCCs move to the basal edge of the NE and begin blebbing. Active Rho levels spike just before the apical tail releases from neighboring cells and remain elevated during apical tail retraction. As retraction completes and NCCs exit the NE, apical active Rho levels decrease. Pharmacological inhibition of Rho/ROCK signaling results in

an increase in the number of NCCs that remain in contact with the apical midline and do not leave the NE, suggesting that active Rho is required for NCC tail retraction and EMT. We also observe active Rho in retracting NCC blebs, behaviors associated with NCC motility. NCC blebbing is blocked by inhibition of Rho/ROCK or myosin II. These results suggest Rho/ROCK signaling may drive contractile forces needed for motile NCC behaviors and EMT.

Conclusions: We have established zebrafish NCCs as an *in vivo* EMT model, and describe the first imaging of endogenous active Rho distribution during EMT in living embryos. Our data support Rho signaling as a source of contractile force that drives retraction of apical NCC tails and blebs to promote NCC motility and EMT.

1535

Oncogenic RABGAP EVI5 is a novel regulator of collective cell migration.

C. Laflamme[1], W. Clements[2], D. Ramel[1], G. Assaker[1], D. Traver[2], G. Emery[1]; [1]Université de Montréal (IRIC), Montreal, QC, Canada, [2]University of California at San Diego

Neuroblastoma (NB) is the most common form of extracranial solid tumors in childhood which develops from failure of neural crest cells to migrate and differentiate properly. Since few predisposition mutations have been identified in NB, very little is known about the molecular mechanism that define the role of those mutated genes in NB development. EVI5, a poorly characterized oncogene, is one of those mutated genes found in NB.

One of the main goals of our laboratory is to investigate the role of vesicular trafficking during cell migration. We study the migration of Drosophila border cells (BC) which migrate collectively during oogenesis. We published recently that Rab11 is essential to restrict guidance receptors at the leading edge of BC. Rab11 is a small GTPase involved in the recycling of cargos such as transmembrane receptors from intracellular endosomes back to the cell membrane. Rab proteins are cycling between an active GTP-bound state and an inactive GDP-bound state through the action of different regulators. Here, we have performed an RNAi screen to identify specific Rab11 regulators and we identified the Drosophila ortholog of EVI5 (dEVI5) as a potential GTPase activating protein (GAP) regulating Rab11 and BC migration.

We demonstrate that dEVI5 fulfill every criteria for a GAP proteins for Rab11. Biochemically, we show that dEVI5 interacts directly with Rab11. Moreover, the overexpression of dEVI5 increases the fraction of inactive Rab11 both in Drosophila S2 cells and in vivo, whereas the knockdown of dEVI5 has opposing effects. Furthermore, overexpressing dEVI5 phenocopies Rab11 loss of function in BC by blocking cell migration and disrupting the polarity of guidance receptors.

Our results suggest that EVI5 induces NB by disrupting the migration of neural crest cells. To test this hypothesis, we overexpressed EVI5 during zebrafish development and found that neural crest cell migration is strongly impaired.

In conclusion, we have identified dEVI5 as a novel regulator of collective cell migration through the regulation of Rab11 and we propose that ectopic activation of EVI5 induces NB by inhibiting neural crest cell migration.

PI3-Kinase Regulation of Myosin-IIA Heavy Chain Phosphorylation Promotes Tumor Cell Invasion.

L. E. Norwood Toro[1], P. Patel[1], N. G. Dulyaninova[1], R. P. House[1], J. Backer[2], A. R. Bresnick[1]; [1]Albert Einstein College of Medicine, Bronx, NY, [2]Molecular Pharmacology, Albert Einstein College of Medicine

EGF stimulation of MDA-MB-231 breast cancer cells results in the transient phosphorylation of S1943 on the nonmuscle myosin-IIA heavy chain (NMHC-IIA), which is known to promote myosin-IIA filament disassembly *in vitro*. We have extended these observations to show that EGF-stimulated NMHC-IIA S1943 phosphorylation occurs in multiple breast cancer cell lines, as well as in a glioma cell line. Using small molecule inhibitors and shRNA approaches, we are mapping signaling pathways downstream of the EGF receptor that modulate NMHC-IIA S1943 phosphorylation. An examination of the regulation of NMHC-IIA phosphorylation by PI-3 kinases in EGF-stimulated cells demonstrated that p110α-selective inhibitors block NMHC-IIA phosphorylation; whereas p110β-selective inhibitors enhance NMHC-IIA phosphorylation. Furthermore, inhibition of downstream PI3-kinase pathway components also blocks NMHC-IIA phosphorylation. To examine the cellular and functional consequences of S1943 phosphorylation, we are using lentiviral-mediated shRNA gene transfer and stable plasmid transfection to produce stable human breast cancer cells in which the expression of the endogenous NMHC-IIA is reduced and an exogenous GFP-tagged wild-type NMHC-IIA, NMHC-IIA phosphomimetic (S1943D/E) or NMHC-IIA non-phosphorylatable analog (S1943A) is expressed. One functional assay used to study tumor cell invasion is the 3D invasion assay, which investigates macrophage-stimulated tumor cell invasion through a collagen matrix. In breast cancer cells with a 50% reduction in NMHC-IIA expression, macrophage-stimulated 3D invasion is reduced 66.6% as compared to control siRNA transfected cells. A similar decrease in macrophage-stimulated 3D invasion was observed in stable shRNA NMHC-IIA knockdown cells where NMHC-IIA levels were reduced by 50-90%. Together, these observations suggest that NMHC-IIA is required for tumor cell invasion and S1943 phosphorylation is regulated by PI3-kinase. Future studies will be directed at examining the role of NMHC-IIA phosphorylation in modulating tumor cell invasion.

1537

The role of NEDD9 in oral squamous cell carcinoma invasion and metastasis.

S. Rosenzweig[1,2], A. Brock[1]; [1]Department of Cell and Molecular Pharmacology, Medical University of South Carolina, Charleston, SC, [2]Hollings Cancer Center, Charleston, SC

Using a phosphotyrosine proteomics screen we demonstrated that vascular endothelial growth factor (VEGF) action on human oral squamous cell carcinoma (OSCC) cell lines leads to the tyrosine phosphorylation of NEDD9 (neuronal expressed developmentally down-regulated9; human enhancer of filamentation1, HEF1; Crk-associated substrate in lymphocytes, CasL), cortactin, paxillin and focal adhesion kinase and an invasive phenotype (Oncogene 29, 4449-4459, 2010). NEDD9 is a scaffold protein implicated in the metastatic signatures of glioma, melanoma and lung cancers and regulated by tumor suppressor LKB1. NEDD9 knockdown decreased and overexpression increased cell migration, invasion and matrix metalloproteinase 2/9 (MMP) levels, respectively. To further define how NEDD9 regulates these events and in particular, the role of its tyrosine-rich substrate domain, we generated: F13 NEDD9, in which all CrkL motifs (YXXP) were mutated to F; Y629F, the site where Src binds to NEDD9 in order to phosphorylate the substrate domain; F14 NEDD9, representing the combined mutations in F13 and Y629F NEDD9. In addition, to determine NEDD9's role in HNSCC progression and metastatic spread NEDD9 null vs. wt mice were treated with the chemical carcinogen/tobacco-

mimetic, 4-nitroquinoline 1-oxide (4NQO; 50 µg/ml in the drinking water for 16 weeks). Analysis of conditioned medium from cells stably expressing F13, F14, or Y629F NEDD9 by zymography revealed a dramatic loss of MMP9 expression/secretion, while MMP2 expression/secretion was only slightly decreased. In contrast, cells stably overexpressing NEDD9 exhibited enhanced expression/secretion of both MMP2 and MMP9, consistent with NEDD9 silencing reducing MMP9 levels to a greater extent than MMP2. Complementary results were seen for invadopodia assays with NEDD9 silencing reducing and NEDD9 overexpression increasing invadopodia formation. In animal studies, NEDD9 null and wt mice all exhibited tumors/lesions on their tongues after 16 weeks of 4NQO treatment. The extent of tumor formation, progression and level of metastasis to cervical lymph nodes is currently being quantified. These findings suggest a role for the NEDD9 substrate domain in MMP9 regulation and signaling to HNSCC cell invasion and metastasis.

Migration during metastasis: the cellular response to tunable cross-linked ECMs.

J. Srivastava[1], M. Zaman[2]; [1]Chemistry and Biochemistry, Univ Texas-Austin, Brookline, MA, [2]Biomedical Engineering, Boston University, Boston, MA

The modalities of cell migration and persistence rely on integrin engagement with the extracellular (ECM), focal adhesion formation, protease secretion and numerous intracellular signaling cascades. Previous investigations utilizing 3D ECM environments have provided invaluable insights to cellular migration and mechanosensing; however, it is still unclear as to which parameters of the ECM a cell mechanically senses in order to elicit biochemical responses.

The exact role of matrix in controlling cellular fate, particularly during invasion and 3D migration remains elusive. To explore the impact of the ECM structure and mechanics on cell adhesion and signaling in native environments, we utilized 3D collagen gels and cross-linked them with naturally secreted tissue transglutaminase (tTG), which exhibits abherrant expression in native prostate cancer environments. The objective of this study was to investigate the molecular mechanisms affected by altering single variables of the ECM as they influence prostate cancer proliferation. Here we quantitatively provide mechanistic understanding of cell migration through 3D ECM substrates of constant ligand density but increased stiffness, implemented by a covalent chemical crosslinker. Our results demonstrate how these mechanisms regulate cellular migratory mechanisms.

Methods used to characterize such environments and cellular responses include Scanning Electron Microscopy (SEM), Confocal Microscopy, Flow Cytometry, Gelatin Zymography, and Immunoblotting. Current studies utilize siRNA and rtPCR quantitation to further elucidate cross-talk between cell-ECM adhesion stimulated signaling as it affects extracellular and intracellular activity of matrix associated MMPs. Our signaling studies of prostate cancer cells in tTG cross-linked systems exhibit a novel mechanism for sensitivity to substrate stiffness, in contrast to ligand density, and substrate cross-linking. We observe cooperative increased expression of the integrin family of adhesion proteins, Src and matrix metalloproteinases (MMPs) from cells cultured in environments of intermediate stiffness. The invasive ability of prostate cancer cells in native environments exhibits novel interactions between integrin-induced signaling pathways and MMP activity. Our data provides a systems level quantitative mechanism of mechanosensing of fibril density, cross-linking and ECM stiffness and its synergistic regulation of adhesion-based prostate tumor cell migration in native like environments.

1539

Cross-talk between matrix tension, PKA, and Ca^{2+} in ovarian cancer cell migration and invasion.

A. Howe[1], A. McKenzie[1]; [1]Pharmacology, University of Vermont, Burlington, VT

The cAMP-dependent protein kinase (PKA) is spatially regulated during chemotaxis, with specific enrichment within the leading edge of migrating cells. However, the mechanism and consequences of this activation are not fully understood. Here, we show that PKA is activated at the leading edge of ovarian cancer (OvCA) cells during migration and during invasion of a three-dimensional extracellular matrix, and that the activity of both PKA and A-kinase anchoring proteins (AKAPs) are required for OvCA cell migration and matrix invasion. Furthermore, we provide strong evidence for cross-talk between PKA, extracellular matrix tension, and intracellular calcium (Ca^{2+}) in the regulation of leading edge dynamics and cell migration in OvCA cells. Increased matrix stiffness induces durotactic migration of individual OvCA cells and also promotes the disaggregation of multicellular OvCA spheroids. PKA is rapidly and locally activated by acute increases in matrix tension. PKA activity within the leading edge is blocked by inhibition of the stretch-activated Ca^{2+} channels, including TRPM7. Conversely, inhibition of PKA activity or AKAP function significantly decreases the appearance of Ca^{2+} flickers - leading edge Ca^{2+} transients that are known to be mediated by TRPM7 and play a role in chemotaxis. These data support a hypothesis in which cell-matrix tension locally controls PKA activity, which serves as both a regulator and an effector for stretch-activated Ca^{2+} currents and is important for leading edge dynamics, cell migration, and matrix invasion.

1540

Protein Kinase A activity and anchoring are required for ovarian cancer cell migration and matrix invasion.

A. J. McKenzie[1], A. K. Howe[1]; [1]Pharmacology, University of Vermont, Burlington, VT

Epithelial ovarian cancer (EOC) is the deadliest of the gynecological malignancies, due in part to its clinically occult metastasis. Therefore, understanding the mechanisms governing EOC dissemination and invasion may provide new targets for antimetastatic therapies or new methods for detection of metastatic disease. The activity of the cAMP-dependent protein kinase (PKA) and its subcellular localization by A-kinase anchoring proteins (AKAPs) are important regulators of cytoskeletal dynamics and cell migration. Moreover, the expression of various PKA subunits and certain AKAPs positively correlates with advanced stage and/or more aggressive disease. Thus, we sought to study the role of PKA and AKAP function in both EOC cell migration and invasion. Using the plasma membrane-directed PKA biosensor, pmAKAR3, and an improved migration/ invasion assay, we show that PKA activity is up-regulated at the leading edge of SKOV-3 EOC cells during migration, and that this activity is mediated via anchoring of the RII subunit of PKA. Importantly, we demonstrate that inhibition of PKA activity or anchoring through either RI or RII subunits blocks SKOV-3 cell migration. Furthermore, we show that PKA activity is also up-regulated at the leading edge of EOC cells invading into a three-dimensional extracellular matrix and demonstrate the necessity of PKA activity and anchoring for functional matrix invasion. Specifically, invasive leading edge PKA is mediated specifically through AKAP-RII interaction, while both type I and type II PKA anchoring are required for invasion. These data are the first to demonstrate a requirement for PKA activity and anchoring during matrix invasion and suggest an important role for PKA and AKAPs in EOC metastasis.

1541

The Regulation of RhoA by Stard13 in Focal Adhesions is Essential for Astrocytoma Cell Motility.

B. Khalil[1], S. El-Sitt[1], M. El-Sabban[2], J. Backer[3], M. El-Sibai[1]; [1]Lebanese American University, Chouiran Beirut, Lebanon, [2]American University of Beirut, [3]Albert Einstein College of Medicine

Malignant astrocytomas are associated with high mortality rates. These tumors are highly invasive into adjacent and distant regions of the normal brain rendering them medically unmanageable. Invasion is a multistep process, which ultimately requires the cell to actively migrate through the ECM. Rho-GTPases, mainly RhoA, Rac, and Cdc42, play a major role in the regulation of the processes that ultimately lead to cell migration. StarD13 is a RhoGAP that inhibits the function of RhoA and Cdc42.
Observations: We first aimed at determining the role of RhoA in the progression of astrocytic tumors, a topic that is still controversial in the literature. Looking at the activation of RhoA through the use of a FRET biosensor showed RhoA to localize to the tail as well as to the leading edge of astrocytoma cells undergoing random movement. Our results also showed that knocking down RhoA by siRNA transfection inhibited cell motility. Surprisingly, when we knocked down StarD13 using siRNA we saw an inhibition of cell motility as well. This was mimicked by transfecting the cells with a dominant active RhoA construct. StarD13 mainly localized to adhesion structures, thus RhoA needs to be inhibited at the sites of adhesion. StarD13 knock down cells were unable to move and showed a phenotype of an elongated tail. This showed us that Rho inhibition by StarD13 pays a role in the cell detaching its tail to move forward. Looking at the adhesion structures we also saw complete inhibition of focal complex formation in cells overexpressing active RhoA or where StarD13 was knocked down. This was also mimicked by Rac knock down, showing that StarD13 also inhibits RhoA at the leading edge of cells for Rac to get activated and focal complexes to form.

1542

hDlg Enhances SGEF/RhoG Activity and is Required for Invasion of HPV-18 Transformed Cells.

V. Krishna Subbaiah[1], P. Massimi[1], M. Myers[1], L. Sharek[2], R. Garcia-Mata[2], L. Banks[1]; [1]ICGEB, Trieste, Italy, [2]Department of Cell and Developmental Biology, University of North Carolina

The Discs Large (Dlg) tumour suppressor forms part of a tri-partite multi macromolecular complex that is integral to the regulation of cell polarity and diverse cell signaling pathways. In support of a tumour suppressive potential in human malignancy, expression of Dlg is frequently lost in many late stage cancers, and most intriguingly, it is also a target of the Human Papillomavirus (HPV) E6 oncoprotein, which is an essential viral protein required for the development HPV-induced cervical cancer. We have been interested in understanding why HPV E6 might interact with Dlg during the development of HPV-induced malignancy. Using a proteomic approach we now show that a strong interacting partner of Dlg is the RhoG-specific guanine nucleotide exchange factor SGEF. This interaction involves PDZ and SH3 domain recognition and this directly contributes to the regulation of SGEF cellular localisation. The interaction between Dlg and SGEF appears to be strictly controlled, with increased levels of association detected during active cell migration. Consistent with this, we show that Dlg is a strong enhancer of RhoG activity, which occurs in an SGEF dependent manner. In HPV transformed cells, a significant proportion of Dlg is subjected to proteasome degradation, in an HPV E6 dependent manner. However, we also show that a part of the E6-Dlg complex contributes to maintaining high levels of SGEF and RhoG activity in these cells. Furthermore, this E6-Dlg complex directly contributes to the invasive capacity of these cells, which occurs in an SGEF dependent manner. These studies demonstrate a novel pro-oncogenic activity for Dlg

in HPV induced malignancy, one of the outcomes of which is increased RhoG activity and increased invasive potential.

1543

Essential role of store-operated calcium entry in serum-induced lung cancer cell migration.

J-H. Kim[1,2], J. Kim[2,3], Y. Jeong[2,3], S-K. Cha[1,2]; [1]Physiology, Wonju College of Medicine, Yonsei University, Wonju, Korea, [2]Institute of Lifestyle Medicine, Wonju, Korea, [3]Biochemistry, Wonju College of Medicine, Yonsei University

The Ca^{2+} influx is essential for the migration of various cell types including cancer cells. Orai/STIM proteins mediate store-operated calcium entry (SOCE) which is important for cell migration and proliferation. However, the functional role of SOCE in tumor cell migration remains poorly understood. Here we investigated the molecular mechanism by which store-operated calcium (SOC) channels regulates cellular migration of lung cancer cell line H1693.
Ca^{2+} influx is critical for serum- or growth factor-induced cell migration. We identified that SOCE was increased by treatment of serum and/or diverse growth factors; epidermal growth factor, insulin-like growth factor 1, and platelet-derived growth factor. Interestingly, serum-induced H1693 cell migration was specifically blocked by SOC channel inhibitors such as SKF96365 and 2APB but not by voltage-gated calcium channel inhibitor, nimodipine. We identified expression of isoforms of Orai (1/2/3) and STIM (1/2) proteins in H1693 cells. In particular, serum treatment increased Orai1 mRNA expression. Orai1 is pore-forming unit of Ca^{2+}-release-activated Ca^{2+} (CRAC) channels. Serum treatment enhanced CRAC currents in both H1693 cells and HEK293 cells overexpressing Orai1. This suggests that SOCE might be critical for serum-induced H1693 cell migration.
Serum and growth factors are known to activate both phosphatidylinositol 3-kinase (PI3K)-Akt and/or Erk1/2 pathways. We questioned if the Orai1 associated cell migration is linked to these pathways. Indeed, serum-induced augmentation of SOCE and cell migration was blocked by treatment of wortmanin, a PI3K inhibitor. This data suggest that the serum-PI3K-Akt pathway is critical for SOCE-mediated cell migration. In addition, U0126, an inhibitor of Erk1/2 pathway also reduced serum-induced cell migration and SOCE.
Taken together, this study revealed the signal transduction pathway in lung cancer cell migration that serum and growth factors stimulate the Orai1-mediated SOCE via activating PI3K-Akt and/or Erk1/2 pathway.

1544

A Rab35/Arf6 recycling complex regulates cell adhesion and migration: implications for cancer biology.

P. D. Allaire[1], M. S. Sadr[1], E. S. Sadr[1], S. Konefal[1], R. Del Maestro[1], P. McPherson[1]; [1]Montreal Neurological Institute, Montreal, QC, Canada

Integrins and cadherins control distinct cell adhesion properties leading to functionally opposite consequences. Specifically, integrins mediate migration over the extracellular matrix whereas cadherins mediate cell-cell adhesion, which inhibits migration. How surface expression and activity of these receptors are coordinated remains unclear. Here we uncover a sorting and recycling compartment that efficiently coordinates cadherin and integrin recycling. Cargo sorting through this compartment is defined by the small GTPases Rab35 and Arf6, which are mutually antagonistic. Knock down of Rab35 prevents E-cadherin recycling inhibiting intercellular adhesion, and promotes Arf6 activity, needed to stimulate beta1-integrin-dependent cellular motility. In fact, Rab35 knock down leads to a global increase in beta1-integrin levels, explained by a switch in trafficking that favours recycling over degradation. Furthermore, the activity of the

signalling kinases FAK, Erk1/2 and Akt downstream of beta1-integrin are strongly elevated. The phenotypes observed following Rab35 knock down are consistent with the epithelial-to-mesenchyme transition, and we find that Rab35 expression is significantly suppressed in surgically retracted breast, skin and brain tumors, cancers where Arf6 activity and levels are upregulated. Our data identify a Rab35/Arf6 molecular module that explains how cadherin and integrin trafficking is coordinated. The importance of this module is highlighted by its disruption in cancer.

1545

Phosphoinositide specificity determines which cytohesins promote β1 integrin recycling.

S. Oh[1], L. C. Santy[1]; [1]Pennsylvania State Univ, University Park, PA

Integrin based cell-to-matrix adhesions provide traction to convert contraction to movement during cell migration. Adhesion remodeling, the disassembly and reassembly of attachments to the substratum, is a critical step in cell movement. Remodeling of these adhesions is carried out by internalization and reinsertion of integrins from the plasma membrane. Stimulation of integrin exocytosis can initiate or promote cell migration. ARF small GTPases initiate vesicle budding during trafficking processes. Guanine nucleotide exchange factors (GEFs) are accessory proteins that turn on GTPases. We have recently determined that two closely related ARF-GEFs, cytohesin-2 and cytohesin-3, have opposing effects on stimulated β1 integrin recycling (Oh, S. J. and L. C. Santy (2010) J Biol Chem 285: 14610-14616.). Cytohesin-2 enhances adhesion, spreading and migration while cytohesin-3 inhibits these processes. Furthermore, only cytohesin-2 is required for β1 integrin recycling to the cell surface. We have now determined the specific sequence differences between these highly related proteins that underlie their differential effects on β1 integrin recycling. We have found that the ability of cytohesins to promote β1 integrin recycling to the plasma membrane depends upon the phosphoinositide specificity of their PH domains. Cytohesin-3 has 2 glycine residues at a critical point in its PH domain and therefore binds with high affinity and specificity to PI-(3,4,5)P_3. Cytohesin-2 on the other hand has 3 gylcine residues at this position and binds with lower and equivalent specificity to both PI-(3,4,5) $_3$ and PI-(4,5)P_2 (Klarlund, J. K. et. al. (2000). J Biol Chem 275: 32816-32821). Switching the number of glycines in the PH domains of cytohesin-2 and cytohesin-3 is sufficient to reverse their effects on adhesion and spreading. Furthermore cytohesin-3 with three rather than two glycine residues in its PH domain can promote β1 integrin recycling. We conclude that phosphoinositide specificity is the sole determinant of which cytohesins can promote recycling of β1 integrin recycling.

1546

R-Ras on recycling endosome membranes is transported to plasma membrane ruffles by endosomal trafficking which requires geranylgeranylation, microtubules and R-Ras activation.

J. G. Wurtzel[1], L. E. Goldfinger[1]; [1]Anatomy & Cell Biology, Temple University School of Medicine, Philadelphia, PA

R-Ras, a member of the Ras family of small G proteins, has distinct cellular functions from K-, H-, and N-Ras; in particular, R-Ras regulates cell spreading and motility through unique signaling pathways. Recently, an activated pool of R-Ras was localized to the membranes of recycling endosomes (REs), specialized tubulo-vesicular organelles involved in receptor recycling and secretory pathways. An important function of REs is delivery of pro-migratory signaling cargo and membranes to the leading edge in migrating cells. In addition to REs, activated R-Ras has also been localized to plasma membrane ruffles at the leading edge, important cellular components participating in forward motility. We investigated a putative role of

REEs in R-Ras sub-cellular targeting. REs containing R-Ras aligned along microtubules, and microtubules were required for R-Ras-dependent cell spreading. Disruption of microtubules with nocodazole dispersed R-Ras vesicles from tubule-vesicle arrays to diffuse cytosolic patterns. We used real-time live cell confocal microscopy coupled with a fluorescence recovery after photobleaching (FRAP) scheme to track the dynamics of REs containing red fluorescent protein (RFP) fusions of R-Ras alongside GFP-Rab11, a marker for REs, in randomly migrating cells. Wild type R-Ras, R-Ras harboring a mutation rendering it constitutively active (38V), and dominant negative R-Ras (43N) all localized to Rab11-positive REs and additional Rab11-negative endosomal structures, as well as at the Golgi, and were concentrated at the endosomal membranes – this phenomenon could be more easily observed in live cells as opposed to fixed cells in which many of the endosomes are often collapsed and appear as dense puncta. R-Ras vesicles appeared to undergo dynamic sorting in the vicinity of the Golgi. In the cytosol, wild type and activated R-Ras engaged in anterograde trafficking in saltatory fashion towards the leading edge on both Rab11-positive and -negative vesicles in migrating cells. FRAP analysis demonstrated that wild type and activated R-Ras vesicles contributed to multi-phasic recovery of bleached fluorescence (subtracting recovery by diffusion) in zones anterior to the nucleus, with continual vesicle-derived peaks at 2.07 ± 0.15 peaks/min. These vesicles appeared in most cases to pause as they reached the actin-dense lamellipodia, and smaller R-Ras structures emerged from these vesicles and continued trafficking to the leading edge, where R-Ras concentrated in membrane ruffles. R-Ras was also recycled in Rab11-negative vesicles from the ruffles and trafficked in retrograde fashion towards the Golgi. Vesicles containing inactive R-Ras(43N) oscillated and also reached the plasma membrane, but with significantly slower dynamics, and these cells had many fewer membrane ruffles. Nocodazole halted R-Ras anterograde traffic, significantly delayed FRAP recovery times with diminished peak intensities, and prevented R-Ras from reaching ruffles. In addition, activated R-Ras mutated at C215 to serine, preventing geranylgeranylation of R-Ras, sequestered R-Ras diffusely in the cytosol, thus eliminating vesicle-derived FRAP recovery, and this R-Ras variant was completely absent from ruffles. However, R-Ras-negative Rab11 endosomes trafficked normally. Thus, we have described a mode of sub-cellular targeting for the pro-migratory protein R-Ras: R-Ras is targeted to the plasma membrane and ruffles by trafficking in endosomal vesicle membranes with the aid of microtubules, in a manner which requires R-Ras geranylgeranylation for membrane anchorage, and R-Ras activity to permit vesicle trafficking. This distinct mechanism of R-Ras targeting likely contributes substantially to its unique signaling and cellular functions.

1547

MARCKS phosphorylation relies on PKC isoform delta(δ) in human neutrophils.

E. Sung[1], K. B. Adler[2,3], S. L. Jones[1,3]; [1]Clinical Sciences, North Carolina State University, Raleigh, NC, [2]Molecular Biomedical Sciences, North Carolina State University, Raleigh, NC, [3]Center for Comparative Medicine and Translational Research, North Carolina State University

MARCKS (Myristoylated alanine-rich C kinase substrate) is a PKC (Protein Kinase C) substrate that is involved in mucin and neurosecretion, postnatal survival and regulation of cell morphology and migration. In most cell types, MARCKS is associated with the cell membrane in the resting state and is translocated into the cytosol when it is phosphorylated by PKC.
We previously determined that MARCKS plays an important role in neutrophil migration and adhesion using a cell permeant peptide derived from the MARCKS myristoylated aminoterminus (MANS). To unravel how MARCKS phosphorylation affects neutrophil migration and adhesion, we identified the PKC isoforms involved in MARCKS phosphorylation. We tested PKC isotypes alpha (α), beta (β), delta (δ), and zeta (ζ), known to be present in human neutrophils, using specific PKC isotype inhibitor Go6976, CG53353, rottlerin and ζ pseudosubstrate, respectively.

Human neutrophils were pretreated with inhibitors and MARCKS phosphorylation was measured after stimulation of cells with fMLF. Pretreatment of neutrophils with the pan-PKC inhibitor staurosporin blocked fMLF induced MARCKS phosphorylation in a dose dependent manner, as did specific inhibition of PKC delta; but other PKC isoforms including alpha, beta and zeta did not affect MARCKS phosphorylation. The IC50 of staurosporin and rottlerin were 1.43 μM and 8.14 μM respectively for the fMLF induced MARCKS phosphorylation. Subcellular fractionation assay showed that the PKC isotype delta, but not others, translocated from cytosol to membrane in response to fMLF and PMA stimulation. These results suggest that PKC delta plays a crucial role in fMLF induced MARCKS phosphorylation in human neutrophils.

1548

Comparative Analysis of Light-stimulated Motility Responses in Diatoms.

S. A. Cohn[1], Y. Zapata[1], M. J. McLaughlin[1]; [1]Biological Sciences, DePaul University, Chicago, IL

Our lab is continuing to study the effects of light irradiation on diatom motility. Our results indicate that the orientation of diatom movement shows light sensitivity, to both irradiance levels and wavelength, that is characteristic for each species. By measuring the time for the leading and trailing ends of the cells to respond to rapid (1 sec) light irradiations, we have been able to compare the responses of three diatom species (*Craticula cuspidata*, *Stauroneis phoenicenteron*, and *Pinnularia viridis*). In contrast to the *Craticula* and *Stauroneis* cells, the *Pinnularia viridis* cells show virtually no sensitivity to red light (650 nm) irradiations. In comparison, at moderate light levels *Craticula cuspidata* are stimulated by light irradiations to move into blue light (450 nm) at moderate light levels while stimulated to move out of red light at the same levels. The *Stauroneis* cells show the strongest sensitivity to red light, showing an stimulated movement into red light even at very dim levels. These light-stimulated movements appear to be regulated by differential responses at the leading and trailing end of the diatom cells. For example, with 1 sec irradiations of high irradiations (10^5 μmol/m^2s) of blue light, the leading end of *Craticula* cells will change direction in 17±1 sec, while the trailing end has no response at all (161 ± 8 sec, compared to unirradiated control response times of 135 ± 7 sec), leading to an “out of the light” response. Such irradiations with more moderate blue light (attenuated with 1.0 OD neutral density filters) shows a faster response time with the trailing end (41 ± 4 sec) than the leading end (79 ± 11 sec) giving rise to an “into the light” response. Similar irradiations on *Craticula* with moderate level red light shows a continued “out of light” response (81 ± 9 sec response for leading end; 117 ± 14 sec response for trailing end). In contrast *Pinnularia* cells show virtually no red responsiveness at any light level, while *Stauroneis* cells shows a strong “into the light” response at low red light levels (198 ± 18 sec response for leading end; 115 ± 12 sec response for trailing end). Moreover, light irradiations on *Craticula cuspidata* and *Pinnularia viridis* show that the blue light irradiations not only stimulate direction changes but also repress further direction changes in the cell for 15-60 sec, helping to reinforce the light-directed changes. Such studies allow us to better understand the regulation of single-celled algae in establishing and maintaining healthy aquatic ecosystems. This work was supported by DePaul University Research Council, the DePaul College of Liberal Arts & Sciences, and equipment purchased through NSF Grant IBN-9982897.

Activation of sperm motility by a seminal fluid protease in *C. elegans.*

J. R. Smith[1], A. A. Hansen[1], C. Chong[2], M. C. Jud[1], G. M. Stanfield[1]; [1]Department of Human Genetics, University of Utah, Salt Lake City, UT, [2]Huntsman Cancer Institute, University of Utah

Sperm motility is controlled to promote the ability of sperm to navigate through the reproductive tract and fertilize an egg. In *C. elegans*, sperm move by crawling and their motility is acquired during a process termed activation, in which immotile round spermatids reorganize to become motile, polarized spermatozoa. Both males and hermaphrodites make sperm, and activation must be triggered at the appropriate time for each sex, or fertility suffers. Although activation is readily induced by a variety of treatments in vitro, the signals that trigger activation in vivo have been elusive. We have identified a serine protease, TRY-5, that is a component of seminal fluid and is required for sperm activation by *C. elegans* males. While misregulation of TRY-5 within males leads to premature activation, males lacking TRY-5 do not transfer activator and must rely on signals from the hermaphrodite to activate their sperm. TRY-5 is expressed in secretory cells of the male somatic gonad, and a TRY-5::GFP reporter is transferred along with sperm during mating. Thus, TRY-5 is a seminal fluid factor that couples the onset of motility in sperm to their transfer to a hermaphrodite. We propose that TRY-5 triggers activation by cleaving proteins on the sperm surface, and we are searching for sperm proteins that may be targets of TRY-5. We have identified a candidate for such a factor: the SLC6 family transporter SNF-10. Sperm lacking SNF-10 fail to activate in response to protease either in vitro or in vivo. Curiously, they show enhanced response to other activators. Thus, analysis of TRY-5 and SNF-10 may reveal how sperm cells integrate a variety of signals from their environment to ensure functional motility.

1550

Poly(vinylmethylsiloxane) elastomer networks as functional materials for cell adhesion and migration studies.

S. Ahmed[1], H-K. Yang[1], J. Genzer[1], J. M. Haugh[1]; [1]North Carolina State University, Raleigh, NC

Cell migration is central to physiological responses to injury and infection and in the design of biomaterial implants. The ability to tune the properties of substrate and relate those properties quantitatively to the dynamics of intracellular processes remains a definite challenge in the manipulation of cell migration. Poly(vinylmethylsiloxane) (PVMS) networks, a novel substrata for cell adhesion and migration, offers the ability to tune chemical functionality and elastic modulus independently. Importantly, PVMS networks are compatible with total internal reflection fluorescence (TIRF) microscopy, which is ideal for interrogating the cell-substratum interface; this latter characteristic presents a distinct advantage over polyacrylamide gels and other materials that swell with water. In addition, a higher ligand density can be achieved using a polymer brush-based approach, which potentially offers better control in making substrates with gradients of mechanical and chemical properties. To demonstrate these capabilities, different adhesive peptides were successfully grafted to the surface of PVMS network. Peptide-specific adhesion, spreading, and random migration of NIH 3T3 mouse fibroblasts show that presence of the synergy sequence (PHSRN) along with the binding motif (RGD) of fibronectin in peptide promotes more productive cell migration without markedly enhancing cell adhesion strength. Using TIRF microscopy, signal transduction dynamics through the phosphoinositide 3-kinase pathway were monitored in cells as they migrated on peptide-grafted PVMS surfaces. These approaches offer a promising avenue for studies of directed migration and mechanotransduction at the level of intracellular processes.

Cadherins and Cell-Cell Interactions

1551

E-cadherin-mediated cell-in-cell formation by compartmentalized Rho activity.

Q. Sun[1], M. Overholtzer[1]; [1]Cell Biology Program, Memorial Sloan-Kettering Cancer Center, New York, NY

Adherens junctions are major cell adhesion complexes that organize epithelia by coordinating cytoskeletal tension between neighboring cells. Dysregulation of adherens junctions is frequent in human tumors, and E-cadherin and alpha-catenin are tumor suppressors that can limit proliferation and inhibit invasion. Recently a mechanism of cell death was described, called entosis, which involves adherens junction-mediated engulfment of live cells. The cell structures formed by entosis directly resemble live cell engulfments found in human cancers, which are commonly referred to as ¡°cell-in-cell¡± or cell cannibalism. Here we find that the expression of epithelial cadherins in cancer cells correlates with their ability to form cell-in-cell structures, and introduction of E- or P-cadherin to tumor cells lacking expression is sufficient to induce cell-in-cell formation, which results in the death of internalized cells. We further show that imbalanced RhoA/ROCK signaling between cells underlies cell-in-cell formation, as actomyosin contraction at the cortex of internalizing cells, distal to E-cadherin, drives their engulfment, and cells with higher RhoA activity tend to be engulfed. Moreover, overexpression of another GTPase, Rac1, is able to transform cells into engulfers by inhibiting RhoA/ROCK activity. Mechanistically, junction-localized p190 RhoGAP is required for compartmentalizing Rho activity within and between cells. Finally, we show that E-cadherin-mediated cell-in-cell formation inhibits transformed growth in vitro. Together, these data demonstrate that cell cannibalism in human breast tumors may result from abnormal cell adhesion, which may underlie a heretofore unrecognized mechanism of tumor suppression by epithelial cadherins.

1552

Rapid Suppression of Activated Rac1 by Cadherins and Nectins during *De Novo* Cell-Cell Adhesion.

K. N. Kitt[1], W. J. Nelson[1]; [1]Biology, Stanford University, Stanford, CA

Cell-cell adhesion in simple epithelia involves the engagement of E-cadherin and nectins, and the reorganization of the actin cytoskeleton and membrane dynamics by Rho GTPases, particularly Rac1. However, it remains unclear whether E-cadherin and nectins up-regulate, maintain or suppress Rac1 activity during cell-cell adhesion. Roles for Rho GTPases are complicated by cell spreading and integrin-based adhesions to the extracellular matrix that occur concurrently with cell-cell adhesion, and which also require Rho GTPases. Here, we designed a simple approach to examine Rac1 activity upon cell-cell adhesion by MDCK epithelial cells, without cell spreading or integrin-based adhesion. Upon initiation of cell-cell contact in 3-D cell aggregates, we observed an initial peak of Rac1 activity that rapidly decreased by ~66% within 5 minutes, and further decreased to a low baseline level after 30 minutes. Inhibition of E-cadherin engagement with DECMA-1 Fab fragments or competitive binding of soluble E-cadherin, or nectin2alpha extracellular domain completely inhibited Rac1 activity. These results indicate that cadherins and nectins cooperate to induce and then rapidly suppress Rac1 activity during initial cell-cell adhesion, which may be important in inhibiting the migratory cell phenotype and allowing the establishment of initially weak cell-cell adhesions. Future studies aim to investigate the GEFs and GAPs involved in establishing and maintaining initial cell-cell adhesion.

1553

Cell contact localized β-actin translation is required for E-cadherin anchoring during adherens junction assembly.

N. Gutierrez[1], I. Eromobor[1], A. J. Rodriguez[1]; [1]Rutgers Univ-Newark, Newark, NJ

Adherens junctions are multi-protein complexes critical during development for cell sorting and establishment of tissue polarity. Previously we demonstrated that *de novo* protein synthesis is required for adherens junction assembly by treating MDCK cells with the translational inhibitors, cycloheximide or puromycin following cell contact. Moreover, we demonstrated contact-localized β-actin translation was correlated with increased contact-localization of N-cadherin in myoblast cells. In contrast, mislocalization of β-actin translation sites reduced cellular polarity and decreased contact-localization of N-cadherin in myoblast cells. The objective of this project was to test the extent to which the location of β-actin translation sites correlated with sites of E-cadherin anchoring at epithelial cell contacts. MDCK cells stably expressing plasmids containing either the β-actin FL or β-actin without its zipcode sequence (Δ zipcode) were grown as monolayers and cell contact was stimulated using the calcium switch method. Pearson's correlation analysis of colocalization was used to quantify the extent of colocalization between E-cadherin and β-actin +/- zipcode at cell contact sites and within the cytoplasm. MDCK cells expressing full-length β-actin exhibited colocalization between E-cadherin and β-actin at cell contact sites following the calcium switch. By contrast, cells expressing Δ zipcode β-actin failed to reform a monolayer and had reduced colocalization between E-cadherin and β-actin. During wound-healing assays, Δ zipcode β-actin expressing cells failed to repair the wound which correlated with a reduced velocity of cell migration relative to MDCK cells expressing full-length β-actin. These results demonstrate that contact-localized β-actin translation is required for cadherin anchoring during the assembly of epithelial adherens junction complexes.

1554

A novel proteolytic processing of talin is associated with cadherin-mediated cell-cell adhesion.

F. Zhang[1], A. Kashina[1]; [1]Animal Biology, University of Pennsylvania, Philadelphia, PA

Talin is an essential cell adhesion molecule that plays a key role in integrin-mediated cell adhesion to the extracellular matrix, but has never been found to be involved in cadherin-mediarted cell-cell adhesions. Talin is a large rod-like molecule that scaffolds multiple components of the actin cytoskeleton. It is regulated by limited calpain-mediated proteolysis with a release of its N-terminal regulatory domain during integrin adhesion maturation and turnover. Other types of cleavages in vivo with functional significance have not been reported. Here we studied talin regulatory proteolysis in response to changes in cell density and found that the formation of cell-cell adhesions in a dense culture is accompanied by calpain-dependent generation of a novel 70 kDa talin fragment, which partially co-localizes with cadherin and accumulates in a dose-dependent manner in cells establishing cell-cell adhesions. Analysis of arginyltransferase (Ate1) knockout cells deficient in cell-cell adhesions revealed that these cells have little or no 70 kDa talin fragment, suggesting that arginylation knockout inhibits this fragment's generation, which in turn may be responsible for the adhesion defects in these cells. Phentype rescue experiments showed that reintroduction of the 70 kDa talin fragment into Ate1 knockout cells rescues their cell-cell adhesion defects, and that arginylation of this fragment further enhances the rescue effect in addition to regulating its turnover. Thus, we have discovered a novel proteolytic cleavage of talin that participates in its novel function in cadherin-mediated cell-cell adhesion and is regulated by a multi-level mechanism that involved cell density, calpain, and arginylation.

1555

Dissecting the Roles of Desmosomal Cadherins in Cell-Cell Adhesion and Epithelium Remodeling.

M. Lowndes[1], N. Borghi[2], W. J. Nelson[1,2]; [1]Cancer Biology Program, Stanford University, Stanford, CA, [2]Biology, Stanford University

During normal development, tissue regeneration and cancer, epithelia undergo dramatic morphogenetic processes, ranging from cohesive sheet migration, cell position changes within cohesive tissues, to individual cell migration after dissociation from tissues. Such cell movements require coordination between cell migration and intercellular adhesion. In epithelial cells, there are two types of intercellular adhesion complexes that involve the *trans*-membrane protein cadherin superfamily: desmosomes and adherens junctions (AJs). AJs contain E-cadherin, a classical cadherin that mediates intercellular adhesion by forming homotypic bonds between neighboring cells. Desmosomes, however, contain multiple isoforms of two types of cadherins (desmocollin/dsc and desmoglein/dsg). Mis-expression of desmosomal cadherin isoforms within the epidermis (a specialized epithelium) compromises tissue integrity. How different desmosomal cadherins form bonds within desmosomes and ultimately contribute to intercellular adhesion - thereby regulating cell migration and tissue integrity - is unknown. To understand desmosomal cadherin functions, we studied desmocollin and desmoglein recruitment and epithelial cell motile behavior by TIRF and live-cell microscopy on epithelial cells adhering to substrates patterned with alternating stripes of desmosomal cadherins and collagenIV. We find that cells assemble desmosomes on the substrate's patterns that are functionalized with dsc or both dsg and dsc, but not dsg alone. Additionally, cell adhesion to surfaces functionalized with dsc or dsc/dsg decreases the rate of cell migration. To address how desmosomal cadherins interact, we engineered a W2A mutation; the W2 is important for *trans*-binding of classical cadherins. The W2A mutation in desmocollin affects protein localization and turnover; DscW2A localizes in punctate spots at nascent cell-cell contacts similar to wild type protein, but within a few hours DscW2A staining becomes diffusely distributed throughout the plasma membrane and is highly mobile, as assessed by FRAP. Preliminary results suggest that there is increased lamellipodia activity in cells expressing DscW2A. Interestingly, the W2A mutation in desmoglein does not have a significant effect on adhesion or localization of DgW2A. These results show that desmocollin and desmoglein have unique binding properties, resulting in differences in their recruitment and stability at cell-cell contacts, and changes in collagenIV-based cell migration. Thus modulation of desmosomal cadherin interactions during development and cancer may contribute to the regulation of morphogenetic cell movements.

1556

M-Cadherin-mediated signaling attenuates GSK-3ß-dependent ß-catenin phosphorylation and promotes myogenic differentiation.

Y. Wang[1], S. E. Alway[1]; [1]West Virginia University, Morgantown, WV

β-catenin is an essential molecule in both cadherin-mediated cell-cell adhesion and canonical Wnt signaling. The phosphorylation of β-catenin by GSK-3β at residues Ser33/37/Thr41 regulates its stability and its role in Wnt signaling. Previously we reported that M-cadherin-mediated signaling protects myoblasts against apoptosis and promotes myogenic differentiation by suppressing GSK-3β activation. In this study, we further investigated if the GSK-3β-dependent phosphorylation of β-catenin will be regulated by M-cadherin and if this regulation mediates M-cadherin's role in promoting myogenic differentiation. We demonstrated that knockdown of M-cadherin expression in C2C12 myoblasts by RNA interference(RNAi) significantly decreased the protein abundance of serine37/Thr41-unphosphorylated β-catenin. M-cadherin RNAi also impaired the myogenic and fibrotic induction by LiCl treatment, which is

an established activator of canonical Wnt signaling. Knockdown of β-catenin expression in C2C12 myoblasts by RNAi also significantly impaired myogenic induction by LiCl treatment. On the other hand, forced expression of phosphorylation-resistant mutant form of β-catenin(S33Y-β-catenin) alone failed to induce myogenesis but partially rescued the phenotype caused by M-cadherin RNAi. We concluded that M-cadherin-mediated signaling attenuates β-catenin phosphorylation at Ser37/Thr41 by GSK-3β and thus has a positive effect on canonical Wnt signaling. Our findings provide a novel mechanism on M-cadherin's role in promoting myogenic differentiation.

1557

Kinesin-1 and Kinesin-2 Mediate Transport of the Desmosomal Cadherins, Desmoglein 2 and Desmocollin 2, and are Required for Keratinocyte Cell-Cell Adhesion.

O. Nekrasova[1], E. Amargo[1], G. Kreitzer[2], K. Green[1,3]; [1]Department of Pathology, Northwestern University, Chicago, IL, [2]Weill Medical College of Cornell University, New York, NY, [3]Department of Dermatology and the R.H. Lurie Cancer Center, Northwestern University, Chicago, IL

Desmosomes are intercellular junctions that appeared late in the evolution of multicellular organisms, and their proper assembly and function are critical for the morphogenesis and mechanical integration of tissues such as skin and heart. The desmosomal adhesive core contains two types of cadherin, desmogleins (Dsgs) and desmocollins (Dscs), both of which are required for desmosome function. However, mechanisms that coordinate desmosomal cadherin trafficking into intercellular junctions to regulate their proper ratio and distribution are unknown. Using live cell imaging we show that Dsgs and Dscs exhibit long range microtubule-dependent transport in epithelial keratinocytes but utilize distinct motors to traffic to the plasma membrane. Inhibition of kinesin-1 by gene silencing or expression of dominant negative (DN) kinesin heavy chain (KIF5) mutants completely blocked transport of vesicles containing Dsg2, resulting in a significant decrease in Dsg2 at cell-cell interfaces. By contrast, inhibition of kinesin-2 function with silencing of KIF3A or KAP3 (kinesin-2 associated protein) or by expression of DN KIF3A blocked transport of Dsc2 and reduced its localization on the plasma membrane without affecting Dsg2 trafficking. In biochemical interaction assays, we found that 14-3-3□ coimmunoprecipitated in a complex with kinesin-1 and Dsg2. Furthermore, 14-3-3□ silencing inhibited Dsg2 accumulation at the plasma membrane, suggesting this scaffolding protein regulates Dsg2 assembly into desmosomes through interaction with kinesin-1. Using a mechanical dissociation assay, we showed that either kinesin-1 or -2 deficiencies weakened intercellular adhesion by ~30- fold, despite the maintenance of adherens junctions and other desmosome components at the plasma membrane. Differential regulation of desmosomal cadherin transport could provide a mechanism to "tailor" adhesion strength during tissue morphogenesis and remodeling.

1559

P-cadherin is a direct Pax3-FOXO1A target involved in myoblast transformation and invasiveness of alveolar rhabdomyosarcoma.

S. Thuault[1], J. Cantaloube[1], S. Hayashi[2], C. Plutoni[1], F. Comunale[1], O. Delattre[3], F. Relaix[2], C. Gauthier-Rouviere[1]; [1]CRBM, CNRS, Montpellier, France, [2]UPMC, CNRS, PARIS, France, [3]U 830, INSERM

Alveolar rhabdomyosarcoma (ARMS) is an aggressive childhood cancer of striated muscle characterized by a chromosomal translocation which generates the chimeric oncogenic transcription factor Pax3-FOXO1A. Identification of Pax3-FOXO1A targets is therefore important to understand pathogenesis of RMS. Analysis of transcriptomic data sets of RMS samples

revealed that P-cadherin is correlated to Pax3-FOXO1A and Pax7-FOXO1A. Using ARMS cells, we showed that expression of Pax3 dominant negative construct inhibits expression of P-cadherin. Analysis of P-cadherin expression during mouse embryonic development revealed that it is expressed in epaxial dermomyotome. Using transgenic mouse embryo, we demonstrated that P-cadherin lies genetically downstream from Pax3. In vitro gel shift experiments and chromatin immunoprecipitation with ARMS cell extracts, show that the P-cadherin gene is a direct target for Pax3-FOXO1A through a conserved 160 bp sequence located -2kb from the transcription start site. We then assessed the role of P-cadherin in the development of RMS and showed that P-cadherin expression in normal myoblast results in myogenesis inhibition and induces myoblast transformation, migration and invasion. Conversely, inhibition of P-cadherin expression by small hairpin RNA decreases the transformation, migration and invasive potential of ARMS cells. Finally, as cadherin switching is a hallmark of metastatic progression, we analyzed if P-cadherin impacts on other skeletal muscle cadherin expression. We showed that P-cadherin controls N- and M-cadherin expression and/or localization in myoblasts and ARMS cells.
Our results show that P-cadherin is a direct Pax3-FOXO1A transcriptional target involved in transformation, migration and invasion of ARMS cells. Therefore, P-cadherin emerges as a new and attractive target for therapeutic intervention in this aggressive rhabdomyosarcoma.

1560

Flotillins are new cadherin partners that control cadherin stabilization and the formation of adherens junctions.

E. Guillaume[1], S. Bodin[1], F. Comunale[1], C. Gauthier-Rouviere[1]; [1]CRBM, CNRS, Montpellier, France

Cadherins are essential in many fundamental processes such as tissue patterning during development, growth control during tumorigenesis, and in the maintenance of adult tissue architecture. At regions of cell-cell contact, cadherins assemble into large macromolecular complexes named adherens junctions. Full knowledge of proteins associated with cadherins is far from complete. Here we identify flotillin 1 and 2 as new partners of cadherins required for their stabilization at the cell-cell contacts. Flotillin 1 (Flot 1 ou reggie-2) and flotillin 2 (Flot 2 ou reggie-1) are ubiquitous and highly conserved proteins, located at the cytoplasmic face of the plasma membrane (PM), involved in the scaffolding of large complexes that signal across the PM thanks to their ability to form hetero-oligomeric complexes. The intracellular domain of cadherin appears not to be involved in the association with flotillins. Therefore, flotillins being proteins localized to the cytoplasmic face of the PM, this association is likely to be indirect. We initially identified flotillin 1 as a novel N-cadherin associated protein, by immunoprecipitation followed by mass spectrometry. We extended this association to cadherin N, E, , P, R and 11 indicating that flotillins probably associate with all classical cadherins. Knockdown of flotillins dramatically affect N- and E-cadherin recruitment at adherens junctions in both mesenchymal and epithelial cell types. At the molecular level, we show that in contacting cells, flotillins stabilize cadherins at the PM and prevent their degradation, by strengthening the coupling to p120 catenin, one of the main cadherin stabilizing partners. In conclusion, we report here for the first time, that flotillins are major regulators of cadherin assembly and stabilization at cell-cell contacts and are thus essential for the formation of adherens junctions.

1561

Biochemical Characterization of αE-Catenin Phospho-Mutant Conformations and Functions.

W. J. Nelson[1], A. V. Kwiatkowski[1]; [1]Biology, Stanford University, Stanford, CA

αE-Catenin binds and bundles F-actin, and binds the cadherin/β-catenin cell-cell adhesion complex. Although it is assumed that αE-catenin links F-actin to the cadherin complex to regulate cell-cell adhesion, biochemical studies of mammalian αE-catenin show that it forms a monomer that binds cadherin/β-catenin but not F-actin, and a dimer that binds strongly to F-actin but not the cadherin/β-catenin complex. It has been suggested that the local concentration of αE-catenin in the cytoplasm (~0.5μM) is sufficient for dimerization of monomers that dissociate from the cadherin complex, yet how the conformation of αE-catenin monomers and dimers affects ligand binding and how dimers are derived from monomers are poorly understood. Clues to a possible regulatory mechanism comes from a proteomic analysis of different mouse tissues that mapped phospho-serine and -threonine residues in a non-α-helical domain between the "Head" and "Tail" domains of αE-catenin: ^{631}MIR**T**PEELDD**S**DFE**T**EDFDVR**S**R**TS**VQ**T**EDD^{661}. Interestingly, these sites are not conserved in species in which α-catenin does not form a dimer (*C. elegans*, *Dictyostelium*). The 7 serine/threonine residues in this region were mutated to alanine (αEcat7A; phospho-null) or glutamatic acid (αEcat7E; phospho-mimic), and the properties of mutant proteins were compared with wild-type αE-catenin (αEcatwt). Like αEcatwt, αEcat7A and αEcat7E formed monomers and dimers in solution. Limited proteolysis showed that αEcatwt and αEcat7E were conformationally similar, although the rates of proteolysis were different. In contrast, αEcat7A monomer and dimer generated similar patterns of proteolysis, that were most similar to those of αEcatwt dimer, indicating that the conformation of αEcat7A monomer was altered to the dimer state. αEcatwt and αEcat7A monomers were rapidly (<2min) converted to dimers at 0°C or 37°C at low concentrations (>0.3 μM), but αEcat7E monomers converted to dimers only at 37°C and at higher concentrations (1-2 μM). αEcatwt, αEcat7E and αEcat7A had similar distributions at MDCK cell-cell contacts, and current studies are investigating protein dynamics. These data show that mutations in these serine and threonine residues in αE-catenin have subtle effects on protein conformation (αEcat7A monomers and dimers have a similar conformation), and dimerization (αEcat7E dimerization is slower and requires a higher protein concentration than αEcatwt or αEcat7E). We speculate that these changes may be important in dynamic control of αE-catenin functions (dimerization, F-actin binding) at the plasma membrane.

1562

Cadherin-23 mediates heterotypic adhesion between tumor cells and stromal fibroblasts and may represent a key initial step in the metastatic cascade.

M. Apostolopoulou[1], L. Ligon[1]; [1]Rensselaer Polytechnic Institute, Troy, NY

Adhesive contacts between invading tumor cells and stromal fibroblasts have been previously observed in cancer pathology samples, but little was known about the molecular identity or function of these heterotypic adhesions. Here we have shown that an atypical cadherin, cadherin-23, is expressed by both the weakly metastatic MCF-7 breast cancer epithelial cells and by normal breast fibroblasts. When these two cell types are grown together in a co-culture model of the tumor microenvironment, cadherin-23 is recruited to sites of heterotypic adhesion. Adhesion assays with inhibitory antibodies to cadherin-23 or after RNAi of cadherin-23 suggest that this adhesion protein is significantly responsible for mediating heterotypic adhesion between tumor cells and stromal fibroblasts. This was particularly surprising as this cadherin with 27 extracellular cadherin domains and an atypical cytoplasmic domain is unlike the type I cadherins typically associated with cell-cell adhesion, and to date, has only been described in

the neurosensory epithelium. However, we find that cadherin-23 is expressed in normal human breast ductal epithelial cells, and is unregulated in both the epithelial cells and the surrounding stroma in cancer tissue samples in a pattern that suggests it may play a role in mediating the tumor-stroma interactions that initiate the metastatic cascade.

1563

Regulation of collective cell invasion of prostate cancer cells by N-cadherin.

Y. Cui[1], A. Blee[1], S. Yamada[1]; [1]Biomedical Engineering, University of California, Davis, Davis, CA

In the United States, prostate cancer is the second leading cause of cancer death in men with a death rate of 1 in 36 prostate cancer patients (American Cancer Society, 2010). This is partly due to recurrence of metastasized cancer after surgery, radiation or androgen deprivation therapy. The dissemination of cancer cells significantly decreases the patient survival rate. Thus, the importance of finding a way to fight metastatic cancer cannot be overstated. However, little is known about how cancer cells invade and initiate metastasis. Using a highly invasive prostate cancer cell line (PC3), we sought to investigate the mechanisms by which prostate cancer cells invade in a three-dimensional (3D) Matrigel. We found that prostate cancer cells did not migrate as single isolated cells, but rather, migrated persistently as multi-cellular clusters in a single file. These data suggest that cell-cell adhesion may promote collective migration. Immunostaining showed that N-cadherin and actin co-localized at cell-cell contacts, suggesting that N-cadherin junctions mediate collective cell invasion. Furthermore, the addition of purified N-cadherin extracellular domain inhibited collective cell invasion in 3D Matrigel, but the purified cadherin-11 extracellular domain did not. In addition, the presence of purified N-cadherin extracellular domain significantly decreased the speed of single cell migration on a 2D surface. Therefore, N-cadherin may regulate cell-cell adhesion between prostate cancer cells as well as cell migration potential of prostate cancer cells. Understanding the regulation of N-cadherin mediated collective cell migration will define unique therapeutic targets to effectively minimize cancer cell invasion, and therefore, metastasis.

1564

The Roles of N-cadherin in Three-dimensional Cell Invasion.

W. Shih[1], S. Yamada[1]; [1]Biomedical Engineering, University of California, Davis, Davis, CA

Almost 80% of cancer originates from epithelial tissue. The high mortality rate of epithelial derived cancer is partly due to the ability of tumor cells to migrate away from the initial growth site and metastasize. To metastasize, cancer cells are thought to undergo a transformation in which they lose typical epithelial cell-cell junctions and develop an invasive phenotype. Surprisingly, some invasive cancer cells appear as a multi-cellular linear cluster, and often highly aggressive cancer cells up-regulate neural (N)-cadherin cell adhesion protein, but we know very little about the roles of N-cadherin in cancer cell interactions and migration. To gain a mechanistic understanding of cancer cell invasion, we analyzed the cell adhesion between invasive, transformed epithelial cells in a three-dimensional (3D) collagen matrix. Transformed epithelial cells were transfected with shRNA specific to N-cadherin, and the N-cadherin knockdown cells were transfected with N-cadherin mutants for phenotype rescue experiments. Using 3D cell invasion assays, transformed epithelial cells formed elongated multi-cellular structures, and migrated as a collective unit. The individual cells in cell clusters migrated faster and more persistently than single cells in isolation. Calcium depletion by EDTA treatment caused the multi-cellular cluster to dissociate and induced membrane extensions in resulting single cells. Furthermore, depletion of N-cadherin disrupted cell-cell contacts and these N-cadherin deficient cells no longer migrated as a collective unit, suggesting that N-cadherin is

required for calcium dependent cell-cell adhesion and multi-cellular invasion. Interestingly, the ectopic expression of the N-cadherin cytoplasmic domain enhanced the formation of membrane extensions in N-cadherin knockdown cells, but could not rescue multi-cellular cluster formation or coordinated migration. In contrast, ectopic expression of the extracellular domain of N-cadherin resulted in the formation of small clusters. Our data suggest that the cytoplasmic signaling of N-cadherin induces membrane extensions while the presence of N-cadherin mediated cell junctions may suppress membrane extensions. This unique role of N-cadherin may distinguish the leader cells that form membrane extensions at the free leading edge, apart from the follower cells with N-cadherin junctions that suppress membrane extensions. Together, our findings suggest that the extracellular and cytoplasmic domains of N-cadherin play an important role in regulating membrane extensions, cell cluster formation, and collective migration, thus N-cadherin up-regulation may be the key requirement for metastasis.

1565

Effects of Neural Cells on the Expression of Semaphorin4A in cocultured Retinal Pigment Epithelial Cells.

J-A. Ko[1], T-I. Chikama[1], K. Yamane[1], Y. Kiuchi[1]; [1]Hiroshima Univ Grad Sch Biomedical, Hiroshima, Japan

The retina is a complicated network of nerve cells that changes light into nerve impulses that travel to the brain where they are interpreted as visual images. The most common disease of retina is age-related ,macular degeneration (AMD). And, the damage to the retina pigmental epithelial cells (RPE) at the macular regions is an early and crucial event in the development of AMD. But, its mechanism has not been studied.
Development of multicellular organisms requires interactions between cells and their local environment and between neighboring cells.
We recently established an in vitro model based on the coculture of human corneal epithelial cells, fibroblasts, or neural cells separated by a collagen membrane.
We have now examined the role of neural cells in retinal homeostasis, and effects of neural cell to the RPE. As a results, we show that presence of neural cells (PC12) resulted in upregulation of neural guidance protein, semaphorin (semaphorin4A) in retinal pigment epithelial cells (ARPE19). Furthermore, the amounts of inflammatory cytokines, interleukin-6 (IL-6) was decreased by the presence of neural cells.
Therefore, our findings indicate that some factor(s) released from neural cells may play an important role in the regulation of intercellular communication between retinal pigment epithelial cells as well as in the maintenance of retina structure and function.
In the future, these finding provide a useful model for understanding cell-cell interactions that occur between photoreceptors and the RPE.

1566

Triggering Receptor in Myeloid Cells (TREM)-Like Transcript (TLT) - 1 Mediates Platelet-Neutrophil Interaction.

G. A. Ortiz[1,2], A. V. Washington[1,2]; [1]Biology, Universidad de Puerto Rico-Mayagüez, Mayagüez, Puerto Rico, [2]Anatomy and Cell Biology, Universidad Central del Caribe, Bayamón, Puerto Rico

Hemostasis and inflammation are intimately linked. Platelets play an indispensable role in mediating this relationship, however the mechanisms that regulate this interaction are poorly understood presenting a gap in our knowledge. Platelet α-granules are secretory granules that house the adhesion receptor P-selectin. Upon activation P-selectin is exposed and mediates primary contact with neutrophils or monocytes through interaction with the P-Selectin Glycoprotein Ligand - 1. Studies with the psel$^{-/-}$ mice reveal increased hemorrhage in response

to inflammatory challenge, and delayed neutrophil migration, demonstrating that P-selectin mediates hemostasis and platelet regulation of neutrophils. Recently, our laboratory has cloned the Triggering Receptor Expressed in Myeloid (TREM)-Like Transcript (TLT)-1, which is also found in the platelet α-granules. Expression of TLT-1 strongly correlates with P-selectin expression ($p< 0.996$). Oddly enough, characterization of treml$^{-/-}$ mice also shows a phenotype similar to the psel$^{-/-}$ mouse with the addition to a severe hemorrhage associated with lipopolysaccharides (LPS) administration in mice. This hemorrhage seems to be mediated by neutrophil deregulation. We hypothesize that, TLT-1 functions in tandem with P-selectin to mediate platelet control over neutrophils. To test our hypothesis, we are developing in vitro and in vivo methods to evaluate TLT-1 influence of neutrophil function. We used a flow cytometric assay to measure platelet-neutrophil conjugates (PNC) in wild type and treml1$^{-/-}$ mice. PNCs are known to be mediated by P-selectin. Mice were treated with LPS nasally and blood was taken from the retro-orbital plexus at 0, 1, 2, and 12 hours and the amounts of PNCs were analyzed by flow cytometry. At base line, there was no significant difference in PNCs between wild type and treml$^{-/-}$ mice. However, after 1 and 2 hours of LPS treatment, PNC were significantly higher over base line in wild type mice compared to null mice. In conjunction with our previously published data, this data supports the hypotheses that platelet-leukocyte conjugates are affected by the presence of TLT-1, and suggest that TLT-1 and P-selectin work in tandem to modulate leukocyte function. To further these studies we are, evaluating if we can use the soluble form of TLT-1 (sTLT-1) to rescue the pulmonary bleeding phenotype seen in the lungs after LPS treatment of treml1$^{-/-}$ mice. We are attempting to introduce sTLT-1 protein into the mice via hydrodynamic injection of DNA into the tail vein before LPS treatment. Soluble TLT-1 is measured in the blood by capture ELISA and pulmonary bleeding is measured by flow cytometric measurement of bronchial lavage fluid. The status of these studies is reported here.

1567

Cell-cell contact dependent regulatory role of RFP in integrin beta1 expression.

T. Kato[1], A. Enomoto[1], W. Liang[1], N. Asai[1], Y. Murakumo[1], M. Takahashi[1]; [1]Department of Pathology, Nagoya University Graduate School of Medicine, Nagoya, Japan

Integrins play central roles in the biology such as apoptosis, growth, differentiation and cell migration by controlling cell adhesion to the extracellular matrix. Although contribution of integrins on development of neoplasia has been well studied, the mechanism how the expression of integrins is regulated remains elusive. Here we report that a transcriptional regulator RET Finger protein (RFP) regulates integrin beta1 expression in a cell-cell contact dependent manner. First, we found that RNAi-mediated knock-down of RFP caused the reduction of integrin beta1 expression in less adhesive cell line MDA-MB-231, but not in adhesive squamous cell carcinoma cell line A431. Based on the difference between these two cell lines, we hypothesized that cell-cell adhesion inhibits the function of RFP on regulation of integrin beta1. Decrease of integrin beta1 by RFP knock-down in A431 was observed when E-cadherin was inhibited by knock-down or neutralizing antibody. These results indicate that cell-cell contact affects the regulatory role of RFP in integrin beta1 expression.

A marker of "Self "extends the circulation of nanoparticles.

P. L. Rodriguez[1], T. Harada[1], D. E. Discher[1]; [1]Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA

A major challenge for injecting particles or implanting biomaterials into the body is that they activate immune cells such as macrophages, the cells that normally function to clear invading pathogens. Interestingly, macrophages have a surface receptor mechanism which prevents

them from phagocytosing our own cells. During initial macrophage engulfment, macrophages recognize foreign and self targets because they both have antibodies or plasma complement proteins on their surface. However, before the macrophage engulfs the target, cells are checked for the presence of the surface protein CD47. Whether the CD47 interaction is functional with small targets of phagocytosis is unclear and relevant perhaps to nano-sized targets. Here we quantified binding and signaling of RBCs as well as soluble-CD47 to its receptor, SIRPα, inhibition of phagocytosis of RBC or CD47 coated beads, and in vivo clearance within NSG mice. The level of CD47 on the surfaces of either virus-sized beads or antibody-blocked NSG-RBCs governs circulation time in vivo, and although the affinity of human-CD47 for NSG-SIRPα is weak, it is within the range of affinities that we measure for ten human variants of SIRPα.

Evidence for the Pre-Metazoan Evolution of Teneurins, a Family of Transmembrane Proteins Necessary for Patterning and Neuronal Development.

R. Tucker[1], J. Beckmann[2], R. Chiquet-Ehrismann[2]; [1]Cell Biology and Human Anatomy, University of California, Davis, Davis, CA, [2]Friedrich Miescher Institute, Basel, Switzerland

Teneurins are large type II transmembrane proteins that are found at sites of pattern formation, in some basement membranes and in interconnected populations of neurons. Teneurins can be processed such that the intracellular domain (ICD) is transported to the nucleus, the extracellular domain (ECD) is shed into the extracellular matrix, and the C-terminus converted into a neuropeptide. Knockout or knockdown of teneurins in *D. melanogaster*, *C. elegans* or mouse leads to abnormal patterning, disorganization of basement membranes, defasciculation of neurites and/or abnormal neuronal development. Here we have identified and analyzed teneurins from a variety of genomes for nuclear localization sequences (NLSs), furin cleavage sites and protein interaction domains. In all bilateria teneurins have the same basic organization: 1) an ICD with or without an NLS, and 2) an ECD with EGF-like domains, a cysteine-rich domain, and a series of NHL and YD-repeats. The ICD of teneurin-1 from amniotes is predicted to have a strong NLS, while teneurins-2 and -3 have furin cleavage sites that could release the ECD. Teneurins were not found in cnidarians, placozoa or sponges, but a teneurin with a domain organization identical to teneurins from bilateria was identified encoded in the genome of the choanoflagellate *Monosiga brevicollis*. Analysis of the predicted *M. brevicollis* teneurin reveals sequence similarity between the cysteine-rich domain and enzymes from diatoms and algae, and similarity between the carboxy half of the teneurin and prokaryotic YD-repeat proteins. Moreover, most of the ECD is encoded on a single giant exon. Thus, teneurins appear to have evolved via horizontal gene transfer to an ancestral choanoflagellate from one or more of its prey, perhaps to facilitate prey capture. The appearance of this hybrid protein in a choanoflagellate may have contributed to the evolution of multicellularity and complex histogenesis in metazoa.

Teneurin homophilic interaction and brain specific functions.

J. Beckmann[1], R. Schubert[2], A. Vitobello[1], F. Rijli[1], D. Müller[2], R. Chiquet-Ehrismann[1]; [1]Friedrich Miescher Inst Biomed Res, Basel, Switzerland, [2]ETH Zurich - D-BSSE, Basel, Switzerland

Many key developmental processes are regulated by transmembrane proteins mediating cell-cell interactions. Teneurins are a unique family of type II transmembrane proteins conserved from Drosophila melanogaster and Caenorhabditis elegans to vertebrates, where four paralogues exist called teneurin 1 4. Using Single-Cell Force Spectroscopy (SCFS) we were able to quantify adhesion forces between single cells expressing different teneurin proteins. We were able to show homophilic, but not heterophilic interaction between teneurin expressing

cells. This suggests that teneurins are target recognition molecules for a subset of neurons. In a primary neuron co-culture assay, we showed that teneurin expressing HEK293 cells are attractive for neurites. This finding might reflect the recently discovered role for the teneurin protein family in establishing arealization and patterning in the developing embryo. These processes are regulated by a network of transcription factors, which are expressed in gradients in the developing cortex. The homeobox containing protein Emx2 is the best studied protein in the network, although direct targets involved in patterning are not established yet. We identified a novel promoter upstream of the published transcription start of teneurin-1, which is conserved in chicken and mice. We show that Emx2 directly binds to and regulates human teneurin-1 expression at this alternative promoter contributing to the patterned expression of the different members of the teneurin family[1]. Taken these results together, we were able to establish teneurins as molecules defining target areas for subsets of neurons both on the transcriptional level as well on the level of their function.

1572

Characterizing osteoclast precursor fusion: contribution of E-cadherin and migration.

C. E. Fiorino[1], R. E. Harrison[2]; [1]Cell and Systems Biology, University of Toronto, Toronto, ON, Canada, [2]University of Toronto

Osteoclasts are giant, multinucleate cells which perform a unique role within the vertebrate system. Osteoclasts actively resorb targeted areas of bone, which is an important part of the bone remodeling process. An important step in the maturation of osteoclasts is the early fusion between multiple precursor cells. Even though this is a key commitment step during osteoclast differentiation, little is known about the mechanisms and molecules involved. Our strategy to observe individual fusion events has been to utilize long-term imaging with an epifluorescent Zeiss AxioObserver equipped with a humidified, temperature-regulated CO_2 incubation chamber throughout the 6-day differentiation process. Live-cell movies revealed that RAW 264.7 cells, stimulated with RANKL, use multiple approaches for the generation of multinucleate osteoclasts. Early differentiation, post-48 hours of RANKL treatment, was characterized by simple fusion events between small multinucleate cells with mononuclear cells. However, by 96 hours of RANKL treatment, multinucleate cells fusing with other multinucleate cells were observed, which has not been previously documented. Further observation revealed fusion preferentially occurred at the leading edge of migrating precursor cells or at sites of active pseudopod extension. Fixed and live immunofluorescent localization of E-cadherin, a potential fusogenic molecule, confirmed these observations. Accumulation of E-cadherin-mCherry at sites of cell-cell contact and prior to the fusion event was captured using live epifluorescent and confocal techniques. Application of functional blocking antibodies against E-cadherin also caused a significant reduction in overall cell fusion. These results suggest an important role for E-cadherin during early stages of osteoclast differentiation, implicate migration as a critical component for successful fusion and demonstrate the utility of live-cell techniques to study the osteoclast fusion event.

1573

Intercellular force transmission through adherens junctions during collective cell migration.

E. Bazellieres[1], X. Serra-Picamal[1], L. Casares[1], R. Vincent[1], X. Trepat[1]; [1]Institute for Bioengineering of Catalonia, Barcelona, Spain

In a wide variety of migratory processes, including embryonic morphogenesis, wound healing, and some forms of epithelial tumor invasion, cells migrate while maintaining adherens junctions. Transmission of physical forces through these junctions has recently been implicated in mechanotransduction and collective cell guidance, but the mechanisms of intercellular force transmission remain poorly understood. Our goal is to study the role of the E-cadherin, beta-catenin and alpha-catenin complex in the regulation of force transmission and cell velocity during migration of an epithelial cell sheet.
We knocked down cell-cell adhesion proteins in human mammary epithelial cells (MCF10A cells) by using siRNA technology. By using Traction Force Microscopy, Monolayer Stress Microscopy and Particle Image Velocimetry, we mapped cell-matrix forces, cell-cell forces and cell velocities, respectively. To ensure robust initial conditions we developed a novel collective cell migration assay based on micropatterning technology. Control cells exhibited strong and punctate traction forces at the cell-substrate interface and long ranged transmission of forces through cell-cell junctions. Depletion of E-cadherin, alpha-catenin and beta-catenin did not affect the generation of traction forces but the transmission of intercellular forces reduced. Our results provide the first direct evidence that E-cadherin, alpha-catenin and beta-catenin transmit intercellular forces during collective cell migration.

1574

Deformation of Endothelial Cells during Leukocyte Rolling.

Y. Chen[1], L. Lu[1], J. Hao[1], J-Y. Shao[1]; [1]Washington University in St. Louis, MO

During the immune response or the atherosclerotic lesion development, leukocytes first roll on the endothelium when they migrate out of the blood vessel. During this process, membrane tethers (i.e., membrane nanotubes) can be extracted from both leukocytes and endothelial cells that line the blood vessel. Tether extraction, which has been shown to stabilize leukocyte rolling, is preceded by surface protrusion, which dictates whether tether extraction can occur. Although surface protrusion of leukocytes has been characterized, surface protrusion of endothelial cells has not. In this work, we present a detailed study of surface protrusion of human umbilical vein endothelial cells (HUVECs). Using the micropipette aspiration technique, we measured the protrusional stiffness and the crossover force during HUVEC surface protrusion. We found that, compared with leukocytes, the protrusional stiffness and the crossover force of HUVECs were both larger at similar force loading rates. The values of these two parameters depended on temperature, the cytoskeletal integrity, asymmetric dimethylarginine, and whether CD31 or CD29 was used as the force handle. However, they did not depend on cell attachment state or intracellular calcium. These results show that similar mechanisms govern surface protrusion, hence also tether extraction in leukocytes and endothelial cells. This new understanding from a biophysical viewpoint is essential for us to eventually control this critical step of leukocyte migration.

1575
Epithelial Contact Expansion Requires *de novo* mRNA Translation.
I. Eromobor[1], R. J. Petrie[2], N. Gutierrez[1], K. M. Yamada[2], A. J. Rodriguez[1]; [1]Rutgers Univ-Newark, Newark, NJ, [2]NIH/NIDCR

Epithelial adherens junctions are important for polarized tissue assembly during development and tissue homeostasis during adulthood. Junction assembly occurs in 3 distinct steps: contact initiation, contact expansion, and junction maturation. The epithelial-specific transmembrane protein E-cadherin regulates the initiation of junction assembly by acting as a molecular sensor, detecting epithelial cell-cell contact through homophilic binding. This initial E-cadherin-mediated engagement results in contact inhibition of movement via assembly of intercellular actin cytoskeleton-cadherin-catenin adherens junction complexes through the local activation of intracellular signal transduction pathways including the Rho family GTPases RhoA and Rac1, along with the tyrosine kinase Src. In mesenchymal cells the peripheral localization of β-actin mRNA relies upon RhoA activity while its local translation relies upon Src activity. We hypothesized that epithelial adherens junction assembly requires RhoA and Src-dependent β-actin translation at E-cadherin homophilic contact sites. To test this, sparse plating assays with and without the translational inhibitors cycloheximide or puromycin were performed using epithelial IAR-2 cells. These studies demonstrated that *de novo* mRNA translation was required for progression from contact initiation to contact expansion during adherens junction assembly. To further investigate protein synthesis inhibition during adherens junction assembly, Ca^{2+} switch experiments, performed with cycloheximide or puromycin, showed that inhibiting protein synthesis significantly delayed adherens junction assembly, correlating with E-cadherin mistargeting and reduced E-cadherin/F-actin anchoring at cell contact sites. Ca^{2+} switch experiments in MDCK cells expressing a RhoA biosensor were performed to investigate the spatial correlation between adherens junction assembly sites and RhoA activity. RhoA activity became plasma membrane-localized within 30 minutes of contact initiation and persisted at the plasma membrane for at least 4 hours following contact initiation. Intriguingly, Ca^{2+} switch experiments with cycloheximide completely prevented the localization of active RhoA to the plasma membrane at all time points. Together, these data suggest that epithelial cell-cell contact stimulates the contact-localized signal transduction activity required for β-actin mRNA targeting and translation and this localization is necessary for the transition from contact initiation to contact expansion during adherens junction assembly.

Focal Adhesions and Invadosomes

1576
FAK recruits talin to nascent adhesions, a paradigm shift in the control of cell motility.
C. Lawson[1], S-T. Lim[1], S. Uryu[1], X. Chen[1], D. Calderwood[2], D. Schlaepfer[1]; [1]Department of Reproductive Medicine, Moores Cancer Center, University of California San Diego, La Jolla, CA, [2]Department of Pharmacology, Yale University School of Medicine

Cell migration is a dynamic process that involves the continuous formation, maturation, and turnover of matrix-cell adhesion sites. Nascent adhesions form at the protruding cell edge in a tension-independent manner and are comprised of integrin receptors, signaling, and cytoskeletal-associated proteins such as paxillin and talin. Integrins generate important signals controlling cell motility mediated in part by the recruitment of focal adhesion kinase (FAK) and talin to nascent adhesions. Canonical models propose that talin functions as an intermediary in binding both integrins and FAK. It is hypothesized that talin facilitates FAK localization and

activation at adhesions. However, how and when talin and FAK form a complex remains unresolved. To investigate the dynamics of protein recruitment to nascent adhesions, we replated FAK-/- fibroblasts and ovarian carcinoma cells (with FAK knockdown) on fibronectin (15 min) to synchronize nascent adhesion formation. As detected by immunofluorescent staining, paxillin was equally recruited in the presence or absence of FAK but talin localization to nascent adhesions was dependent on FAK re-expression. By evaluating cells expressing integrin cytoplasmic domain mutations, talin nascent adhesion recruitment occurred in the absence of direct talin binding to integrins. Combined in vitro pull down, mutagenesis, co-immunoprecipitation assays identified the direct binding site of the talin head domain to FAK C-terminal domain residues 1011-1042. E1015A point-mutation of FAK selectively disrupted binding to talin without affecting FAK-paxillin association. Re-expression of FAK E1015A in FAK /- fibroblasts prevented talin localization to nascent adhesions without altering FAK recruitment and activation at adhesions. Moreover, FAK E1015A inhibited ovarian carcinoma cell motility and proteolytic talin cleavage needed for efficient adhesion dynamics. Our results support a model whereby FAK association with talin at adhesions facilitates the recruitment of a protease such as calpain that would mediate talin cleavage, trigger focal adhesion turnover, and enable cell movement. This study defines a paradigm shift and a new FAK to talin hierarchical linkage controlling cell migration.

1577

Differential Requirement for Vinculin in Actin Engagement and Growth of Focal Adhesions.

I. Thievessen[1], S. Berlemont[2], S. Plotnikov[1], A. Zemljic-Harpf[3], R. Ross[3], G. Danuser[2], C. Waterman[1]; [1]Cell Biology and Physiology Center, Laboratory of Cell and Tissue Morphodynamics, National Heart, Lung and Blood Institute/NIH, Bethesda, MD, [2]Department of Cell Biology, Laboratory for Computational Cell Biology, Harvard Medical School, [3]Department of Medicine, Division of Cardiology, University of California San Diego School of Medicine

Cell migration is critical for various tissue morphogenic and homeostatic processes and requires the dynamic integration of cell adhesion to the extracellular matrix (ECM), and the actin cytoskeleton. Migrating cells form nascent ECM-adhesions within their leading edge lamellipodia in association with rapid filamentous actin (F-actin) polymerization and retrograde flow. Engagement of nascent adhesions to lamellipodium F-actin flow transmits cytoskeletal force to the ECM and establishes a flow velocity gradient between the lamellipodium and the lamellum. In the lamellum, nascent adhesions undergo myosin II-dependent maturation in which they grow and increase ECM traction force. Although cytoskeletal engagement, force transmission and growth of nascent adhesions require interactions with F-actin, it is unclear whether these processes are mechanistically coupled during adhesion maturation. Here we analyze the role of the adhesion protein vinculin in these distinct aspects of adhesion maturation. Cre/loxP-mediated vinculin depletion in primary murine fibroblasts inhibited nascent adhesion formation, perturbed the segregation of lamellipodium and lamellum, and reduced ECM traction. In contrast, vinculin depletion accelerated adhesion growth. Thus, vinculin promotes nascent adhesion assembly and engagement to lamellipodial F-actin flow for ECM traction generation, but inhibits adhesion growth. Our findings show that cytoskeletal engagement and growth of ECM-adhesions are mediated by distinct mechanisms of interaction with the actin cytoskeleton, which interdependently control adhesion maturation and actin cytoskeleton dynamics during cell migration.

Cellular mechanosensing of dynamic force and stiffness signals.

W. Ng[1], K. D. Webster[1], B. L. Ricca[1], D. A. Fletcher[2]; [1]University of California, Berkeley, Berkeley, CA

Mechanical signals from the cellular and tissue microenvironments have been implicated in the regulation of a number of cellular processes including differentiation, migration and proliferation. However, the mechanisms by which cells sense different types of mechanical cues, such as external force or extracellular stiffness, remain an active area of study. Here, we implement an atomic force microscopy (AFM)-based force and stiffness clamp technique to dynamically and independently modulate the external force and stiffness that is presented to a single cell as it spreads onto both the extracellular matrix-coated AFM cantilever on the top and a glass coverslip on the bottom. Cells studied with this technique experience a pseudo-three-dimensional microenvironment in which horizontal spreading on the two surfaces is resisted in the vertical direction by the force of deflecting the cantilever. We characterized the response of NIH 3T3 fibroblast cells to changes in external force and stiffness in the vertical direction by tracking cell spreading, cell contraction and focal adhesion dynamics. We found that both focal adhesion dynamics and cell contraction respond rapidly to step changes in force and stiffness, with contraction rate response occurring on a timescale of less than one second. The technique we describe here provides a useful platform for investigating how dynamic mechanical inputs are interpreted by cells during mechanosensing.

1579

Ventral F-actin waves are coupled to a novel integrin-mediated adhesion complex.

L. Case[1], C. Waterman[1]; [1]National Heart, Lung and Blood Institute, National Institutes of Health, Bethesdsa, MD

At the leading lamellipodium of migrating cells, protrusion of an Arp2/3-nucleated actin network is coupled to formation of integrin-based adhesions, suggesting that Arp2/3-mediated actin polymerization and integrin-dependent adhesion may be mechanistically linked. Arp2/3 also mediates actin polymerization in structures distinct from the lamellipodia, in "ventral F-actin waves" that propagate as spots and wavefronts along the ventral plasma membrane. We tested the hypothesis that, similar to Arp2/3 mediated actin polymerization in the lamellipodia, ventral F-actin waves were also coupled to integrin adhesion. We used two-color Total Internal Reflection Fluorescence Microscopy to examine fluorescently tagged F-tractin, an F-actin reporter, coexpressed with fluorescently tagged alpha V integrin. We found that integrins localize to ventral F-actin waves downstream of actin polymerization in several mammalian cell lines. These "adhesive F-actin waves" require a cycle of integrin engagement and disengagement to the ECM for their formation and propagation, and exhibit morphometry and a hierarchical assembly and disassembly mechanism distinct from other integrin-containing structures. Following Arp2/3-mediated actin polymerization, zyxin and VASP are co-recruited to adhesive F-actin waves, followed by paxillin and vinculin, and finally talin and integrin. Adhesive F-actin waves thus represent a previously uncharacterized integrin-based adhesion complex associated with Arp2/3-mediated actin polymerization. The spatiotemporal coordination of actin polymerization and integrin adhesion is important for adhesive cell migration, and our findings support the notion of an inherent mechanistic coupling between Arp2/3-mediated actin polymerization at the plasma membrane and integrin-based adhesion.

1580

Tension is insufficient to drive focal adhesion maturation in the absence of a dorsal stress fiber template.

Y. Beckham[1], P. Oakes[1], J. Stricker[1], M. Gardel[1]; [1]Institute for Biophysical Dynamics and James Franck Institute, University of Chicago, Chicago, IL

Myosin-II mediated focal adhesion maturation is crucial to modulate physical and biochemical signaling between cells and the extracellular matrix (ECM). Since myosin drives both dorsal stress fiber assembly and enhanced tension at adhesions simultaneously, the extent to which focal adhesion maturation is driven by tension or changes in actin architecture is unknown. Here, we distinguish between the roles of tension and lamellar actin architecture by selectively inhibiting dorsal stress fiber assembly, either through formin inhibition or reduced expression of alpha-actinin 1. We find that force transmission to adhesions can occur in the absence of prominent dorsal stress fibers linking adhesion plaques to lamellar actin. Force-mediated cues are sufficient to stabilize nascent adhesions to the ECM over a wide range of forces and facilitate adhesion dynamics. In the absence of dorsal stress fibers, however, focal adhesions exhibit a decreased length and lifetime relative to those in wildtype cells. In addition, force-mediated adhesion signaling is not sufficient to facilitate classic hallmarks of focal adhesion maturation including the accumulation of phosphorylated paxillin and focal adhesion kinase and the formation of fibrillar adhesions required for fibronectin remodeling. For these compositional and morphological signatures of adhesion maturation, the assembly of a dorsal stress fiber at the focal adhesion plaque must occur. Thus, myosin-mediated mechanotransduction pathways are insufficient to drive essential aspects of focal adhesion maturation in the absence of a dorsal stress fiber template.

1581

A novel method for the enrichment of structurally intact cytoskeleton and focal adhesions.

K. Huryn[1], H. Liu[1], J. Anderl[1], R. Klemke[2], J. Ma[1], L. Armstrong[1]; [1]Bioscience Division, EMD Millipore, [2]Dept. of Pathology and Moores Cancer Center, University of California, San Diego, La Jolla, CA

The core mammalian cytoskeleton consists of actin microfilaments, focal adhesions, microtubules, and intermediate filaments, which are constructed through the assembly of free subunits of the cytoskeletal components into highly organized arrays. The biochemical changes of these proteins during assembly are incompletely understood, as the presence of both free and assembled subunits within the cell complicates analysis. Here we present a method for selectively separating soluble cytosolic proteins from adherent cells, which permits sensitive biochemical (including Western blot and mass spectrometric) and imaging analyses of the insoluble cytoskeleton and associated proteins in their native conformations.
The enrichment method entails 1) in situ permeabilization of the plasma membrane with low detergent concentration, 2) partial digestion of nucleic acids, and 3) fixation for immunofluorescence or solubilization for Western blotting or mass spectrometry. Integrity of the HeLa cell cytoskeleton was indicated by comparable rhodamine-phalloidin labeling and vimentin immunostaining in intact and enriched cells. Efficiency of extraction was indicated by complete removal of immunoreactive GAPDH. Staining for vinculin in intact cells yielded diffuse staining with punctae indicative of focal adhesions, whereas enriched cells exhibited staining solely in focal adhesions. Similarly, immunostaining for beta-catenin in intact cells resulted in staining of both cell-cell contacts and cytoplasm, whereas in enriched cells, only the cell-cell contacts were evident. Comparison of intact and cytoskeleton-enriched cells by Western blotting also indicated that GAPDH was completely extracted, whereas vimentin was entirely present in the remaining

adherent fraction. In summary, our methods will facilitate the characterization of mechanisms for regulated partitioning of cytoskeleton-associated proteins between the soluble cytosol and insoluble cytoskeleton.

1582

The Focal Adhesion: A Regulator of Vascular Stiffness?

R. Saphirstein[1], M. Jensen[2], S. Vetterkind[3], J. Moore[4], K. Morgan[5]; [1]Biomedical Engineering, Boston Univ, Boston, MA, [2]Physics, Boston Univ, [3]Health Sciences, Boston Univ, [4]Physiology & Biophysics, Boston Univ, [5]Health Sciences, Boston Univ, Boston, MA

Despite the fact that arterial stiffening with age is now known to be an independent and early predictor of cardiovascular disease, relatively little is known about the contributions of different tissue components to vascular stiffness. The extracellular matrix (ECM) has traditionally been regarded as the main determinant of vascular tissue stiffness, but a recent study (Qiu et al. Circ Res. 2010) implicates the actomyosin-based stiffness of vascular smooth muscle cells as a significant contributor. Here, we investigated the role of differentiated vascular smooth muscle cells in determining tissue stiffness. We measured the stiffness of vascular tissue strips in vitro and observed that stiffness increases unexpectedly when tissue strips are treated with PP2, a small molecule inhibitor of the master focal adhesion (FA) tyrosine kinase Src. This result suggests that FAs, which mechanically link the ECM to the internal actin CSK, may regulate vascular tissue stiffness. To further confirm FA involvement, we examined tyrosine phosphorylation as a biochemical signature of FA signaling and turnover. Phosphotyrosine screening of vascular tissue homogenates via Western blots reveals roles for the FA proteins Src, FAK, and CAS in vasoconstrictor-induced signaling. To directly confirm the role of FAs in the regulation of stiffness, we used optical tweezers to measure stiffness in A7r5 smooth muscle cells by applying piconewton forces localized directly to FAs via cell-bound RGD-coated microbeads. We found that A7r5 stiffness is modulated by FAs and by A7r5 activation state. Stimulation with the vasoconstrictor lysophosphatidic acid (LPA) increases stiffness in a PP2-attenuated manner. Cell immunofluorescence imaging suggests that A7r5 stiffness is related to FA size as well as FA stiffness, since FA size increases in a PP2-attenuated manner with LPA stimulation. Our findings indicate that the FA is a significant component of vascular stiffness. Support: NIH HL86655, HL8003, HL31704.

Imaging the Cell-Basement Membrane Interface during Anchor Cell Invasion in C. elegans.

E. J. Hagedorn[1], D. R. Sherwood[1]; [1]Department of Biology, Duke University, Durham, NC

Basement membranes are dense, sheet-like forms of extracellular matrix that underlie all epithelia and endothelia and function in part as natural barriers to cell migration. Despite the impediment posed to migrating cells, specialized cells transmigrate or invade through basement membranes during development, immune surveillance and cancer. Because the complex environments where most cell invasions occur are difficult to experimentally access, researchers have predominately used *in vitro* systems to model cell invasion. These studies have provided considerable mechanistic insight into cell invasion, identifying actin-based membrane structures called invadosomes, which localize to sites of matrix degradation at the ventral surface of invasive cells. It has been postulated that invadosomes are critical to cell invasion through basement membrane, however, whether these structures exist in invading cells *in vivo* and how they would be used to breach a native basement membrane is unclear.

Anchor cell invasion into the vulval epithelium in *C. elegans* provides a simple *in vivo* model of cell invasion through basement membrane that uniquely combines predictability, ease of

visualization and tractable genetic analysis. We have used 3D time-lapse microscopy to focus on the cell-basement membrane interface over the time-course of anchor cell invasion. Using this accessible model, we have identified dynamic actin-based membrane protrusions that mediate the initial stages of basement membrane penetration by the anchor cell. These structures share striking similarities with invadosomes– the invasive membrane structures found in many cell types when cultured *in vitro* or *ex vivo*. The predictability of the event, inherent to the worm's stereotyped development, allows for rigorous quantitative analysis of the dynamics (*i.e.,* numbers, sizes, lifetimes) of these structures and their relationship to the initial breach of the basement membrane. While these structures closely resemble invadosomes that have been described *in vitro*, we have also observed important differences. For example, we find that typically one or two holes are generated in the basement membrane, as opposed to numerous holes being degraded in the matrix. This work provides some of the first clear evidence of invadosome-like structures being used during basement membrane transmigration *in vivo*. Moreover, the powerful genetic tools of *C. elegans* are allowing us to rapidly screen for genes required for invadosome formation and that modulate invadosome dynamics and activity.

1584

How To Make a Pretzel: the Molecular Machinery That Orchestrates Synaptic Maturation.

T. J. Proszynski[1], J. R. Sanes[1]; [1]Department of Molecular and Cellular Biology and Center for Brain Science, Harvard University, Cambridge, MA

During the formation of neuromuscular junctions NMJs), postsynaptic acetylcholine receptors AChRs) initially cluster in plaque-shaped aggregates that are subsequently transformed into a complex, pretzel-shaped topology. The machinery that orchestrates this transformation remains to be unraveled. We are using cultured myotubes, in which the plaque-to-pretzel transition occurs aneurally, to elucidate its mechanism. Unexpectedly, we found that muscles utilize podosomes, dynamic actin-based organelles, to remodel postsynaptic clusters. Synaptic podosomes influence organization of AChRs by degrading the underlying extracellular matrix (ECM), which is essential for the stability of AChR at the cell surface. As a next step, we are focusing on two proteins, LL5beta (LL5b) and alpha-dystrobrevin-1 (aDB1), which we showed to be components of podosomes(Proszynski, PNAS, 2009) and implicated in AChR organization Grady, JCB, 2003; Kishi, JCB, 2005). We are now using proteomic methods to seek their binding partners. We have identified Flii, Amotl2 and Asef2, all of which organize actin and regulate Rho GTPases, as LL5b interactors. All three interacting proteins are localized to the podosomes and RNAi experiments demonstrated that Amotl2 is essential for podosome formation in Src3T3 cells. We are currently characterizing the roles of these novel podosome components, as well as aDB1 interactors, in AChR clustering using RNA interference.

TGF-β-induced invadosomes in human trabecular meshwork cells.

H. Han[1], D. Kampik[2], F. Grehn[1], G. Schlunck[1,3]; [1]Dept. of Ophthalmology, Wuerzburg University Medical Center, Wuerzburg, Germany, [2]Institute of Ophthalmology, University College London, London, United Kingdom, [3]Dept. of Ophthalmology, Freiburg University Hospital, Freiburg, Germany

Primary open-angle glaucoma (POAG) is a leading cause of blindness due to chronic degeneration of retinal ganglion cells. It is associated with elevated intraocular levels of TGF-β2, aberrant extracellular matrix (ECM) deposition and increased outflow resistance in the ocular trabecular meshwork (TM). Cell-matrix interactions have a decisive role in TM maintenance and it has been suggested that TGF-β-induced MMP-inhibition may drive ECM deposition in POAG. Invadopodia and podosomes (invadosomes) are distinct sites of cell-matrix interaction and

localized matrix-metalloprotease (MMP) activity. Here, we report on the effects of TGF-β2 on invadosomes in human trabecular meshwork cells. Human TM (HTM) cells were derived from donor tissue and pretreated with vehicle or TGF-β2 (2ng/ml) for 2d. Invadosomes were studied in ECM degradation assays, protein expression and MMP-2 activity were assessed by western blot and zymography and ECM protein transcription was detected by RT-qPCR. HTM cells spontaneously formed podosomes and invadopodia as detected by colocalization of Grb2 or Nck1 to sites of gelatinolysis. Pretreatment with TGF-β2 enhanced invadosomal proteolysis and zymographic MMP-2 activity as well as MMP-2, TIMP-2 and PAI-1 levels in HTM cell culture supernatants. Rho-kinase inhibition blocked the effects of TGF-β2. Concomitant transcription of fibronectin and collagens-1, -4 and -6 was increased by TGF-β2. In contrast to a current hypothesis, our data suggest that TGF-β2 induces an active ECM remodelling process in TM cells, characterized by concurrent increases in localized ECM digestion and ECM expression. Invadosomal cell adhesion and signaling may have a role in POAG pathophysiology.

Bioengineering of Cell-Matrix Interactions

Molecular dissection and reconstruction of laminin-111 using synthetic peptides conjugated chitosan.

K. Hozumi[1], A. Sasaki[1], Y. Yamada[1], F. Katagiri[1], Y. Kikkawa[1], M. Nomizu[1]; [1]Tokyo Univ Pharm & Life Sci, Hachioji, Japan

Laminins, a major component of basement membrane and consisting of alpha, beta, and gamma chains, exert multiple biological functions through interactions with cell surface receptors and with other matrix molecules. Five alpha chains (alpha1- alpha5), three beta chains (beta1-beta3), and three gamma chains (gamma1-gamma3) have so far been identified and they comprise at least 19 different laminin isoforms (laminin-111 to laminin-523). Each laminin isoforms are tissue- and/or developmental stage-specifically expressed and play their own laminin isoform-specific functions. Laminins-111, consisting of laminin alpha1, beta1, and gamma1 chain, plays a critical role during embryonic development and in maintaining the many biological functions of basement membrane. We previously identified about 60 active sequences from laminin-111 through the peptide screening method using over 673 peptides covering the entire sequence of laminin-111. Further, some biological active peptides from laminin-111 had been used to develop the artificial cell sheet by conjugated on chitosan matrix and found that cell-peptide-chitosan sheet accelerate the wound healing. Here, we conjugated 60 cell adhesive peptides from laminin-111 on chitosan matrix and assessed their biological functions to analyze the peptide specific functions. Twenty-six cell adhesive peptide-conjugated chitosan matrices promoted human dermal fibroblasts (HDFs) attachment and twelve peptide-chitosan matrices showed cell spreading. HDF attachment to nine peptide-chitosan matrices was inhibited by heparin and to twelve peptide-chitosan matrices was inhibited by EDTA. Additionally, HDF attachment to several peptide-chitosan matrices was inhibited by anti-beta1 integrin antibodies. Further, seventeen peptide-chitosan matrices promoted neurite outgrowth with PC12 cells. These results suggest that peptide-chitosan matrices exhibited different activities depending on peptide specific manner. We could categorize these active peptide-chitosan matrices into eight groups depend on their biological activities. Next, we conjugated five HDF active peptides, which showed the strongest HDF adhesive activity in the each group, on a chitosan matrix to mimic the multifunction of laminin-111. The mixed peptides-chitosan matrix significantly promoted cell attachment and cell spreading as laminin-111. The peptide-chitosan matrices interact with different cell surface receptors in a peptide dependent manner.

These cell adhesive peptide-chitosan matrices could use to analyze the cellular functions mediated by specific cell surface receptors and have a potential to use as a biomedical material.

High Cell Aspect Ratio Alters Stem Cell Traction Stresses and Lineage.

L. G. Vincent[1], T. Yong[2], J. del Alamo[3], L. Tan[2], A. J. Engler[1]; [1]Bioengineering, University of California, San Diego, La Jolla, CA, [2]Nangyang Technological University, Singapore, [3]Mechanical and Aerospace Engineering, University of California, San Diego, La Jolla, CA

Degenerative diseases, such as muscular dystrophies, often cause abnormal stiffening as a result of fibrosis. Adult mesenchymal stem cells (MSCs) "feel" this stiffness and differentiate in response to it; thus aberrant stiffness could misdirect MSCs into the wrong lineage. Conversely, MSCs have been shown to respond to changes in area and shape in a myosin-dependent mechanism: cells respond to adipogenic and osteogenic media when spread cell area changes from 10^3 to 10^4 μm^2, or when cultured as circles versus rectangles, and polygons, respectively. When both cues are present in a disparate fashion, e.g. highly elongated cells similar to muscle despite the presence of an abnormally stiff microenvironment, we hypothesized that a myosin contraction-dependent balance could induce a subset of the MSC population to differentiate in to a muscle-like phenotype despite residing in a dystrophic-like stiffness. Using microcontact printing to regulate MSC morphology, we patterned fibronectin with polydimethylsiloxane molds in shapes of varying aspect ratios but common area on polyacrylamide substrates of known stiffness. Traction force microscopy (TFM) was used to monitor substrate strain energy from cell-generated normal and tangential forces. Cells on patterns were also fluorescently stained for focal adhesion kinase and vinculin to overlay with traction force measurements and separately with muscle-specific myosin heavy chain (mMHC) to identify early muscle differentiation. MSCs spread to the stamped patterns after two days of culture and localized their focal adhesion in a stiffness and shape-dependent manner. While strain energy scaled with stiffness, it decreased as a function of cell elongation with isotropic cell patterns producing the highest contractile energy in contrast to our hypothesis. mMHC also was expressed in a stiffness and elongation dependent manner. On muscle-like stiffness of 11 kiloPascals (kPa), cells with only minimal elongation, i.e. 1:1 and 3:1 patterns, expressed mMHC most strongly. In contrast on osteogenic-like matrices of 34 kPa, highest MHC expression corresponded to the most elongated patterns. These shape- and stiffness-dependent lineage changes with muscle markers correlated to contractility-based observations suggest that muscle induction may be possible in non-permissive stiffer environments. These results are suggestive of a subpopulation of MSCs that is more responsive to an elongated shape than pathogenically stiff matrix, and could prove to be beneficial for regenerative therapies for fibrotic muscle diseases. Efforts to test this newly identified subpopulation of MSCs in the *mdx* mouse model of muscular dystrophy are ongoing.

In Vivo Application of Dynamic Hyaluronic Acid Matrix For Myocardial Infarction Therapy.

J. L. Young[1], J. Schaefer[1], J. Tuler[1], P. Schup-Magoffin[1], K. L. Christman[1], A. J. Engler[1]; [1]Bioengineering, University of California, San Diego, La Jolla, CA

Tissue-specific elasticity arises from developmental changes that occur in the environment over time, e.g. ~10-fold myocardial stiffening from E3 to E10 in the chick embryo. Recently, we have shown that pre-cardiac mesodermal cells plated on top of a thiolated hyaluronic acid (HA) matrix engineered to mimic this time-dependent stiffening improves cardiomyocyte maturation compared to cells on static compliant matrices. Here we determined cell-matrix interactions using *in vitro* encapsulation assays and *in vivo* injections. Improved pre-cardiac and embryonic

stem cell (ESC) distribution and viability was observed when cells were encapsulated and bound to immobilized, thiolated fibronectin conjugated to the HA matrix. Though not toxic to cells, we also assessed HA's local and systemic biocompatibility. Prior to assembly, HA was injected subcutaneously into Sprague-Dawley rats and samples were removed over a post-injection time course and subject to histological, immunological, and mechanical analysis. Histological analysis showed minimal infiltration of host cells and capsule formation around the matrix. Hematological analysis showed no significant systemic immune response was elicited in pre- vs. post-injection animals for all time points. Most importantly, atomic force microscopy (AFM) analysis showed dynamically increasing hydrogel stiffness over time similar to that previously found *in vitro*. Finally before cell-matrix co-injection into infarcted tissue, we sought to determine the appropriate time of injection into the stiffened infarct; thus post-infarct remodeling in a total occlusion rat model was monitored using histology and AFM. Minimal infarct remodeling occurred 48 hours-post occlusion, but sufficiently elevated stiffness was observed alongside wall thinning and collagen deposition two weeks post-infarct (monitored out to two months), which suggests two separate approaches with combined HA matrix and ESC or pre-cardiac cell therapy: injection before and after wall thinning to encourage either the prevention of thinning or restoration of myocardial contraction. These *in vitro* data indicate that the combination of cells and developmentally appropriate matrix stiffness may significantly improve cell differentiation while *in vivo* data indicate the injectable feasibility of the HA matrix and an optimal injection time to restore function and prevent myocardial remodeling.

1589

Fibrillar collagen is equivalent to stiff matrix in driving marrow stromal cell differentiation into matrix-deficient, myofibroblastic-like phenotype.

P. C. Dave P. Dingal[1], A. Buxboim[2], J-W. Shin[3], D. E. Discher[1]; [1]Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA, [2]Physics and Astronomy, University of Pennsylvania, Philadelphia, PA, [3]Pharmacology, University of Pennsylvania, Philadelphia, PA

Scars tend to be stiffer than normal tissue, which has prompted the use of stiff matrices as models of scars, but scars are also rich in fibrillar collagen-I. Here, we introduce a soft matrix embedded with distinctly fibrillar collagen type I, and show that this is sufficient to drive bone marrow derived stromal cells (MSCs) into a contractile, myofibroblastic-like phenotype – 'myo-MSCs'. These cells have been reported to minimize scarring in a unique wound healing response, exemplified by their application to myocardial infarcts [1]. Transcriptome analysis in response to matrix rigidity points to an upregulation of genes that participate in the cellular contractile machinery, notably α-smooth muscle actin, but a decreased expression of matrix protein genes for collagens type I and VI. MSCs cultured on the embedded-fiber, soft matrix exhibit many similarities to cells on rigid substrates. Phosphorylation at serine-1943 of non-muscle myosin IIA, which deactivates stress fiber assembly, is decreased on both fibrosis-like and rigid substrates but almost twice higher on a soft substrate. Interestingly, nano-indentation measurements of these 'myo-MSCs' hint that, unlike myofibroblasts, they do not become hyper-contractile. This supports the notion that MSC engraftment into wounded tissues suppresses fibrosis, highlighting the promise of these cells in restoring normal tissue function.

Investigating the role of vinculin in mechanosensitive stem cell differentiation.

A. W. Holle[1], D. Tandon[1], J. Del Alamo[2], A. J. Engler[1]; [1]Bioengineering, UC San Diego, La Jolla, CA, [2]Mechanical and Aerospace Engineering, UC San Diego

Human mesenchymal stem cell (hMSC) proliferation, migration, and differentiation have all been linked to extracellular matrix stiffness, but despite serious scientific inquiry, a consensus on the signaling pathways that are necessary and sufficient for this mechanosensitive ability has yet to be reached. An analysis of kinase binding site accessibility revealed MAPK1 to be both prevalent and inaccessible in many focal adhesion/mechanosensing candidate proteins. One binding partner for MAPK1, vinculin, is activated upon binding to talin in a force-sensitive manner. A Cysteine Shotgun/Western Blot was used to confirm the unfolding of vinculin in response to changes in substrate stiffness. RNA interference was used to knock down vinculin, resulting in an 80% decrease in stiffness-induced MyoD, a muscle transcription factor; control cultures that induce Runx2 expression, an osteoblast transcription factor, were insensitive to vinculin knockdown. Vinculin knockdown was not observed to interfere with focal adhesion assembly, alter adhesive properties, or diminish cell traction force generation, indicating that its deletion only adversely affected MAPK1 signaling. In addition, vinculin domains were also selectively deleted and added back into knocked-down cells to assess which domains of the protein were sufficient for stiffness-induced differentiation. Together, these data provide some of the first in situ evidence that force-sensitive focal adhesion proteins can activate stem cell differentiation signals.

1591

Elastomeric Substrate Panel for Investigation of Cell Adhesion, Proliferation, and Morphology.

J. Anderl[1], Y. Zhou[2], J. Ma[1], L. Armstrong[1]; [1]Bioscience Division, EMD Millipore, Temecula, CA, [2]Bioscience Division, EMD Millipore, Danvers, MA

The rigidity of the microenvironment provides important mechanical cues in directing cellular processes, including cell adhesion, spreading, migration, cytoskeletal organization, growth, differentiation, apoptosis, and tissue morphogenesis. Such cellular behavior can result from a complex combination of inputs (cell shape, mechanical forces, chemical cues, etc.), but an elastic matrix assay may facilitate isolating a component of these mechanical cues from chemical signals. In our studies, we have sought to develop a convenient platform of substrates of varying elasticity to investigate changes in cellular behavior caused by mechanically distinct surfaces. Our platform utilized a chemically stable polymer base, polydimethylsiloxane (PDMS), cast and cross-linked within 24-well polystyrene plates for ease of use in the cell culture laboratory. The PDMS was formulated into a range of flexible substrates, which were characterized via parallel plate rheometry. Rheological data demonstrated formulation elastic moduli in the range of 3 kPa to 3 MPa that were stable and consistent over an extended time in storage and across multiple batches of prepared material. PDMS surfaces were first coated with fibronectin to allow for cell adhesion, and then seeded at low density with fibroblast or smooth muscle cell types (primary and immortalized cell lines). The initial extent of cell attachment and spreading were quantified utilizing an acid phosphatase assay and fluorescent imaging, respectively. Cell proliferation and growth distribution were also analyzed following multiple days (~96 hours) in culture. Although the amount of initial (<24 hour) cell adhesion appeared to be comparable between PDMS substrates, average area per cell was observed to decrease with decreasing elasticity/stiffness, and histograms of cell circularity (or roundness) displayed variations in the distribution of cell shape in a surface elasticity-dependent manner. Stiffness-dependent trends in growth were also observed, suggesting that these PDMS substrates may

be successfully utilized in the analysis of mechanical contributions to cellular behavior. A thoroughly characterized elastic matrix panel has the potential to greatly facilitate and increase the reproducibility and throughput of a variety of biomechanical investigations.

1592

Three-Dimensional Hyaluronic Acid-Based Hydrogel Systems for Mechanistic Studies of Prostate Cancer.

L. A. Gurski[1,2], X. Xu[2,3], K. L. van Golen[1,2], X. Jia[2,3], M. C. Farach-Carson[2,4]; [1]Biological Sciences, University of Delaware, Newark, DE, [2]Center for Translational Cancer Research, Newark, DE, [3]Materials Science and Engineering, University of Delaware, [4]Biochemistry and Cell Biology, Rice University

We developed a cell culture system using three-dimensional (3D) hyaluronic acid (HA)-based hydrogels optimized to grow bone metastatic prostate cancer (PCa) cells. The choice of HA is consistent with the prevalence of HA within the bone marrow microenvironment, providing a typical environment for bone metastatic PCa cells. Correctly simulating the native environment provides more physiologically relevant mechanistic data about the biology of PCa bone metastasis. The biocompatible cross-linking process used allows PCa cell lines to be directly encapsulated within the HA hydrogel where their growth is limited only by time and space. Cells representing distinct stages of metastasis were encapsulated, where patterns of cell growth were found to differ depending on the aggressiveness of the PCa cells. Aggressive PCa cell lines invaded the hydrogel displaying clear filopodia, while less-aggressive PCa cells did not similarly form these invasive processes. Because the HA hydrogel can interact with HA's two receptors (cluster of differentiation 44 (CD44) and receptor for hyaluronan-mediated motility (RHAMM), we studied the impact of 3D culture in the HA hydrogel on localization of the HA receptors and on the activation of pathways downstream of these receptors. A particular focus was on the downstream pathways able to promote invasion and migration of PCa cells during metastasis. We will show the patterns of activation of the Rho GTPases and their downstream effectors in cells grown in 3D hydrogels compared to cells grown conventionally in tissue culture plates. This work highlights the importance of using physiologically relevant culture conditions to simulate a native process *in vivo*.

Distinct responses to cyclic strain by fibroblasts confined to square versus rectangular fibronectin micro-patterns on elastomer membranes.

N. Gadhari[1], M. Charnley[2], M. Chiquet[1]; [1]Department of Orthodontics and Dentofacial Orthopedics, University of Bern, Bern, Switzerland, [2]Department of Materials, ETH Zurich, Zurich, Switzerland

Fibroblasts sense mechanical cues arising from the extracellular matrix via integrin receptors, which transmit forces to the cytoskeleton and transduce them into downstream chemical signals. As we have shown previously, when fibroblasts grown on fibronectin-coated elastomer substrates are subjected to cyclic strain, RhoA is activated, actin stress fibers increase, and the cells contract. This response is more efficient if cells are pre-stressed, i.e. already develop some cytoskeletal tension. Cytoskeletal pre-stress is known to be related to cell shape. On a fibronectin square of limited size, cells form stress fibers along the edges and in the diagonals, and maximal force is localized to focal adhesions at corners. We hypothesized that by manipulating cell shape and hence the arrangement of cell-ECM adhesions, different levels of pre-stress might be generated within cells, which should change their response to externally applied cyclic strain. To this aim, we micro-contact printed fibronectin squares and rectangles of the same area (2000 μm^2) but with different aspect ratios (1:1, 1:2 and 1:4) onto elastomer

membranes. When mouse embryo fibroblasts were plated on the fibronectin patches and allowed to spread, the majority assumed the shape of the patch. We then applied 90 cycles of 10% cyclic strain over 30 min with a custom-made device, fixed the cells, and monitored the changes in cell shape, cell-matrix adhesion points and actin cytoskeleton by anti-vinculin and phalloidin staining. For cells on fibronectin squares, we observed a 40% decrease in total cell area (indicating contraction), a 2-fold increase in the area and a 4-fold increase in integrated intensity of stress fibers after cyclic strain. In about half of the cells on fibronectin squares, cyclic strain induced their polarization along one of the diagonals. Contrary to our expectation, for cells on rectangles (1:4) we could not measure significant differences in the same parameters after cyclic strain, although a redistribution of stress fibers was visible by eye. In summary, our results indicate that cells forced into square (non-polarized) or rectangular (polarized) shape, respectively, react to externally applied cyclic strain with distinct changes in their actin cytoskeleton. However, the rules and mechanisms remain to be determined.

1594

Mapping mechanical stresses reveals their role in morphogenesis of three-dimensional epithelial tissues.

N. Gjorevski[1], C. M. Nelson[1,2]; [1]Chemical & Biological Engineering, Princeton University, Princeton, NJ, [2]Molecular Biology, Princeton University

Mechanical forces regulate a variety of cellular and morphogenetic processes and drive the changes in shape which sculpt tissues and organs. Deregulation of the mechanical environment can contribute to malignant transformation and progression. Quantitative information about the mechanical forces imparted and experienced by cells and tissues in a physiologically relevant context is important to understand the physical basis of development and disease. Although early development and organogenesis are largely epithelial phenomena and epithelial tissues are the sites of numerous diseases, efforts in mechanobiology have been focused on measuring the forces generated by single cells. Here, we used three-dimensional (3D) traction force microscopy to measure the mechanical stresses exerted by epithelial tissues of arbitrary geometry, embedded within native collagen matrices. Quiescent epithelial tissues were found to exhibit emergent mechanical behavior, different from the individual behavior of their constituent cells. The traction present at the cell-matrix interface was found to be non-uniformly distributed across the epithelium. The mechanical profile of the tissues was dictated by the epithelial geometry, with certain geometrical features consistently exhibiting high levels of traction. Intriguingly, contraction of the epithelial tissue could cause compressive stresses to arise in the microenvironment. The use of native collagen matrices enabled us to recapitulate physiologically relevant tissue-mediated changes in the local material properties. We found that these non-uniformities have a profound effect on the mechanical profile of the tissues. The method presented here allows us to directly measure the mechanical stresses generated by 3D epithelial tissues, define the parameters which govern epithelial force generation and subsequently fabricate tissues with precisely tuned mechanical profiles. The spatially resolved measurement and controlled application of mechanical stress are powerful tools for elucidating the mechanical regulation of epithelial morphogenesis and disease.

1595

Substratum Compliance and Latrunculin B Regulate Matricellular Gene and Protein Expression in Human Trabecular Meshwork Cells.

P. Russell[1], J. Wood[1], S. Thomasy[1], C. Murphy[1]; [1]University of California, Davis, Davis, CA

Objective: To determine how substrate compliance influences the matricellular proteins SPARC (serine protein, acidic, and rich in cysteine) and myocilin (Myoc) when human trabecular

meshwork cells are treated with Latrunculin B (Lat B). Lat B disassembles actin cytoskeleton and is currently in clinical trials to reduce intraocular pressure for the treatment of glaucoma.
Methods: Human trabecular meshwork (HTM) cells from three different donors were cultured on hydrogels that are similar to glaucomatous HTM (75 kPa) and on tissue culture plastic (TCP – gigaPascal compliance). Cells were exposed to 2 µM Lat B or vehicle alone (DMSO) for thirty minutes. Seven hours after recovery from Lat B, RT-PCR was done to measure changes in gene expression of SPARC and Myoc. Immunofluorescence was used to compare changes in mRNA to changes in protein expression.
Results: SPARC and Myoc mRNA expression were dramatically increased on the 75 kPa hydrogels compared to TCP. Even on the cells from the least responsive donor, SPARC was increased 2.7 fold and MYOC increased 11.9 fold. Treatment with Lat B significantly decreased the expression of both SPARC and Myoc on the hydrogels. In contrast, cells grown on TCP produced similar amounts of SPARC and Myoc mRNAs under control and treatment conditions. The changes in immunofluorescence of these two matricellular proteins paralleled changes measured by mRNA.
Conclusions: Substratum compliance directly impacts matricellular gene and protein expression and dramatically alters the effects of Lat B exposure. Our results illustrate that the use of stiff TCP may yield incorrect results when employed for *in vitro* studies of HTM cells.

1596

Optimization of cell adhesion, cell spreading and extracellular matrix assembly on mixtures of immobilized fibronectin domains.

N. W. Karuri[1], S. Karuri[2], P. Kshatriya[1]; [1]Chemical and Biological Engineering, Illinois Institute of Technology, Chicago, IL, [2]National Cancer Institutes

Our research was motivated by the challenge of designing for multiple biological functionalities on synthetic scaffolds. We investigated the influence of varying mixture compositions of a fibronectin and cell binding domains, III_{1-2} and III_{9-10} respectively, on cell adhesion, cell spreading and the amount of fibronectin in the extracellular matrix (ECM) on activated polyurethane surfaces. We used enzyme-linked immunosorbent assays (ELISAs) to detect III_{1-2} and III_{9-10} on the surface and identified a design space defined by the maximum and minimum limits of protein loading. We then obtained a coverage design from the design space; that is, a set of III_{1-2} and III_{9-10} mixture compositions that uniformly covered the design space. NIH-3T3 fibroblasts were cultured on surfaces treated with the coverage design. Cell adhesion and spreading was measured through fluorescence microscopy and the amount of fibronectin in the ECM was determined through immunoblotting. Cell adhesion, spreading and ECM fibronectin were dependent on the ratio of III_{9-10} to III_{1-2}. Models fit to the data were significant ($p<0.05$) and showed maximum values for cell adhesion and ECM fibronectin when III_{1-2} and III_{9-10} were equal. The results obtained from this demonstrate a strategy for the instructive design of multiple biological functions on synthetic scaffolds using different protein domains.

1597

Characterization of Schwann Cells in Self-Assembled Sheets from Thermoresponsive Substrates.

N. Pesirikan[1], W. Chang[1], X. Yu[1], J. Xu[1]; [1]Chemistry, Chemical Biology and Biomedical Engineering, Stevens Institute of Technology, Hoboken, NJ

Schwann cells are the vital glial cells in the development and regeneration of the peripheral nervous system (PNS). Recently, Schwann cell transplantation has emerged as one of many attractive candidates in treating demyelinating diseases resulting from injuries in the central nervous system (CNS) and PNS. Schwann cells for transplantation are usually injected as cell

suspensions or seeded on scaffolds composed of ECM proteins or biodegradable polymers. In these approaches, the adherence junctions between Schwann cells present in vivo are not readily replicated as Schwann cells in suspensions or in scaffolds dispersed as individual cells. Here we describe a procedure to grow large amounts of Schwann cells in a sheet architecture that can be either transplanted or injected, and try to answer some fundamental questions regarding cell viability, proliferation, cell cycle, adhesion, and migration of Schwann cells in the cell sheet. The Schwann cell sheet was successfully generated through coating culture surfaces with layer-by-layer self-assembly of temperature responsive polymer (poly-N-isopropylacrylamide) (PNIPAAM). Further characterization of Schwann cell sheet showed that Schwann cells in sheet were highly viable and maintained lower proliferation rate than individual Schwann cells. The protein level of a cyclin-dependent kinase inhibitor, p27, is increased in Schwann cell sheet. Expression of cadherins and alignment with axon-like nanofibers during adhesion and migration by Schwann cells in cell sheets were not significantly different from these by individual Schwann cells. We conclude that Schwann cell sheet engineering presents a promising method for cell-based nerve injury therapy as well as a model to study the role of interactions between Schwann cells in Schwann cell behavior, i.e. proliferation.

1598

Biomechanical and Biochemical Regulation of Muscle Stem Cell Expansion in Bioengineered Niches.

P. Gilbert[1], B. Cosgrove[2], H. Blau[2]; [1]Stanford University, Stanford, CA

Adult muscle stem cells (MuSCs) are a relatively rare cell type and their stem cell properties are rapidly lost once plated in culture limiting their clinical utility. We hypothesized that the long term culture of MuSCs on surfaces mimicking key features of the in vivo microenvironment would be able to increase their viability, promote division, and maintain their in vivo function. To this end, we employed a novel bioengineered hydrogel culture platform in conjunction with a newly developed automated image analysis computer algorithm and assayed the in vitro and in vivo behavior of MuSCs cultured on hydrogels with different biomechanical and biochemical microenvironmental cues. We found that culture upon soft hydrogel that mimics muscle elasticity greatly enhances MuSC viability and prevents their differentiation compared to rigid plastic. Further, transplantation studies revealed that MuSCs exposed to a soft hydrogel surface with mechanical properties similar to native skeletal muscle self renew and retain similar regenerative potential to freshly isolated MuSCs. Though maintenance of self-renewal potential was achieved using this culture paradigm, MuSCs demonstrated a somewhat limited proliferative capacity. As such, recent efforts focused on identifying biochemical cues that promote MuSC proliferation and expansion in the context of our biomimetic culture platform. Here we report that pharmacological manipulation of key signaling pathways in conjunction with culture upon a biomimetic hydrogel substrate can support MuSC expansion in culture. Our results establish parameters for the long term culture and self renewal of MuSCs in vitro that maintain MuSC function in vivo; an essential step to translate MuSC biology to the clinic for treatment of human muscle degenerative disorders.

1599

Quantitatively tuning cell motility, mechanics, and matrix remodeling by graded genetic activation of RhoA.

J. MacKay[1], A. Keung[1], S. Kumar[2]; [1]Chemical and Biomolecular Engineering, University of California, Berkeley, Berkeley, CA, [2]Bioengineering, University of California, Berkeley, Berkeley, CA

The small GTPase RhoA is a well-known activator of actin polymerization and stress fiber formation and has been shown to regulate a number of cell behaviors, including cell migration, contraction, and extracellular matrix (ECM) remodeling. How these behaviors vary quantitatively with the level of RhoA activation, however, is largely unknown since most direct manipulations of mechanotransductive signaling in living cells have focused only on turning specific proteins "on" or "off". Thus, exploring the effects of more measured changes in RhoA activation will advance our quantitative understanding of mechanotransductive signaling and could reveal important nonlinear relationships (such as an optimal activity level for migration). Towards this goal, we have developed a genetic strategy for modulating the activity of RhoA and its downstream effectors by placing mutant genes under a tetracycline-repressible promoter. The expression level of the mutant proteins can be varied in a graded and dynamic fashion by simply changing the concentration of tetracycline in the cell culture media. Here we have introduced the genetic constructs into human glioblastoma cells to investigate the quantitative dependence of cell motility and mechanics on RhoA signaling in the context of glioblastoma multiforme, a very invasive and lethal brain cancer. We show that graded increases in RhoA activation translate to graded increases in stress fiber assembly, cellular stiffness, and traction force generation. We also show that by temporally varying RhoA activity in cells cultured on collagen hydrogels, we can dynamically control complex cell behaviors, including cell migration, invasion, and ECM remodeling. Thus, in addition to providing quantitative relationships between mechanotransductive signal activation, cellular mechanical properties, and dynamic cell behaviors, this genetic strategy could be used to manipulate cellular mechanobiology both as an experimental tool and as a means of directly controlling cell behavior in bioengineering applications.

1600

Elucidating the mechanobiology of malignant brain tumors using brain matrix-mimetic hyaluronic acid hydrogels.

B. Ananthanarayanan[1], Y. Kim[2], S. Kumar[2]; [1]Bioengineering, Univ California-Berkeley, Berkeley, CA

Glioblastoma multiforme (GBM) is a malignant brain tumor characterized by diffuse infiltration of single cells into the brain parenchyma, which is a process that relies in part on aberrant biochemical and biophysical interactions between tumor cells and the brain extracellular matrix (ECM). A major obstacle to understanding ECM regulation of GBM invasion is the absence of model matrix systems that recapitulate the distinct composition and physical structure of brain ECM while allowing independent control of adhesive ligand density, mechanics, and microstructure. To address this need, we synthesized brain-mimetic ECMs based on hyaluronic acid (HA) with a range of stiffnesses that encompasses normal and tumorigenic brain tissue and functionalized these materials with short Arg-Gly-Asp (RGD) peptides to facilitate cell adhesion. Scanning electron micrographs of the hydrogels revealed a dense, sheet-like microstructure with apparent nanoscale porosity similar to brain extracellular space. On flat hydrogel substrates, glioma cell spreading area and actin stress fiber assembly increased strongly with increasing density of RGD peptide. Increasing HA stiffness under constant RGD density produced similar trends and increased the speed of random motility. In a three-dimensional (3D)

spheroid paradigm, glioma cells invaded HA hydrogels with morphological patterns distinct from those observed on flat surfaces or in 3D collagen-based ECMs but highly reminiscent of those seen in brain slices. This brain-mimetic model system will be used to investigate the mechanisms underlying ECM mechanobiological regulation of brain tumor progression.

1601

Vascular Endothelial Cell Inflammatory Pathways are Dynamically Regulated by Basal and Apical Biophysical Cues.

J. Wood[1], J. Morgan[2], I. Ly[1], M. Hughbanks[1], K. Murphy[1], P. Russell[1], A. Barakat[2], C. Murphy[1,3]; [1]Vet Med: Surg & Rad Sci, Univ of California-Davis, Davis, CA, [2]Mech and Aero Eng, Univ of California-Davis, Davis, CA, [3]Sch of Med, Univ of California-Davis

Over one third of all deaths in the United States were attributable to cardiovascular disease (CVD) in 2006 and the total direct and indirect cost of CVD is estimated at $503.2 billion in 2010. Human vascular endothelial cells (VECs), involved in the onset and progression of CVD, are exposed to biophysical cues on their apical (shear flow) and basal (compliance and nanoscale topography) surfaces. Previous research from our laboratories and others has demonstrated intrinsic biophysical cues of the extracellular matrix profoundly modulate a host of fundamental VEC behaviors. Importantly, the attributes of the biophysical environment of VECs are known to be altered in CVD. Shear flow also regulates VEC behavior, with unidirectional flow inducing an anti-inflammatory cell phenotype and multidirectional flow leading to a pro-inflammatory profile. Despite the fundamental importance of biophysical cues, a significant knowledge gap remains in our understanding of how these biophysical cues are integrated when provided simultaneously to both apical and basal surfaces. Furthermore, how these cues modulate VEC responsiveness to inflammatory mediators remains unknown. Yorkie-homologues YAP (Yes-associated protein) and TAZ (transcriptional co-activator with PDZ-binding motif) are both mediated by biophysical cues and serve as a pair of transducers linking cytoplasmic signaling events to transcriptional regulation in the nucleus. Importantly, they have recently been implicated as nuclear relays of mechanical signals exerted by substratum rigidity. We hypothesize that the biophysical attributes of substratum topography and local stiffness will influence VEC behavior, gene expression, and inflammatory response in an interdependent manner in the presence of either apical unidirectional or multidirectional shear flow. We also hypothesize that YAP/TAZ are critical mediators of the VEC response to both apical and basal biophysical cues. Exciting data demonstrate a dynamic interaction between multiple biophysical cues (shear flow, physiologically relevant substratum topography and compliance) that ultimately result in modulation of endothelial cell behaviors. In addition, data demonstrate that substratum compliance and nanoscale topography significantly modify YAP/TAZ expression. Patterned substrates with 200 nm wide ridges and grooves (400 nm pitch) were found to down-regulate YAP by 1.7 fold and TAZ by 3.2 fold compared to planar surfaces. Similarly, downstream proteins that are either regulated by or influence the YAP/TAZ pathway are also modulated by biophysical cues including ICAM-1, CTGF, KLF-2, and KLF-4 (participants in VEC inflammatory response). Hydrogels with stiffer (75 kPa) compliance values were found to significantly up-regulate ICAM-1 expression in HAECs when treated with TNFa in contrast to 700 nm wide ridges which were found to down-regulate expression. Overall, these data demonstrate that multiple biophysical cues regulate VEC behavior and expression. The results of these studies contribute to our understanding of biophysical cues and vascular biology, have relevance to the design of improved vascular prosthetics and may identify new therapeutic targets for the treatment of CVDs.

1602

A fibrous poly-L-lactic acid substrate promotes mesenchymal phenotype in human epithelial breast cancer cells.

J. McLane[1], C. Rivet[1], R. Gilbert[1], L. Ligon[1]; [1]Rensselaer Polytechnic Inst, Troy, NY

It has become increasingly clear that the tumor microenvironment is a key component in the regulation of cancer progression. However, the effect of physical, acellular cues on cellular phenotype remains poorly understood. The stromal tissue surrounding most epithelial cancers are largely comprised of fibrous extracellular matrix such as type I collagen. Here we developed an in vitro model system to test the effect of the fibrous environment alone, independent of ECM composition, on cell morphology and behavior. We grew cells directly on an acellular fibrous material made up of electrospun poly-L-lactic acid (PLLA), and then examined the effect of the fibrous environment upon growth rate, cell morphology, substrate adhesion, cytoskeletal arrangement, and epithelial to mesenchymal transition markers. We compared the growth of the phenotypically normal breast epithelial cell line MCF10a and the breast cancer cell line MDA-MB-231 on three different substrates: glass coverslips, coverslips coated with a thin film of PLLA or coverslips upon which fibers of PLLA had been electrospun. The role of fibers in promoting a more mesenchymal phenotype was apparent in both cell lines and generally exaggerated in the more metastatic MDA-MB-231. These results suggest that the physical structure of fibers alone, regardless of their ECM content, can promote the mesenchymal phenotype observed in metastasizing cancer cells.

1603

Soluble eggshell membrane stimulate dermal fibroblasts to give young ECM environment in vitro.

Y. Atomi[1], E. Ohto-Fujita[2], T. Konno[3,4], M. Shimizu[2], K. Ishihara[3,4], T. Sugitate[3], J. Miyake[3,5], K. Yoshimura[6], K. Taniwaki[7], T. Sakurai[8], Y. Hasebe[7]; [1]Radioisotope center, The University of Tokyo, Yayoi, Japan, [2]Graduate School of Information Science and Technology, The University of Tokyo, [3]Department of Bioengineering, School of Engineering, The University of Tokyo, [4]Center for NanoBio Integration, The University of Tokyo, [5]Department of Mechanical Science and Bioengineering, Graduate School of Engineering Science, University of Osaka, [6]Department of Plastic Surgery, Graduate School of Medicine, The University of Tokyo, [7]Almado Inc., [8]Department of Life Science, Graduate School of Arts & Science, The University of Tokyo

Deterioration of dermal extracellular matrix (ECM), mainly constituting fibrous collagens and proteoglycans containing carbohydrate, with aging is due to decreased ECM protein turn over. With increasing age, collagen synthesis reduces and matrix metalloproteinases activity levels are elevated in naturally aged human skin. Avian eggshell membrane (ESM) has long been reported to utilize for recoveries from burns and wound, which may activate dermal regeneration. ESM is similar to basal lamina, therefore we hypothesized ESM may contribute to cell adhesion and facilitate ECM molecule synthesis of young dermal tissue. We found that water-soluble alkaline-digested form of eggshell membrane (ASESM) can be used as a material to provide extracellular matrix (ECM) environment for human dermal fibroblast cells (HDF) in vitro. Avian eggshell membrane (ESM) has fibrous-meshwork structure and has long been utilized as a Chinese medicine for recoveries from burns injuries and wound in Asian countries. Therefore ESM is expected to be providing an excellent natural material for biomedical use but those applications were hampered by the insolubility of ESM proteins. In this study a novel 2-methacryloyloxyethyl phosphorylcholine polymer (PMBN) biointerface selectively capture the ASESM proteins were used. The surface shows fibrous structure under atomic force microscope (AFM) and adhesion of HDF to ASESM was ASESM-dose dependent. Quantitative mRNA analysis showed expression of type III collagen, MMP2, and decorin mRNAs was high at

more than two-fold when HDF was faced to lower dose ASESM-PMBN scaffold, which ECM molecules were produced in young dermis and at the begining of would healing. Particle exclusion assay using fixed erythrocytes visualized secreted water-binding molecules around the cells. Thus HDF seems to provide ECM environment on newly designed PMBN-ASESM biointerface and future application of ASESM-PMBN system for biomedical use will be of great interest.

1604

Development of a Method to Non-invasive Ultra-thin Cell Surface Modification of Hepatocytes with PEG-lipid Derivatives.

K. Ohashi[1], K. Tatsumi[1], Y. Teramura[2], H. Iwata[2], R. Utoh[1], T. Okano[1]; [1]Inst Adv Biomed Eng and Sci, Tokyo Women's Medical University, Shinjuku-ku, Japan, [2]Institute for Frontier Medical Sciences, Kyoto University

Introduction: The use of primary hepatocytes for cell transplantation or tissue engineering is considered as a promising regenerative approaches for liver diseases. In addition, primary hepatocytes have been used in culture study for offering an important research tool to study liver-specific functions and metabolism. However, hepatocytes are known to poorly engraft in vivo and to lose their functions within several days under culture condition. Since these problems are likely initiated by the inappropriate interactions between the cellular surface and surrounding extracellular situations, a conceivable strategy to overcome these problems would be to modify the hepatocyte cellular surface. In the present study, we created polymers in which PEG was conjugated with 3 different types of phospholipids and investigated their effectiveness to modify surfaces of primary hepatocytes in vitro. Furthermore, we attempted this surface modification procedure on fabricated hepatocyte sheets.
Mehtods: The surface of murine primary hepatocytes was modified using poly(ethylene glycol)-phospholipids conjugate bearing FITC (FITC-PEG-lipid) in suspension. Hepatocyte function was assessed in vitro by examining cell viability, plating efficiency, protein production, metabolizing activity, hepatocyte-specific gene expressions, and cytochrome P450 induction. The engraftment of the PEG-lipid modified cells was studied following transplantation to both the liver or alternate ectopic sites.
Results: Among the types of phospholipids analyzed in our study, 1,2-dimyristoil -sn-glycerol-3-phosphatidylethanolamine (DMPE) was found to be uniformly anchored to the hepatocyte cell membrane (>99% of hepatocytes). Cell surface modification using FITC-PEG-DMPE did not result in any loss of in vitro functional parameters nor affect the engraftment potential in vivo of modified cells. This modification was also successfully performed on fabricated hepatocyte sheets as wells as dispersed hepatocytes.
Conclusions: The present study an efficient and simple surface modification approach to primary hepatpocytes using FITC-PEG-lipid. The replacement of FITC with functional proteins has the potential to move hepatocyte-based cell therapy another step forward as viable therapeutic application.

Rab GTPases

1605

Guanine nucleotide exchange factor is required for the intracellular transport of proglutelins to protein storage vacuole in rice endosperm.

M. Fukuda[1], M. Satoh-Cruz[2,3], L. Wen[4], T. W. Okita[2], Y. Kawagoe[4], M. Ogawa[5], T. Kumamaru[1]; [1]Faculty of Agriculture, Kyushu University, Fukuoka, Japan, [2]Institute of Biological Chemistry, Washington State University, [3]Faculty of Agriculture, Kyushu University, [4]National Institute of Agrobiological Sciences, [5]Department of General Education, Yamaguchi Prefectural University

Rice glutelins are synthesized on the endoplasmic reticulum as a precursor, which is then transported via the Golgi to protein storage vacuole (PSV) where it is processed to smaller subunits. The glup6 mutant, which contains abnormally large amounts of proglutelin, contains a defective guanine nucleotide exchange factor (GEF), a protein which activates Rab GTPases, key regulators of membrane trafficking. A microscopic study was undertaken to determine the role of GEF in the intracellular transport of proglutelin. Immunofluorescence microscopy of several independent glup6 lines demonstrated the appearance of a novel structure, paramural body (PMB), so named for their location in the paramural space between the cell wall and the plasma membrane. Electron microscopy of glup6 endosperm revealed the presence of proglutelin –containing electron-dense granules within the cell wall in young cells; these granules disappeared at later stages accompanied by increases in the size and number of PMBs. Therefore, the loss of GEF function disrupts proglutelin transport from Golgi to PSV, resulting in secretion of these proteins to the extracellular space, which ultimately leads to the formation of PMBs. Further microscopic analysis showed that PMB contained marker proteins of the prevacuolar compartment and the Golgi apparatus as well as layers of ß-glucan, which were continuous with the cell wall. Overall, GEF functions in the formation of the endomembrane system in rice endosperm and participates in intracellular transport of proglutelin to PSV.

1606

The relationship between Rab5a GTPase and guanine nucleotide exchange factor in the intracellular transport of glutelin in rice seed.

L. Wen[1], M. Fukuda[1], M. Satoh-Cruz[1,2], T. W. Okita[3], M. Ogawa[4], T. Kumamaru[1]; [1]Faculty of Agriculture, Kyushu University, Fukuoka, Japan, [2]Institute of Biological Chemistry, Washington State University, [3]Institute of Biological Chemistry, Washington State University, Pullman WA, [4]Department of General Education, Yamaguchi Prefectural University, Japan

Glutelins, major storage proteins in rice seeds, are initially synthesized on the endoplasmic reticulum as a 57-kDa precursor and then transported via the Golgi apparatus to the protein storage vacuole (PSV) where it is proteolytically processed and stored. Two mutants, *glup4* and *glup6*, have been identified, which contain defects in the small GTPase Rab5a and guanidine exchange factor (GEF) VPS9a, respectively. Both *glup4-rab5a* and *glup6-gef* mutants over-accumulate proglutelin and contain a novel structure, paramural bodies (PMBs), in developing endosperm cells. As rice endosperm expresses several Rab5a and GEF homologues, the relationship between GLUP4-Rab5a and GLUP6-GEF in the intracellular trafficking of glutelin was studied. Immunoprecipitation studies showed that Glup6-GEF and Glup4-Rab5a proteins interacted with each other, suggesting that the Glup6-GEF activates Glup4-Rab5a. Results from additional studies suggest that other Rab5a and GEF homologues may also participate in proglutelin transport, although to a much lesser extent. The ratio of proglutelins to glutelin subunits in mature seeds of the double recessive type of *glup4-rab5a* and *glup6-gef* mutants was significantly higher than seen in each single mutant, indicating that the mutations were

additive. Moreover, microscopic analysis of the double recessive *glup4-rab5a* - *glup6-gef* mutant showed a more severe PMB phenotype than that seen for each individual mutation. These results suggest that although GLUP6-GEF and GLUP4-Rab5a are the dominant GEF and Rab5a partners responsible for intracellular transport of proglutelins to the PSV, other Rab5a and GEF homologues may also play a role, albeit to less prominent extent.

1607

Activation of Rab5 via Diverse Routes of Epidermal Growth Factor Receptor Endocytosis.

I. Jozic[1], C. V. Stefancin[1], M. A. Barbieri[1]; [1]Biological Sciences, Florida International Univ, Miami, FL

The process of endocytosis is a complex pattern of membrane vesicle trafficking, which permits the continuous flow of membrane between cell surface and various intracellular compartments, via fusion and fission events, with Rab5 mediating the fusion events of early endosomes. Since it has been well established that varying concentrations of EGF during the endocytosis of EGF Receptor (EGFR) can elicit uptake via numerous endocytic routes, we examined which of these endocytic pathways is/are responsible for activation of Rab5.
We have found that with respect to the quantity of EGF administered, Rab5 is activated in a concentration dependent manner. It was also observed that if cells are stimulated with low quantities of EGF [2ng/ml], temporal activation of Rab5 peaks at about 2.5 minutes and diminishes within 10 minutes. However, if cells are stimulated with high concentration of EGF [>100ng/ml], the temporal activation of Rab5 is both heightened as well as prolonged, where even 10 minutes after stimulation, relative activity of Rab5 is much higher than at the maximum point during stimulation with low concentration of EGF. Furthermore, by utilizing specific inhibitors as well as siRNA against key regulators of endocytosis and varying the concentration of EGF stimulation we have provided evidence for the existence of at least three distinct pathways of Rab5-dependent internalization of growth factor receptors.

1608

CLN5 is necessary for Rab7 recruitment and activation.

F. Jules[1], A. Mamo[2], S. Lefrancois[2]; [1]Biochemistry, Université de Montreal, Montreal, QC, Canada, [2]Medecine, Université de Montreal, Montreal, QC, Canada

Neuronal ceroid lipofuscinoses (NCL) constitute a family of neurogenetic lysosomal storage disorders which show the highest prevalence, reaching 1 in 12 500 in American and European populations. These diseases are characterized by an accumulation of autofluorescent lipopigments in the cells of affected patients. The accumulation of lipofuscin in neuronal cells leads to a progressive loss of motor and psychological skills and eventually death of affected individuals. The Finnish Late Infantile variant of NCL (vLINCL) is caused by mutations in ceroid lipofuscinosis neuronal protein-5 (CLN5), the biological function of which has yet to be determined. Here we show that CLN5 is in a complex with the small GTPase Rab7 located at the late-endosome. Using a membrane topology assay we show that CLN5 is a transmembrane protein with its N-terminal extremity located in the cytosol. We also demonstrate by co-immunoprecipitation that HA-CLN5 can interact with wild-type RFP-Rab7 and with both the dominant active, Rab7Q67L, and the dominant negative, Rab7T22N, mutants suggesting that CLN5 is not an effector of Rab7. We demonstrate using a GTP loading experiment with Guanosine 5'-triphosphate [g] 4-azidoanilide-2',3'-biotin-long chain-hydrazone (GTPγAA) that knockdown of CLN5 expression leads to a decrease of RFP-Rab7 activation. The use of a GST linked Rab7-interacting lysosomal protein (RILP) allowed us to show a decrease in the ability of Rab7 to recruit this effector following CLN5 suppression. CLN5 deletion in HeLa cells also lead

to a deficiency in the recruitment to endosomes of the retromer subunit VPS26. Taken together these data suggest a role for CLN5 at the late-endosome/lysosome via the activation of Rab7.

1609

Centriolin regulates the Rab11-dependent endosomal-recycling pathway through exocyst anchoring at the centrosome.

H. Hehnly[1], C. Powers[1], S. Doxsey[1]; [1]University of Massachusetts Medical School, Worcester, MA

Centriolin, a component of the mother centriole, localizes to the cytokinetic midbody and is required for cytokinesis. During cytokinesis, the vesicle-tethering complex known as the exocyst is anchored at the midbody through an interaction with the exocyst subunit Sec15 and centriolin. This anchoring regulates vesicle fusion at the cytokinetic bridge. Exocyst subunits were also found to localize at the centrosome, but it is unclear by what mechanism or for what purpose. Here we have examined a role for centriolin in anchoring the exocyst at the centrosome by first defining whether Sec15 is a bona fide centrosome protein. Centrosomes were isolated after the microtubule and actin cytoskeleton were disassembled. Surprisingly, Sec15 and its binding partner, the GTPase Rab11, were both isolated on centrosomes with centriolin. Furthermore, in cells incubated with centriolin siRNAs the exocyst no longer localized to the centrosome. By confocal microscopy and membrane fractionation, centriolin colocalized with the Rab11- and Sec15-decorated recycling endosome. These results suggest that centriolin, Rab11, and Sec15 are centrosome and the pericentrosomal localized recycling endosome components. In addition, electron microscopy confirmed the intimate association of the recycling endosome with the centrosome. Based on these findings, we examined whether centriolin is required for recycling endosome function. Cells incubated with centriolin siRNAs created a disorganized recycling endosome compartment and caused abnormalities in transferrin recycling. In conclusion, centriolin plays a role in regulating the recycling endosome compartment by anchoring the recycling endosome-associated-exocyst complex at the centrosome.

1610

Rab11-Family Interacting Proteins Regulate Distinct Steps in Transferrin Recycling.

N. W. Baetz[1,2], J. R. Goldenring[1,2]; [1]Department of Surgery and Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN, [2]Epithelial Biology Center, Vanderbilt University Medical Center, Nashville, TN

The Rab11-Family Interacting Proteins (Rab11-FIPs) are critical for efficient recycling of proteins to and from the cell surface. The purpose of the current study was to determine whether Rab11-FIPs (FIP1A, FIP1B, FIP1C, FIP2, FIP3, and FIP5) participate in spatially and temporally distinct steps of the recycling pathway. We transfected HeLa cells with fluorescently labeled Rab11-FIPs, conducted live cell studies, and processed the resulting images using deconvolution microscopy. We evaluated compartment size, distribution, movement, and overlap between Rab11-FIPs as well as fluorescent-Transferrin entry into endosomal compartments labeled with Rab11-FIPs. Our results revealed differences in endosomal tubule size, distribution, and movement following expression of GFP-Rab11-FIPs in live HeLa cells. Rab11-FIP1A, Rab11-FIP2, and Rab11-FIP5 each maintained a wide distribution while labeling shorter tubular compartments (1-2 microns in length) that displayed mobility throughout the entire cell with speeds on the order of 1micron per second. Conversely, Rab11-FIP1B, Rab11-FIP1C, and Rab11-FIP3 each occupied more centrally located compartments with a tighter distribution in the perinuclear region with evidence of longer (3-6 microns in length) tubules emanating from this region. Co-expression studies of Rab11-FIPs revealed overlapping signals on tubular endosomal structures and while some members such as FIP1A induced more

elaborate tubulation of other FIP compartments, FIP3 promoted an accumulation of these proteins in the perinuclear region suggesting these proteins have different effects on components of the recycling system. In addition we learned that some FIPs which appear to occupy similar regions of the cells and display similar types of movement, as in the case with FIP1A and FIP2, do not necessarily overlap, indicating a potential difference in functional roles in recycling. Finally, we observed temporal differences in the overlap of fluorescent Transferrin signal with Rab11-FIP compartments. Transferrin overlap with FIP1A, FIP2, and FIP5 occurs the earliest following loading (5-15 minutes) with Transferrin, whereas Transferrin overlap with FIP1B, FIP1C, and FIP3 does not occur until later (20-30 minutes) suggesting these proteins are involved in temporally different steps of the recycling process. In summary, our current data indicate that the Rab11-FIPs occupy different parts of the recycling network and that the participation of these proteins in the recycling process occurs at spatially and temporally distinct steps.

1611

Rab22 controls biogenesis of signaling endosomes in NGF signal transduction.

L. Wang[1], Z. Liang[1], G. Li[1]; [1]Biochemistry and Molecular Biology, University of Oklahoma HSC, Oklahoma City, OK

It’s mostly unknown how growth factors and receptors are sorted into signaling endosomes necessary for signal transduction processes. Here we demonstrate that Rab22 is the only endosomal Rab that promotes the sorting of NGF and activated receptor pTrkA into signaling endosomes to sustain the signal and induce neurite outgrowth/differentiation in PC12 cells. NGF binding induces the endocytosis of pTrkA into Rab22-containing endosomes. Knockdown of Rab22 via shRNA blocks NGF-induced pTrkA endocytosis into the endosomes, gene expression (VGF) and neurite outgrowth. Overexpression of human Rab22 can rescue the inhibitory effects of the Rab22 shRNA, suggesting a specific Rab22 function in NGF signal transduction rather than off-target effects. Furthermore, the Rab22 effector, Rabex-5, is necessary for NGF-induced neurite outgrowth and gene expression, as evidenced by the inhibitory effect of shRNA-mediated knockdown of Rabex-5. Disruption of the Rab22-Rabex-5 interaction via overexpression of the Rab22-binding domain of Rabex-5 in the cell also blocks NGF-induced neurite outgrowth, suggesting a critical role of Rab22-Rabex-5 interaction in the biogenesis of NGF signaling endosomes to sustain the signal for neurite outgrowth. The data provide the first evidence for an early endosomal Rab GTPase as a positive regulator of NGF signal transduction and cell differentiation.

1612

The small GTPase Rab27B regulates invasive tumor growth and metastasis through extracellular HSP90α.

A. Hendrix[1], W. Westbroek[2], O. De Wever[1]; [1]Ghent University, Ghent, Belgium, [2]NIH

Background:
Vesicle exocytosis and exosome release, controlled by small GTPases such as Rab27B, deliver critical pro-invasive growth regulators into the tumor environment. The biological role and expression status of Rab27B in breast cancer was unknown.
Methods:
Rab27B was studied in estrogen receptor (ER)-positive human breast cancer cell lines (MCF-7, T47D, ZR75.1) using GFP-fusion constructs, including wild type Rab3D, Rab27A, Rab27B and Rab27B point mutants defective in GTP/GDP-binding or geranylgeranylation, and transient siRNA targeting. In cell culture, cell-cycle progression was evaluated by flow cytometry, Western blotting and measurement of cell proliferation rates, invasion was assessed using

Matrigel and native collagen type I substrates. Orthotopic tumor growth, local invasion and metastasis were analyzed in mouse xenograft and chick chorioallantois membrane models. Mass spectrometry was performed to identify Rab27B-secreted pro-invasive growth regulators. In clinical breast cancer, Rab3D, Rab27A and Rab27B mRNA levels were analyzed by quantitative real time-polymerase chain reaction (RT-PCR) and Rab27B protein level was evaluated by immunohistochemistry.

Results:

Rab27B-upregulation promoted G1/S phase cell cycle transition and increased proliferation, F-actin reorganization and invasion in cell culture, and invasive tumor growth and haemorrhagic ascites in a xenograft mouse model . Proteomic analysis of purified Rab27B-secretory vesicles and the secretome of exogenous Rab27B-expressing breast cancer cells identified heat shock protein (HSP)90α as key pro-invasive growth regulator. HSP90α secretion occurred in a Rab27B-dependent manner and was required for matrix metalloproteinase(MMP)-2 activation. All Rab27B-mediated functional responses were GTP- and geranylgeranyl-dependent. Endogenous Rab27B mRNA and protein, but not Rab3D and Rab27A mRNA, associated with lymph node metastasis (P=0.0002) and differentiation grade (P=0.0014) in ER-positive human breast tumors.

Conclusions:

Cancer cells communicate with the environment through delivery of surface proteins, release of soluble factors (growth factors and cytokines) and sophisticated nanovehicles (exosomes) for establishment of invasive tumor growth. This communication occurs in part through constitutive exocytosis, regulated exocytosis or release of intraluminal vesicles and is modulated by small Rab GTPases, the master regulators of vesicle traffic. We studied Rab GTPases implicated in regulated exocytosis and demonstrated a unique role for Rab27B in invasive tumor growth. Emerging evidence indicates that various exocytic routes are implemented by cancer cells to relay crucial information for fostering growth, migration and matrix degradation.

1613

Rab33a stimulates vesicular trafficking and promotes axon outgrowth.

H. Nakazawa[1], T. Sada[1], M. Toriyama[1], K. Tago[1], M. Fukuda[2], N. Inagaki[1]; [1]Graduate School of Biological Sciences, Nara Institute of Science and Technology, Ikoma, Japan, [2]Graduate School of Life Sciences, Tohoku University

Axon outgrowth is accompanied by the transport of newly synthesized membranes from the cell body to the neurite tip. Although the small GTP-binding proteins of the Rab family play a key role in membrane trafficking, the molecules involved in membrane transport for axon outgrowth are largely unknown. Previously, we reported a protrein singar1 which suppresses formation of multiple axons in cultured rat hippocampal neurons. Here, we identified rab33a as a singar1-interacting protein. Expression of rab33a became up-regulated during axon outgrowth of cultured rat hippocampal neurons. Rab33a showed relatively high accumulation in the axonal shaft and growth cone, where it colocalized with synaptophysin. Synaptophisin is well known as a major protein localized to synaptic vesicles, but also preferentially localized in the developing axons before synapse formation. Live cell imaging of EGFP-rab33a showed that it is dynamically transported along the neurite shaft together with synaptophysin. Overexpression of rab33a in cultured neurons stimulated trafficking of synaptophysin positive vesicles and induced multiple axon formation. On the other hand, reduction of the expression of rab33a by RNAi inhibited the trafficking of synaptophysin positive vesicles and axon outgrowth. We propose that rab33a promotes axon outgrowth by regulating the trafficking of synaptophysin positive vesicles in neurons.

1614

Rab GTPase-MyosinVb Complex Regulates Exocytosis of Discoidal/Fusiform Vesicles in Bladder Umbrella Cells.

P. Khandelwal[1], W. G. Ruiz[1], D. R. Clayton[1], D. Van Roekel[1], J. R. Goldenring[2], G. Apodaca[1]; [1]Medicine, University of Pittsburgh, Pittsburgh, PA, [2]Surgery and Cell and Developmental Biology, Vanderbilt University

Umbrella cells, the outermost cell layer of the bladder uroepithelium form a selective barrier and experience large variation in hydrostatic pressure and mechanical stress. To neutralize such changes, the umbrella cell modulates its apical surface area by regulated exocytosis of sub apically localized discoidal/fusiform-shaped vesicles (DFV) in response to filling, but little is understood about the molecular machinery that modulates this process. Furthermore, the GTPases that regulate these trafficking events are poorly characterized. We previously localized the small GTPase Rab11a on DFV and showed it regulates DFV exocytosis independent of its well-described role in endocytosis and recycling. Here, we showed that Rab11a-effector MyosinVb was associated with DFV, and the expression of dominant negative (DN) mutant form of MyosinVb inhibited stretch-induced increase in apical cell surface area. Furthermore, the expression of DN-MyosinVb blocked the release of human growth hormone, a secretory protein known to package into DFV. The expression of MyosinVb mutants lacking affinity to Rab8a, Rab10 or Rab11a suggested a role of Rab8a in stretch-induced changes. We observed that Rab8 was expressed in umbrella cells and was partially associated with Rab11a and DFV. Our results indicate that DFV exocytosis depends on the function of the Rab8-Rab11a-MyosinVb complex.

1615

Distinct Roles of Two Rab GAPs, AS160/Tbc1d4 and Tbc1d1, in Intracellular GLUT4 Trafficking Analyzed by Single Molecule Imaging of GLUT4 Behavior.

H. Hatakeyama[1], M. Kanzaki[1]; [1]Graduate School of Biomedical Engineering, Tohoku University, Sendai, Japan

Insulin facilitates translocation of GLUT4, the insulin-responsive glucose transporter, from intracellular storage compartments to the plasma membrane. Insulin signaling regulating these processes is mediated by AS160/Tbc1d4, a TBC1 domain family Rab GTPase-activating protein (GAP), which itself appears to be regulated chiefly by Akt-dependent phosphorylation. Another TBC1 domain family member Rab GAP, Tbc1d1, which is highly homologues with AS160/Tbc1d4 but is abundantly expressed in skeletal muscle cells, has been suggested to control GLUT4 translocation in responses to both insulin and exercise in skeletal muscles. However, due to the technical limitations of conventional approaches, how these proteins regulate intracellular GLUT4 behavior and how their actions differ among each other remains ambiguous. We recently developed a novel method for directly quantifying intracellular GLUT4 movement based on single molecule imaging of GLUT4 behavior (Mol. Biol. Cell 2010) and successfully determined insulin-responsive GLUT4 trafficking systems. Specifically, “static GLUT4 retention” and its “insulin-dependent liberation” are critical properties of these systems, and the former is generated by orchestrated actions of sortilin, a Vps10p family sorting receptor upregulated upon cellular differentiation, with retromer-dependent retrograde trafficking and golgin-97. We herein analyzed the actions of the two Rab GAPs on GLUT4 trafficking systems. In undifferentiated 3T3L1 fibroblasts expressing neither sortilin nor AS160/Tbc1d4 endogenously and therefore incapable of insulin-responsive GLUT4 trafficking, exogenous expression of these two proteins successfully reconstituted the insulin-responsive liberation of static GLUT4. In contrast, fibroblasts expressing both sortilin and Tbc1d1 exhibited no GLUT4 liberation in response to insulin. Interestingly, triple expression of sortilin, AS160/Tbc1d4 and

Tbc1d1 resulted in complete loss of insulin-responsive GLUT4 liberation, indicating that the actions of Tbc1d1 dominate over AS160/Tbc1d4 function. These data suggest that the two analogous Rab GAPs, AS160/Tbc1d4 and Tbc1d1, each have distinct roles in GLUT4 trafficking systems and that the molecular basis of insulin-responsive liberation in muscle cells expressing abundant amounts of Tbc1d1 are more complex than in fat cells expressing mainly AS160/Tbc1d4 alone.

Post-Golgi Trafficking

1616

Super Hypersensitivity to Hygromycin B (s-hhy) Mutants Converge at the Trans-Golgi and Have a Role in Tor1p Localization to the Vacuole.

K. M. Locken[1], D. E. Ejzykowicz[1], E. Gharakhanian[1]; [1]California State-Long Beach, Long Beach, CA

The vacuole in *Saccharomyces cerevisiae* serves as a useful and functional model for the mammalian lysosome. In a genome wide screen for mutants with severe growth hypersensitivity to hygromycin B, our lab identified 14 *HHY* genes. Each of the *hhy* mutants is defective in vacuolar trafficking and/or function (Banuelos et al., 2010). Each of the *hhy* mutants is also sensitive to rapamycin and caffeine suggesting a compromised target of rapamycin (TOR) kinase pathway. Our current research divides the *hhy* mutants into two distinct groups based on quantitative growth analyses in the presence of hygromycin B. 1) a super affected group inhibited at any concentration of hygromycin (s-*hhy's*) and 2) a dose-dependent group, which is more affected as the concentration of hygromycin B increases (d-*hhy's*). The s-*HHY* genes include *ARF1, CHC1, DRS2, SAC1, VPS1, VPS34, VPS45, VPS52,* and *VPS54*. Evaluation of s-*HHY* gene products reveals localization or function at the trans-Golgi to be a common factor. Interestingly, two of the s-*HHY* gene products, Vps52 and Vps54, are components of the GARP complex involved in protein trafficking between the late Golgi and the vacuole, while the deletion strain of a third component of the GARP complex, *vps53Δ*, is unaffected by hygromycin treatment. To assess Tor1 kinase localization, we utilized a strain expressing endogenously tagged Tor1-GFP and assayed localization to the vacuolar membrane in each of the s-*hhy* mutants using confocal microscopy. In wild-type cells, Tor1-GFP co-localizes with the vacuolar membrane marker FM4-64 while several deletion strains including *vps52Δ* and *vps54Δ* fail to localize Tor1-GFP to the vacuolar membrane when treated with hygromycin B. Additionally, s-*hhy* mutants are unable to recover growth after a 4-hour treatment with hygromycin B, similar to EG_0 mutants, which fail to exit from G_0 after treatment with rapamycin.

Based on our data, we propose a model in which the s-*HHY* gene products converge at a hygromycin B hypersensitive microdomain at the trans-Golgi that is involved in post-Golgi vesicular trafficking including recruitment and subsequent transport of Tor1p to the vacuolar membrane. We also propose that Tor1 kinase localization at the vacuole is essential for its cell cycle regulatory function.

1617

Cargos Specify the Site and Identity of Adaptor Recruitment to the Golgi and Recycling Endosomes.

A. Caster[1], P. Shrivastava-Ranjan[2], R. Kahn[1]; [1]Biochemistry, Emory University, Atlanta, GA, [2]Special Pathogens Branch, Division of Viral and Rickettsial Diseases, CDC, Atlanta, GA

About thirty percent of the human proteome moves through the secretory pathway on its way toward secretion from the cell or localization to specific membrane bound organelles. Movement between organelles is marked by the recruitment to nascent carriers by members of the Arf/Sar family of GTPases of specific protein adaptors that mark sites of export, assist in the sorting of transmembrane protein cargos, and help direct movement to the next destination in the endomembrane system; e.g., COPII regulates export from the ER, COPI from the cis-Golgi and AP-1, GGA1-3, and Mint3 are each thought to mark the TGN and help move cargos to endosomes and the plasma membrane. We developed methods to examine specificity and initial sites of adaptor recruitment of Arf-dependent adaptors in a cargo-dependent fashion, with a focus on the Golgi. These methods faithfully recapitulate in cells the specificities determined using in vitro protein binding assays. We find that the same adaptor can be specifically recruited to different organelles by different cargos. In addition, different cargos can recruit a common adaptor to the same organelle but with different consequences to the cargo's export. These results are discussed with respect to the generation of models for molecular mechanisms of membrane traffic and the dangers in extrapolating from one cargo-adaptor pairing to others.

1618

Loss of adaptor protein AP-3 perturbs the regulated secretory pathway *in vivo.*

D. W. Sirkis[1,2], C. S. Asensio[2], R. H. Edwards[1,2]; [1]Graduate Program in Pharmaceutical Sciences & Pharmacogenomics, University of California, San Francisco, San Francisco, CA, [2]Departments of Physiology and Neurology, University of California, San Francisco, San Francisco, CA

The regulated secretion of many neural peptides and peptide hormones depends on their sorting to large dense-core vesicles (LDCVs) capable of regulated exocytosis. LDCVs form at the trans-Golgi network, but the mechanism for protein sorting to this regulated secretory pathway (RSP) is poorly understood. We have recently described a role for the heterotetrameric adaptor protein AP-3 in targeting proteins to the RSP of both *Drosophila* S2 cells and mammalian neuroendocrine PC12 cells. In both cell types, loss of AP-3 dysregulates exocytosis, resulting in decreased regulated secretion and increased constitutive secretion of LDCV proteins. We are currently assessing the role of AP-3 in sorting to the RSP *in vivo*. Using AP-3 mutant *mocha* mice, we have observed marked reductions in the levels of the major LDCV-resident adrenal proteins Secretogranin II and Chromogranin A, suggesting a defect in RSP formation *in vivo*. To directly assess the regulation of secretion, we have used optical imaging by total internal reflection fluorescence (TIRF) microscopy of *mocha* adrenal chromaffin cells. After lentiviral transduction with neuropeptide Y (NPY)-pHluorin, exocytosis was monitored before and after stimulation. Consistent with our previous findings, we observed a significant increase in constitutive secretion of NPY-pHluorin in cells lacking AP-3, but surprisingly, we found no defect in regulated secretion. To extend these findings to another neuroendocrine tissue and assess secretion of an endogenous peptide hormone, we isolated pancreatic islets from wild type and *mocha* mice, measuring basal and regulated insulin secretion. As in the chromaffin cells, we observed a significant increase in unregulated insulin secretion from *mocha* islets, but no change in regulated secretion. We conclude that loss of AP-3 *in vivo* is sufficient to dysregulate the RSP in multiple neuroendocrine tissues, although the differences observed between cell lines and primary *mocha*-derived cells suggest partial compensation for the loss of

AP-3 *in vivo*. Future work will be aimed at elucidating changes to the molecular composition of LDCVs after loss of AP-3 which result in dysregulated secretion.

1619

Clathrin and adaptor-dependent trafficking of Atg27.

V. A. Segarra[1], S. K. Lemmon[1]; [1]University of Miami Miller School of Medicine, Doral, FL

Clathrin is involved in the formation of transport vesicles (CCVs) during endocytosis and protein sorting at the trans-Golgi network (TGN)/endosome. It is recruited to membranes by adaptors that recognize sorting motifs on cargo proteins collected into CCVs and/or regulate CCV formation. Proteomic analysis found that purified CCVs are enriched for Atg27, a type-I membrane protein involved in autophagy. Previous studies have shown Atg27 localizes to the pre-autophagosomal structure (PAS), the Golgi, and Atg9-containing compartments. The possibility that clathrin is involved in the trafficking of Atg27 is consistent with previous findings from our lab showing that clathrin mutants display autophagic phenotypes.

In this study, we further investigate the trafficking of Atg27. Atg27 localized to the TGN/endosome and the vacuolar membrane, in addition to autophagy-related structures like the PAS. Atg27 did not accumulate at the plasma membrane upon treatment with Latrunculin-A, which blocks endocytosis, suggesting it does not cycle through the cell surface along its trafficking itinerary.

A class E *vps* mutant that affects multivesicular body function and CPY sorting to the vacuole did not prevent Atg27 from localizing to the vacuolar membrane, suggesting Atg27 does not follow the vacuolar protein sorting (Vps) pathway to the vacuole. Instead, Atg27's vacuolar membrane localization was dependent on the AP-3 pathway.

We looked for potential sorting signals in Atg27's cytosolic C-terminus. The last four amino acids of Atg27 (YSAV) resemble a classic tyrosine sorting motif (YXXΦ) recognized by the μ chains of AP adaptors. Mutation of the YSAV abrogated Atg27's ability to traffic to the vacuolar membrane, consistent with this functioning as an AP-3 dependent sorting signal. Also, YSAV mutants were still recruited to the PAS and endosomal compartments, although Atg27's co-localization with TGN markers was more prominent, consistent with a defect in export from the TGN.

Studies in yeast have indicated that the AP-3 pathway is clathrin-independent. Inclusion of Atg27 in CCVs suggests that, in addition to AP-3 sorting to the vacuole, Atg27 also undergoes clathrin-dependent trafficking. Interestingly, deletion of *CHC1* resulted in Atg27 localization to many small puncta/vesicles and transport to the vacuolar membrane was impaired. Similar results were found for endosomal epsins (*ent3Δ*/*ent5Δ*), but not *gga1Δ*/*gga2Δ* or AP-1/*apm1Δ*. This suggests an interplay between the AP-3 and clathrin-dependent trafficking pathways, which has not been reported to date in yeast.

1620

Interaction of PAM with μ1A subunit of AP-1 affects trafficking in AtT-20 cells.

M. Bonnemaison[1], Y. Lin[2], J. Bonifacino[2], R. Mains[3], B. Eipper[1]; [1]Molecular Microbial and Structural Biology Dept, U Conn Health Ctr, Farmington, CT, [2]Cell Biology and Metabolism Program, NICHD, [3]Neuroscience Dept, U Conn Health Ctr, Farmington, CT

Peptidylglycine α-amidating monooxygenase (PAM-1), a transmembrane protein, is essential in the biosynthesis of many neuropeptides. The trafficking of PAM-1 in AtT-20 mouse corticotrope tumor cell lines revealed essential roles for its luminal catalytic domains and for its heavily phosphorylated, unstructured cytosolic domain (CD). Upon exit from the *trans*-Golgi network (TGN), PAM-1 is directed to immature secretory granules (ISGs), which must undergo a maturation process before their release becomes secretagogue-responsive. Once in the plasma

membrane after exocytosis, PAM-1 is internalized, entering the endocytic pathway. After passage through multivesicular bodies, PAM-1 can be degraded in lysosomes or sent back to the regulated secretory pathway via the TGN. Both the entry of PAM-1 into SG and its endocytic trafficking are affected by phosphorylation of Ser^{949} in its CD. The adaptor protein 1 complex (AP-1) is involved in cargo recognition for proteins moving between the TGN and endosomes in clathrin-coated vesicles. AP-1 has also been found in patches on ISG membranes, where it removes cargo proteins, facilitating ISG maturation. Although the CD of PAM-1 lacks a canonical AP-1 binding site, a yeast-two-hybrid screen showed that it interacts with the µ1A subunit of AP-1. No interaction with µ2, µ3A, µ3B or µ4 was observed. Alanine scan mutagenesis identified a 10 amino acid region of the PAM-1 CD as the µ1A-binding site. Mutation of Ser^{949} revealed a role for this residue in the interaction. Immunofluorescence studies demonstrated co-localization of AP-1 and PAM-1 in the TGN and SGs. PAM-1 AtT-20 cells were infected with lentiviruses encoding five shRNAs specific for µ1A. Based on Western blot analysis for µ1A, a stable line in which expression of µ1A was reduced by 70% was selected. Cleavage of PAM-1 in SGs produces soluble PHM (sPHM), whose secretion can be quantified. Secretion of mature SGs was stimulated with $BaCl_2$. Secretion of sPHM in PAM-1/µ1A knockdown cells was 45% less responsive to $BaCl_2$ than in PAM-1 cells. The endocytic trafficking of PAM-1 in PAM-1/µ1A knockdown cells was quantified using surface biotinylation. Endocytosed PAM-1 was more stable in PAM-1/µ1A knockdown cells than in PAM-1 cells. The biosynthetic and endocytic trafficking of PAM-1 mutants unable to interact with µ1A resembles PAM-1 trafficking in µ1A knockdown cells. The interaction of PAM-1 with AP-1 is essential for PAM trafficking in the secretory and endocytic pathways.

1621

Dimerization of a model raft-independent protein facilitates apical targeting through transient clustering at the trans-Golgi network.

R. Youker[1], F. Lanni[2], H. Teng[3], Y. Rbaibi[1], O. Kashlan[1], O. Weisz[1]; [1]Department of Medicine, Renal-Electrolyte Division, University of Pittsburgh, Pittsburgh, PA, [2]Biological Sciences, Carnegie Mellon University, Pittsburgh, PA, [3]Molecular Biosensor and Imaging Center, Carnegie Mellon University, Pittsburgh, PA

Defective intracellular delivery of proteins to the apical surface of renal epithelial cells can disrupt polarity, compromise organ function and lead to chronic kidney disease. Proteins sorted to the apical plasma membrane in polarized epithelial cells can be categorized in two classes based on their differential association with cholesterol and glycolipid-enriched membrane microdomains commonly termed “lipid rafts”. Our laboratory and others have previously demonstrated that newly synthesized lipid raft-associated and lipid raft-independent proteins take different routes to the apical surface. Interestingly, these cargoes appear to be segregated into distinct subdomains even within the *trans*-Golgi network (TGN). Self-association or “clustering” is known to be important for the segregation of raft-associated apical proteins but whether oligomerization also contributes to raft-independent sorting is unclear. The apical sorting determinant in p75, a non-raft associated protein that is expressed in bladder and embryonic kidney, resides within its O-glycosylated stalk, and galectin-mediated crosslinking has been proposed as a sorting mechanism for this protein. Additionally, dimerization motifs within the transmembrane region of p75 could contribute to the formation of oligomers. We used fluorescence correlation spectroscopy (FCS) and photon counting histogram (PCH) analyses to measure the spatial and temporal dynamics of p75 trafficking in live cells. As predicted, p75 exists as a dimer at the plasma membrane in the absence of ligand, as previously reported. However, PCH analysis revealed that p75 forms higher-order oligomers within the *trans*- TGN and this oligomerization is abrogated upon mutation of a conserved transmembrane cysteine residue (C257A). In addition, clustering of p75 in the TGN appears to be dynamic, based on the

range of complex sizes observed and because only the dimer form was detected at the plasma membrane. Finally, the C257A mutation increased the levels of p75 at the basolateral membrane in polarized cells, suggesting that dimerization plays a role in apical targeting.

1622

STK16, a Novel MAL2 Binding Partner, Regulates Basolateral Secretion in Polarized Hepatic Cells.

J. G. In[1], A. Bernad[2], P. L. Tuma[1]; [1]Department of Biology, The Catholic University of America, Washington, DC, [2]Department of Regenerative Cardiology, Centro Nacional de Investigaciones Cardiovasculares, Madrid, Spain

Most classes of newly synthesized hepatic apical proteins take an indirect pathway to the cell surface. They are delivered from the TGN to the basolateral domain, selectively internalized then transcytosed to the apical surface. MAL2 has been implicated in regulating at least two steps in this pathway. Because vesicle formation and delivery are driven by complex machineries, we predict that MAL2 exists in large multi-protein complexes. To identify MAL2 interactors, we performed a split-ubiquitin yeast two hybrid screen using human MAL2 as bait. From a human liver cDNA library, serine-threonine kinase 16 (STK16) was identified. This lipid-anchored kinase is enriched in liver and shown to regulate mammary gland development implicating it as a likely candidate for regulating polarized protein trafficking. In rat liver, MAL2 and STK16 both distributed to the same membrane fractions after differential centrifugation suggesting they interact. This was confirmed by co-immunoprecipitations in rat liver and polarized, hepatic WIF-B cells. When overexpressed in WIF-B cells, STK16 localized mainly to the Golgi with a lesser amount at the basolateral membrane. However, kinase-dead STK16 (E202A) localized to bright puncta in the cell periphery. To determine whether E202A expression disrupted the Golgi, we double labeled with several Golgi markers. Surprisingly, we found that the Golgi remained intact. Treatment with Brefeldin A did not affect E202A, implying they are in post-Golgi vesicles. Additionally, a total TGN block at 20°C followed by a 37°C chase led to redistribution of E202A from the TGN back to the bright puncta, confirming that E202A is in a post-Golgi vesicle. Interestingly, when E202A-expressing cells were labeled for the secretory proteins, albumin and haptoglobin, no staining was detected. Immunoblotting revealed that all albumin forms were decreased to the same extent in E202A-expressing cells indicating that the protein was being properly processed. To account for decreased albumin staining, we reasoned that albumin and haptoglobin were either hypersecreted (preventing Golgi-accumulation) or were misrouted to the lysosome for degradation. Immunoblotting of media from E202A-expressing cells revealed that albumin and haptoglobin were not being hypersecreted. In contrast, in E202A-expressing cells treated with ammonium chloride to deacidify lysosomes, intracellular levels of albumin were increased. Thus, we predict that in E202A-expressing cells, the secretory proteins are being diverted from the TGN to lysosomes for degradation. We are actively examining how MAL2 is involved in this process.

1623

Basolateral sorting of VSVG and LDLR involves the sub-apical Rab11 compartment.

C. E. Retamal[1,2], A. L. Gonzalez[1,2]; [1]Center for Aging and Regeneration (CARE), Facultad de Cs Biologicas, P. Universidad Catolica de Chile, Santiago, Chile, [2]Departamento de Inmunologia Clinica y Reumatologia, Fac. Medicina P. Universidad Catolica de Chile, Santiago, Chile

Polarized epithelial cells maintain a distinct apical (AP) and basolateral (BL) plasma membrane (PM) protein composition through sorting events in exocytic and endocytic pathways. After exiting the trans-Golgi network (TGN), proteins en route to the cell surface can traverse distinct endosomal compartments. So far, the rab11 sub-apical recycling endosomes have been

identified as an intermediary only for the basolateral sorting of E-cadherin. Here we analyzed by three dimensional live cell imaging the post-TGN routes of three classical basolateral model proteins (VSVG, LDLR and TfR) in MDCK cells stably expressing either TGN38-CFP or Rab11-CFP. After microinjection of plasmids encoding VSVG-mCherry, LDLR-GFP, and TfR-GFP, the expressed proteins were accumulated at the TGN by 20º block and then released at 37°C. VSVG-mCherry and endocytosis defective LDLR-GFP was detectable in the rab11 compartment within 15-30 min, reaching a maximun at about 40 min and then gradually decreased until almost disappearing, while the basolateral cell surface localization increased. TfR reached the basolateral surface without being detectable in this compartment. Membrane permeable peptides carrying competitive BL sorting signals for VSVG and LDLR block trafficking of the corresponding cargo towards both the rab11 endosomes and the basolateral surface. Strikingly, VSVG and LDLR colocalize in the same transport vesicles. These results show for the first time the involvement of the rab11 sub-apical compartment in biosynthetic basolateral sorting of VSVG and LDLR, but not TfR. Experiments with competing peptides indicate that trafficking from TGN to the rab11 compartment is sorting signal mediated and involves different recognition elements, which nevertheless seems to segregate them into the same transport carriers (Financed by CONICYT grant#PFB12/2007, grant#AT24100203 and FONDECYT grant#1110849).

1624

Rho GTPases are involved in regulating transport of influenza A virus hemagglutinin and neuraminidase in host cell.

S. Wang[1], H. Li[1], H. Wei[1], Y. Chen[1], J. Chen[2]; [1]Chinese Academy of Sciences, China, [2]Chinese Academy Scis-Inst Microbiol, Beijing, China

Influenza A virus, a highly infectious respiratory pathogen, is the major cause of annual epidemics and occasional pandemics. Influenza A virus assembles at the plasma membrane of infected host cells, releases by budding, so that possesses a lipid membrane derived from the host cell. This envelope contains two important transmembrane glycoproteins: hemagglutinin (HA) and neuraminidase (NA). Both HA and NA play a critical role throughout the virus life cycle. Because HA and NA are responsible for binding to and release from host cell receptors, they are crucial in determining host specificity. On the other hand, influenza A virus uses the machineries of host cells to synthesize and transport HA and NA. However, little is known about what host cellular factors that are involved in the regulation of intracellular and cell surface transport of HA and NA. Additionally, the mechanism by which viral HA and NA usurps the components of the host trafficking machineries to undergo exocytic transport remains to be further determined. In this study, we have investigated whether Rho family GTPases are involved in regulating the trafficking of HA and NA in the host cell. Using expression of constitutively active or inactive mutants of GTPases, we found that RhoA, Rac1 and Cdc42 exhibited different functions in regulating the intracellular and cell surface transport of HA and NA. Furthermore, using shRNAs to disrupt the expression of these Rho family members, we observed that some but not all Rho family members are required for intracellular and cell surface transport of HA and NA, and thereby affect virus life cycle. Together, our results reveal that members of Rho family are involved in the transport of HA and NA in host cell and thereby impacts virus replication.

1625

Myosin V transports secretory vesicles via a Rab GTPase cascade and direct contact with the exocyst complex.

Y. Jin[1], A. Sultana[2], P. Gandhi[3], E. Franklin[2], S. Hamamoto[4], A. Khan[2], M. Munson[3], R. Schekman[4], L. Weisman[1]; [1]Life Sciences Institute, University Michigan, Ann Arbor, MI, [2]School of Biochemistry and Immunology, Trinity College, Dublin, Ireland, [3]Department of Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA, [4]Department of Molecular and Cell Biology, HHMI, University of California at Berkeley, Berkeley, CA

Vesicle transport requires four steps: vesicle formation, movement, tethering and fusion. In yeast, two Rab GTPases, Ypt31/32 are required for post-Golgi vesicle formation. A third Rab GTPase, Sec4, and the exocyst act in the subsequent tethering and fusion of these vesicles. Vesicle production is coupled to transport via direct interaction between Ypt31/32 and the yeast myosin V, Myo2. Here we show that Myo2 interacts directly with Ypt31/32, Sec4, and the exocyst subunit Sec15. Disruption of the interaction between Myo2 and Sec15, or Myo2 and the Rab GTPases, results in severe growth defects and the accumulation of secretory vesicles. Furthermore, mutants that are defective in the interaction of Myo2 with Sec15 result in the mislocalization of Sec15. We identified the Sec15-binding region on Myo2, and found that it is on the opposite face from the Rab-binding site. This suggests that Myo2, Sec4 and Sec15 may form a ternary complex. In addition, we identified residues on Sec15 required for interaction with Myo2. Moreover, we identified a suppressor mutation in this region of Sec15, which rescues the growth defect of the Myo2 mutants that have a defect in binding to Sec15. The finding that Myo2 interacts with Sec15 uncovers a new role for the exocyst as an adaptor for molecular motors, and implies a similar role for other structurally related tethering complexes. Moreover, these studies predict that for many pathways, molecular motors attach to cargoes prior to their formation, and remain attached until fusion at the target membrane.

1626

The Role of the Exocyst in Ciliogenesis.

J. Lipschutz[1], B. Fogelgren[1], S-Y. Lin[2], X. Zuo[1], K. Jaffe[2], S. McKenna[1], K. Park[3], P. Bell[4], R. Burdine[2]; [1]University of Pennsylvania, Philadelphia, PA, [2]Princeton, [3]Kyungpook National University, [4]Medical University of South Carolina

ADPKD is characterized by cyst formation that destroys the kidney. Primary cilia, found on many cell types, including renal tubule cells, participate in flow sensing. Cilia disruption has been linked to ADPKD pathogenesis. Mutations in PKD1 and PKD2, encoding polycystins-1 and-2, cause ADPKD. Polycystins are thought to function in cilia, but it is not well understood how these and other proteins are targeted to cilia. We previously showed that the exocyst, a highly conserved eight-protein trafficking complex, localizes to primary cilia of renal tubule cells and is required for ciliogenesis. We also showed that when a crucial exocyst component, Sec10, is knocked down, the results are ADPKD cellular phenotypes including: loss of flow-generated calcium increases; hyperproliferation; and abnormal activation of the mitogen activated protein kinase (MAPK) pathway. In vivo, Sec10 knockdown in zebrafish phenocopied many aspects of polycystin-2 knockdown, including: curly tail up; left-right patterning defects; glomerular expansion; and MAPK activation. Sec10 morphants also had disorganized cilia. Importantly, we demonstrated a synergistic genetic interaction between zebrafish sec10 and pkd2, in that co-injection of small amounts of sec10 and pkd2 morpholinos, which individually had no effect, together resulted in a severe phenotype. We went on to show that Sec10 biochemically interacts with polycystin-2, IFT88, and IFT20, a ciliary protein known to be trafficked on vesicles. We next wanted to answer the question of how the exocyst first localizes

to primary cilia so that it can participate in ciliary trafficking. Multiple Rho and Rab GTPases regulate the exocyst, and Cdc42, which we previously showed to be involved in cystogenesis, is a candidate to regulate the exocyst at the primary cilium. We now show Cdc42 biochemically interacting with Sec10, and co-localizing with Sec10 at the primary cilium. Dominant negative Cdc42 expression, shRNA-mediated knockdown of Cdc42, and shRNA-mediated knockdown of Tuba, a Cdc42 GEF, all prevent ciliogenesis in Madin-Darby canine kidney cells. Furthermore, exocyst Sec8 and polycystin-2 no longer localize to primary cilia, or the ciliary region, following Cdc42 and Tuba knockdown. We also show Sec10 directly interacting with the Par complex member Par6, which, itself, directly interacts with Cdc42. Finally, we show Cdc42 knockdown resulting in MAPK activation. Several groups have shown that the exocyst interacts with Rab8, the mammalian homologue of yeast Sec4. Sec4/Rab8, a protein found on the surface of vesicles, interacts with Sec10 and Sec15 for vesicle targeting and docking at plasma membranes. Taken together, these data support a model whereby Cdc42 localizes the exocyst to primary cilia, the exocyst is stabilized by binding to Par6, and the exocyst then targets and docks Rab8-positive vesicles carrying ciliary proteins.

1627

The Oculo-Cerebro-Renal Syndrome of Lowe as a Ciliopathy: Role of Ocrl1 in Primary Cilia Assembly.

B. G. Coon[1], K. Madhivanan[1], V. Hernandez[2], D. Mukherjee[1], C. B. Hanna[1], M. Lowe[3], P. Beales[2], C. Aguilar[1]; [1]Department of Biological Sciences and Purdue Center for Cancer Research, Purdue University, West Lafayette, IN, [2]Molecular Medicine Unit, University College London Institute of Child Health, United Kingdom, [3]Life Sciences, University of Manchester, United Kingdom

Lowe syndrome is a devastating, X-linked genetic disease characterized by the presence of congenital cataracts, profound learning disabilities and renal dysfunction. Unfortunately, children affected with Lowe Syndrome often die early of health complications including renal failure. Although this syndrome was first described in the early fifties and the affected gene, OCRL1, was identified more than 17 years ago, the mechanism by which Ocrl1 defects lead to Lowe syndrome's symptoms remains unknown.

Here we show that Lowe syndrome display some of the the characteristics of a ciliopathy. Specifically, we found that patients' cells have defects in the assembly of primary cilia and this phenotype was reproduced by knock-down of Ocrl1 in cells in culture. Importantly, this defect could be rescued by re-introduction of WT Ocrl1 in both, patient's and Ocrl1 knock-down cells. In addition, a zebrafish animal model of Lowe syndrome exhibited cilia defects and multiple morphological and anatomical abnormalities typically seen in ciliopathies. Mechanistically, we show that Ocrl1 is involved in protein trafficking to the primary cilia in a Rab8-, Appl1- and IPIP27/Ses-dependent manner via the secretory and endocytic pathways.

Taking into consideration the relevance of the signaling pathways hosted by the primary cilium, our results suggest hitherto unrecognized mechanisms by which Ocrl1 deficiency may contribute to the phenotypic characteristics of Lowe syndrome. This conceptual change in our understanding of the disease etiology may provide an alternative avenue for the development of therapies.

1628

Relaxin improves cystic kidney disease in rats and alters transcription of ciliary trafficking genes.

H. Ward[1], L. Danielson[1], G. Pickett[2], S. Ness[2], C. Phillips[3], B. Cowley[4], A. Wandinger-Ness[1];
[1]Pathology, University of New Mexico, Albuquerque, NM, [2]Molecular Genetics and Microbiology, University of New Mexico, Albuquerque, NM, [3]Pathology, Indiana University School of Medicine, Indianapolis, IN, [4]Medicine, Oklahoma University HSC, Oklahoma City, OK

Human autosomal dominant polycystic kidney disease (ADPKD) is characterized by renal epithelial cell proliferation and renal cyst formation, ultimately destroying kidney structure and function. Underlying the pathogenic mechanisms are changes in signaling pathways that affect cellular behavior predominately in the kidney, liver and vasculature. The hormone relaxin is essential for renal vasodilation during pregnancy, regulation of nitric oxide production and several signaling pathways, cAMP production, and collagen formation and degradation. The same pathways and processes are aberrant in ADPKD. Heterozygous Han:SPRD rats manifest ADPKD similar to human ADPKD. We treated male Cy/+ and +/+ Han:SPRD rats with relaxin or vehicle control. The effects on renal structure and function included decreased cyst size and decreased fibrosis. Analyses of renal mRNA profiles from treated and untreated animals revealed expression changes in genes encoding signaling and trafficking proteins. Notable changes were detected in Ras, Rab7, Rab8, and ArfGEF1, in addition to intraflagellar transport protein 80, exocyst complex component 8 and RIMS1. The findings concur with our previous studies demonstrating the importance of GTPase-mediated trafficking in the proper delivery of polycystin-1 to cilia. The data suggest relaxin mediated alterations in GTPase and exocytic protein expression may contribute to improved renal structure and function in the Han:SPRD rat model of ADPKD following relaxin treatment.

1629

Novel role of PICK1-ICA69 complex in insulin granule biogenesis.

Z. Mao[1], M. Cao[1,2], J. Xia[1]; [1]Hong Kong University of Science and Technology, Hong Kong, [2]Yale University

Diabetes is a group of metabolic diseases characterized by hyperglycemia that result from defects in insulin secretion and/or action. However, the cellular mechanisms and molecular components responsible for the biogenesis of insulin granules are not fully understood and remain an area of intense investigation. PICK1 (Protein Interacting C Kinase 1) is a membrane-associated protein which contains PDZ (PSD-95/Dlg/ZO-1) domain and BAR (Bin/ Amphiphysin/ Rvs) domain. It is widely expressed with high levels in brain, testis and also in pancreas. ICA69 (Islet Cell Autoantigen 69kD), another BAR domain-containing protein, forms tight heteromeric BAR complex with PICK1. As the PDZ domain binds to membrane proteins and the BAR domain binds to liposome, PICK1-ICA69 complex is able to couple several kinds of membrane proteins to the vesicles and regulate their trafficking. We found that that PICK1-ICA69 was also associated with insulin granules and played important roles in insulin granule biogenesis. Deficiency of PICK1 in mice leads to abnormal insulin level and glucose intolerance. To further understand how PICK1 and ICA69 regulate insulin granule trafficking, we have investigated the molecular mechanism underlying PICK1 and ICA69 mediated insulin granule biogenesis and our results have revealed an interesting link between PICK1-ICA69 and insulin granule formation. (Supported by Research Grant Council of Hong Kong).

1630

Adiponectin is released via a unique regulated exocytosis pathway upon insulin stimulation.

C-Y. Lim[1], W. Hong[2], W. Han[1]; [1]Laboratory of Metabolic Medicine, Singapore Bioimaging Consortium, Singapore, [2]Institute of Molecular and Cell Biology, Singapore

Adiponectin, a key regulator of insulin sensitivity at the whole body level, is released from adipocytes at high rate into circulation. Reduced serum level of adiponectin and down-regulation of its mRNA expression are strongly associated with insulin resistance, early onset of Type 2 diabetes and obesity. Despite the importance of this adipokine in metabolism and energy homeostasis, the mechanism of its secretion from adipocytes remains poorly understood. Here, we investigated the subcellular localization of adiponectin, and its secretion regulation in differentiated 3T3-L1 and primary mouse adipocytes by using biochemical methods and fluorescence microscopic imaging. Adiponectin was localized in vesicular compartments, with no apparent overlap with p115, GM130 or syntaxin 6. Adiponectin-containing vesicles were enriched in two distinct pools: one at the plasma membrane and the other co-fractionating with ER membranes. We established a stable 3T3-L1 cell line expressing adiponectin-Venus, and confirmed that the adiponectin-venus vesicles completely overlap with endogenous adiponectin vesicles. When viewed under a TIRF microscope, a subset of adiponectin-venus vesicles were readily detected within the evanescent field in close proximity to plasma membrane, and could be released in response to insulin. The N-terminal signal peptide was required to direct the delivery of adiponectin into proper vesicles. Moreover, overexpression of adiponectin-venus carrying an ER retention motif (KDEL) impeded the detection of tubule-vesicular structure, indicating that the adiponectin-containing vesicles in the TIRF zone are post-ER and post-Golgi. Immuno-electron microscopy showed that adiponectin-venus proteins were present in vesicular structures in the vicinity of the plasma membrane. Finally, insulin-stimulated adiponectin release appeared to be from a pre-exiting pool of vesicles, and was not dependent on de novo protein synthesis, as adiponectin mRNA level remained unchanged over a 6-hour period of insulin treatment, and inhibition of protein synthesis had no effect on adiponectin release. Taken together, our results show that adiponectin is stored in a unique subcellular compartment, and a subset of adiponectin is released through a distinctive regulated exocytosis pathway.

1631

Regulation of cAMP-dependent Weibel-Palade body exocytosis from endothelial cells.

K. van Hooren[1], E. van Agtmaal[1], M. Fernandez-Borja[2], R. Bierings[1], J. Voorberg[1]; [1]Plasma Proteins, Sanquin, Amsterdam, Netherlands, [2]Molecular and Cellular Biology, sanquin, amsterdam, Netherlands

Vascular endothelial cells provide a dynamic interface between circulating blood and underlying tissues that is critically involved in maintaining vascular integrity and homeostasis. Rapid recruitment of bio-active components from intracellular storage pools has been shown to contribute to the critical role of endothelial cells in maintaining vascular homeostasis. A significant number of haemostatic components and inflammatory mediators originate from endothelial cell-specific, cigar-shaped organelles called Weibel-Palade bodies (WPBs). WPBs function as storage vesicles for von Willebrand factor (VWF), a multimeric adhesive glycoprotein crucial for platelet plug formation, the leukocyte receptor P-selectin and a number of bioactive compounds that include the chemoattractants IL-8 and eotaxin-3. WPBs release their content following stimulation with agonists increasing intracellular Ca^{2+}, like thrombin, or agonists increasing intracellular levels of cAMP, such as epinephrine.

The physiological importance of this cAMP mediated pathway is illustrated by the rise in VWF levels in patients with von Willebrand's disease and mild hemophilia A following administration

of the vasopressin analogue desmopressin (DDAVP) or epinephrine. We have previously shown that this cAMP mediated WPB release is partly dependent on protein kinase A and involves the activation of the small GTPase RalA.During PKA regulated exocytosis a subset of the WPBs is able to escape secretion by perinuclear clustering at the microtubule organizing centre (MTOC), which involves retrograde transport of vesicles mediated by the dynein-dynactin complex
Here, we explored whether guanine nucleotide exchange factor Epac1 (exchange protein activated by cAMP 1) and its substrate, the small GTPase Rap1, are involved in cAMP-dependent regulation of WPB exocytosis. Epinephrine stimulation of endothelial cells leads to activation of the small GTPase Rap1 in a PKA-independent fashion. siRNA-mediated knockdown of Epac1 completely abolishes epinephrine-induced activation of Rap1 and decreases epinephrine-induced WPB exocytosis. We subsequently addressed whether Rap1 is crucial for WPB release using siRNA specific for Rap1. Downregulation of Rap1 expression abolished epinephrine but not thrombin-induced release of WPBs. Prevention of Rap1-activation through over-expression of Rap1GAP also effectively inhibits epinephrine-induced WPB exocytosis. Taken together, these data show that the Epac1-Rap1 pathway regulates WPB exocytosis by endothelial cells in response to cAMP-raising agonists.

1632

TLR-dependent regulation of MHC molecule transport is orchestrated by MARCH E3 ligase-dependent ubiquitination in antigen presenting cells.

A. De Gassart[1], F. De Angelis-Rigotti[1], P. Pierre[1], E. Gatti[1]; [1]Centre d' Immunologie de Marseille Luminy, CNRS-INSERM- Universite de la Mediterranee, Marseille, France

MARCH ubiquitin ligases have been recently identified on the basis of their homology to immunosuppressive viral factors. In mammalian cells, some MARCHs target immunorelevant receptors, promoting downregulation of specific antigen presentation molecules. Out of a family of 10 related ligases, we have identified MARCH I as the mediator of MHCII downregulation in human dendritic cells. MARCH VIII also targets MHCII and CD86, while MARCH IX acts on MHC I. MARCHs expression in human DCs is differentially regulated in response to specific environmental signals, such as TLR ligation or IL-10. The alteration of the correct expression pattern of these ligases could constitute for tumor cells a strategy to escape for immunosurveillance. To understand their function, we characterized the transcriptional regulation of MARCH E3 ligases in response to different conditions and its effect on the export of neosynthesized MHCI molecules through the secretory pathway, in the attempt to explore their function in the global coordination between pathogen stimulation and antigen presentation up-regulation of DC function.

1633

A zebrafish mutation in an exocytic machinery component reveals a requirement for membrane trafficking during chondrocyte cytokinesis.

D. S. Levic[1], D. B. Melville[1], E. W. Knapik[1]; [1]Medicine, and Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

Vesicular trafficking is a fundamental cellular process and is central to maintaining organization and function along the secretory pathway. In addition to this role during interphase, however, membrane transport is also critical for completing cytokinesis, the terminal stage of mitosis. The mechanisms associated with membrane targeting to the midbody during cytokinesis remain poorly understood. Using a forward genetics approach in zebrafish to identify genes required for craniofacial development, we have identified a mutation in a novel component required for cytokinesis in chondrocytes. We show that mutant chondrocytes initially deposit cartilage extracellular matrix (ECM) proteins normally but then undergo apoptosis at later stages,

disrupting craniofacial morphogenesis. Histological and immunohistochemical analyses reveal that mutant chondrocytes appear to be stalled in cytokinesis; these cells form actin-rich cleavage furrow but fail to complete abscission. Using immunofluorescence and transmission electron microscopy, we show that mutant chondrocytes accumulate vesicular structures similar in morphology to transport vesicles during both cytokinesis and interphase. Unexpectedly, we discovered that although these cells fail to secrete N-glycosylated cargo, secretion of type II collagen is unaffected. Our results suggest that the exocytic machinery is not a homogenous conduit. Instead, we propose a model in which specific components of exocytic machinery differentially regulate ECM protein secretion. Our study further suggests that matrix secretion and membrane trafficking during cytokinesis share common regulatory mechanisms.

Endosomes, Lysosomes, and Lysosome-related Organelles

1634

To enter or not to enter: differentiating machinery from cargo in the MVB pathway.

S. Mageswaran[1], M. Babst[1]; [1]Biology, University of Utah, Salt Lake City, UT

The Multivesicular body (MVB) pathway is the major pathway for the degradation of integral membrane proteins under normal cellular conditions. It is also important for the termination of cellular signals by sequestering the signaling membrane proteins away from the cytosol. MVBs are mature endosomes that contain internalized vesicles derived from the limiting membrane by an invagination process. This process is catalyzed and directed away from the cytosol by cytosolic protein complexes called ESCRTs (Endosomal Sorting Complexes Required for Transport). They recognize ubiquitinated (Ub) integral membrane proteins on the endosomal membrane and package them into the intralumenal vesicles. These internalized cargo proteins/lipids are ultimately delivered to the vacuole/lysosome for degradation upon fusion between endosomal and vacuolar/lysosomal limiting membranes. This function of ESCRTs is conserved from yeasts to humans. ESCRTs themselves predominantly stay outside MVBs by getting recycled off the endosome into the cytosol to be used for subsequent rounds of cargo sorting and vesicle formation. This process of ESCRT-recycling is not clear although we know that it requires the AAA ATPase Vps4 and that Vps4 directly binds to the final ESCRT complex, ESCRT-III. It is particularly intriguing as to how the early ESCRTs (ESCRT-0, -I and –II) are recycled back into the cytosol without any known direct interaction with Vps4. In this study, we explored a lattice/strong interaction-mediated recycling model in Saccharomyces cerevisiae wherein the ESCRTs get released off the endosome by virtue of their strong interactions with each other. To test this model, we constructed a chimeric ESCRT-like protein that binds ESCRT-III and endosomal membrane with GFP as a reporter. The ESCRT-III interacting domain is the MIT domain of Vps4 and the endosomal membrane interacting domain is the FYVE domain of the mammalian protein EEA1 that binds phosphatidyl inositol 3-phosphate on endosomes. Like ESCRTs, this chimeric protein gets recycled back into the cytosol. But when its interaction strength with ESCRT-III is weakened, the ESCRT-like protein gets packaged into MVB as a cargo. This observation agrees with recent evidence for ESCRT-I being partially packaged into the MVB. We are currently trying to directly test this interaction-strength-model for the recycling of ESCRT-I and ESCRT-I–like chimeras. Thus this study attempts to explain how ESCRTs manage to stay away from the vacuole to repeatedly function at the endosome. From the cargo point of view, it is noteworthy that we show for the first time that cytosolic cargo can be packaged into MVBs in a Ub-independent fashion.

1636

Mucolipin-1 induces fusion of lysosomes with the plasma membrane.

J. Martina[1], R. Puertollano[1]; [1]NIH, Bethesda, MD

Mucolipins represent a newly described family of cation channels that mediate release of calcium from the lumen of endosomes and lysosomes. It is well established that efflux of luminal calcium is required for endosomal fusion and plays a critical role in the maintenance of luminal pH and homeostasis. In humans, mutations in Mucolipin-1 (MCOLN1) cause Mucolipidosis type IV (MLIV), a lysosomal storage disorder characterized by severe and debilitating neurological and ophthalmologic abnormalities. In agreement with the significant role of calcium efflux in membrane trafficking, we have previously described that fusion between autophagosomes and lysosomes is impaired in fibroblasts from MLIV patients and this leads to defective autophagy and neuronal death. Here we describe a new and novel function for MCOLN1 in inducing lysosomal exocytosis. Expression of MCOLN1 induces fusion of lysosomes with the plasma membrane as revealed by secretion of active lysosomes hydrolases into the medium and by the accumulation of LAMP-1 at the cell surface. Depletion of ALG-2, a penta-EH-hand calcium-binding protein that interacts with MCOLN1 in a calcium-dependent manner, dramatically reduced the secretion of lysosomal enzymes mediated by MCOLN1. Lysosomal exocytosis was also significantly decreased by depletion of Rab7, while absence of PLEKHM1, a negative regulator of Rab7, increased the release. Importantly, no effect was observed upon depletion of VAMP-7, SNAP-23 or syntaxin-4. These results strongly suggest that the fusion machinery involved in this process is different from the one described in lysosomal-mediated membrane repair. Finally, we propose that MCOLN1-mediated lysosomal exocytosis may play a critical role in the clearance of accumulated undegraded material in lysosomal storage diseases.

1637

Localization and functional requirement of yeast Na^+/H^+ exchanger, Nhx1p, in the endocytic and protein recycling pathway.

A. Kojima[1], C. Kanno[1], C. Kawata[1], J. Y.Toshima[1,2], J. Toshima[1,2]; [1]Department of Biological Science and Technology, Tokyo University of Science, Noda, Japan, [2]Research Center for RNA Science, RIST, Tokyo University of Science

Acidification of the lumen of intracellular organelles is important for post-transcriptional processing, endosomal maturation, receptor recycling, and vesicle trafficking, being regulated by an intricate balance between H^+ influx through vacuolar-type H^+-ATPase and efflux through ion channels and transporters, such as the Na^+/H^+ exchanger (NHE). The eukaryotic NHE family comprises two major subgroups, one residing in the plasma membrane and the other in intracellular organelles. While mammalian intracellular NHE isoforms are localized to various organelles, including the mid-trans-Golgi compartments, early and late endosomes, and recycling endosomes, Nhx1p, the sole NHE in yeast, has been reported to be localized predominantly to the late endosomal/prevacuolar compartment. Here, using live cell imaging, we demonstrated that Nhx1p is localized to the trans-Golgi compartments, late endosomes, and recycling endosomes, similar to mammalian intracellular NHE isoforms. Loss of Nhx1p led to accumulation of components of the retromer complex and late endosomal/prevacuolar compartments, but not trans-Golgi compartments, in aberrant prevacuolar compartments. Importantly, Nhx1p was also required for recycling of the plasma membrane v-SNARE Snc1p. These observations suggest that Nhx1p plays an important role in regulation of the luminal pH of various intracellular organelles, and that this regulation is critical for the protein recycling pathway as well as the biosynthetic and endocytic pathway.

1638

Saccharomyces cerevisiae ENV7 gene encodes a novel vacuolar membrane protein-kinase and is a homolog of human ser/thr kinase STK16.

S. Manandhar[1], S. Cocca[1], M. Serranilla[1], F. Ricarte[1], E. Gharakhanian[1]; [1]Biological Sciences, California State University, Long Beach, Long Beach, CA

Yeast vacuoles are analogous to mammalian lysosomes and serve as a seminal model system in understanding lysosomal trafficking, biogenesis and function. A genome wide screen for genes involved at endosome and vacuole interface function by our laboratory has identified several novel *ENV* genes. Here we report on multifaceted characterization of the novel *ENV7* gene product. Confocal microscopic studies confirm localization of both endogenously and ectopically expressed GFP tagged Env7p to vacuolar membranes. Sub-cellular fractionation revealed co-fractionation of HA-tagged Env7p with vacuolar CPY, and biochemical manipulations established that membrane association is resistant to salt and carbonate treatments. Bioinformatic analyses suggest no signal peptide or membrane-spanning domains, but identify two highly conserved regions: an N-terminal string of cysteines that may serve as putative palmitoylation sites for membrane anchoring, and a ser/thr kinase domain. By employing site-directed mutagenesis, we show that triple cysteine residues at N-terminus of the protein are essential for its proper membrane association and stabilization. Using *in vitro* kinase assays, we report that Env7p is a novel protein-kinase capable of mediating both autophosphorylation and phosphorylation of exogenous substrates. Bayesian phylogenetic analyses revealed that the *ENV7* gene is well conserved across a wide array of eukaryotes including humans yet is absent in prokaryotes – an evolutionary pattern consistent with endomembrane proteins. The analyses strongly support Env7p as a homolog of human STK16, a palmitoylated and myristoylated ser/thr kinase localized to the endomembrane system with no known function. Site-directed mutagenesis revealed that glutamic acid at position 269 of Env7p is critical for its kinase activity, as it has been reported for its human homolog. E269A substitution resulted in a kinase-dead allele. Interestingly, E269A mutant is unstable *in vivo*, but could be significantly stabilized by chemical as well as genetic interrruption of the proteasomal system. Based on these findings, we conclude that Env7p is a novel and conserved vacuolar membrane protein-kinase whose membrane association and phosphorylation are essential for its *in vivo* stability. We also propose that misfolded or mislocalized Env7p is a substrate for proteasomal degradation.

1639

The Family of V- Domain Proteins as Endosomal Ubiquitin Sorting Receptors.

N. Pashkova[1], L. Gakhar[2], S. Winistorfer[1], R. Piper[1]; [1]Molecular Physiology and Biophysics, Univ Iowa, Iowa City, IA, [2]Crystallography Facility, Univ Iowa, Iowa City, IA

Ubiquitin is used as a lysosomal sorting signal for post-Golgi integral membrane proteins. Ubiquitin induces both internalization and subsequent sorting into endosomal intralumenal vesicles that accumulate in late endosomes/multivesicular bodies. Entry into the MVB pathway is guided by the ESCRTs (Endosomal Sorting Complex Required for Transport) as well as critical ESCRT-associated proteins such as Bro1 and the AAA-ATPase Vps4. ESCRT-0, -I and –II all have ubiquitin binding domains, making at least some of these components excellent candidates for ubiquitin-sorting receptors that could recognize, gather, and sort ubiquitinated cargo proteins into MVB intralumenal vesicles. We present data showing that Bro1p may work as Ub-sorting receptor that works at endosomes in parallel with ESCRT-0. The Bro1p family includes several proteins such as Alix, HD-PTP, and RIM20, which function in a variety of cellular processes such as sorting of cargoes into MVB vesicles, viral budding from cells, cytokinesis, and many of which associate with the ESCRT machinery. These proteins comprise

conserved ESCRT-III targeting Bro1-domain at the N-terminus followed by a middle V-domain. We find that by targeting an engineered Bro1 protein tethered to a deubiquitinating enzyme dramatically inhibits the sorting of ubiquitinated cargo into the MVB pathway, consistent with its role early in the process of sorting. Like other endosomal Ub-sorting receptors such as GGAs, Hrs/STAM (ESCRT-0), and Tom1, Bro1 also binds clathrin via its central V-domain. Mutations that abolish the interaction of Bro1 with clathrin also abolish its ability to affect MVB sorting. We also have discovered that the V-domain of Bro1 binds to ubiquitin. In addition, crystallography, NMR, modeling predictions, and mutagenesis studies show that all V-domains bind Ub, although via distinct binding modes. Together our results indicate that Ub interaction with Bro1 and other family members may provide a variety of functions, and in the case of Bro1, provides a means by which Bro1 acts as an Ub-sorting receptor.

1640

The Mon1-Ccz1 Complex Promotes Endosome Maturation in *Saccharomyces cerevisiae.*

T. Shideler[1], M. Russell[2], G. Odorizzi[2]; [1]MCDB, University of Colorado, Boulder, Boulder, CO

Many proteins destined for the lysosome are trafficked through the endocytic pathway. The directionality of transport is regulated by a rab cascade involving Rab5 and Rab7. Rab5 is found on early endosomes and mediates fusion of incoming endocytic vesicles. As an early endosome matures into a late endosome Rab5 is lost and Rab7 is acquired. Acquisition of Rab7 allows for fusion of a late endosome with a lysosome. This transition from Rab5 to Rab7 is regulated by SAND1/Mon1 in *C. elegans* and in mammalian cells. SAND1/Mon1 stimulates this transition by displacing RABX-5, the guanine nucleotide exchange factor (GEF) for Rab5. In the absence of RABX-5, Rab5 is no longer active. The yeast homolog, Mon1, in complex with Ccz1, has recently been shown to be the GEF for Ypt7, the Rab7 homolog. In *Saccharomyces cerevisiae*, Ypt7 regulates fusion with the vacuole, the yeast lysosome. The aim of this work is to understand the role of the Mon1-Ccz1 complex in the yeast endocytic pathway. Using light microscopy we show that deletion of *MON1* leads to a punctate accumulation of the Rab5 homolog, Vps21, as well as its GEF, Vps9. Analysis of *mon1Δ* cells by electron microscopy shows an accumulation of enlarged endosomes, consistent with extended Vps21 activity. However, Vps9 is not displaced following overexpression of either Mon1 alone or both Mon1 and Ccz1. This indicates that Mon1/Ccz1 has a role in down-regulating Vps21 activity but perhaps not through displacement of Vps9, as seen in other systems. Endosomal maturation also involves the sorting of transmembrane cargo, such as carboxy peptidase S (CPS), into inward budding intralumenal vesicles. This requires the action of the Endosomal Sorting Complexes required for Transport (ESCRTs). Upon fusion with the vacuole the intralumenal vesicles are released into the hydrolytic interior of the vacuole lumen. Cells lacking Mon1 are still able to sort GFP-CPS to the vacuole lumen, and electron microscopy shows that these cells contain normal intralumenal vesicles. Taken together these data indicate that Mon1 is not required for ESCRT function. We conclude that the Mon1-Ccz1 complex contributes to endosome maturation by promoting termination of early endosome fusion and this occurs after sorting of cargo by ESCRTs.

1641

ESCRT-II links RNA localization to endosomal trafficking and translational control.

J. Plant[1], A. Emerman[1], M. Blower[2]; [1]Mass. General Hospital, Boston, MA

Spatial and temporal control of mRNA expression is essential for establishing cell polarity and proper embryonic development. Endosomes are linked to subcellular mRNA localization and translational control, yet little is known about the mechanism of RNA localization to endosomes. Using Xenopus egg extracts we found that the endosomal-sorting complex ESCRT-II bound to

hundreds of mRNAs, including many mRNAs previously identified to localize asymmetrically in oocytes as well as many mRNAs that regulate cell cycle progression. Purified, recombinant ESCRT-II bound directly to single-stranded RNA in vitro. In addition to RNA, ESCRT-II bound to membranes containing PI3P phospholipids, the main phospholipid of endosomes. Interestingly, ESCRT-II simultaneously bound directly to RNA and membranes in vitro and was sufficient to tether RNA to specific phospholipids. Furthermore, immunodepletion of ESCRT-II abolished mRNA localization to endosomes, demonstrating that ESCRT-II is both necessary and sufficient for mRNA localization to endosomes. Finally, ESCRT-II functioned as a translational regulator in vitro and in vivo, and immunodepletion of ESCRT-II from Xenopus egg extracts resulted in multiple defects in cell cycle progression resulting from disregulation of translational control. In sum, our data suggest that ESCRT-II-mediated mRNA localization to endosomes is likely to be a key step in the spatial and temporal control of mRNA expression in all cells.

Investigating the therapeutic potential of HDAC Inhibitors for the treatment of Niemann-Pick type C1 Disease.

N. H. Pipalia[1], F. R. Maxfield[1]; [1]Biochemistry, Weill Cornell Medical College, New York, NY

Although some progress has been made in recent years, suitable treatment options for reversal of Niemann-Pick type C1 disease are lacking. Recently, we have shown that treating fibroblasts from NPC1 patients with histone deacetylase inhibitors (HDACi) at sub-micromolar concentrations corrects the NPC1 phenotype (Pipalia et.al. PNAS 108: 5620). This effect was observed in two different NPC1 mutant fibroblasts, but not in NPC2 cells. Although the two NPC1 mutant cells were from different patients, both had one common mutation at I1061T (GM03123 with compound heterozygous and GM18453 with homozygous mutation). These results raised an important question: is the efficacy of HDACi is mutant specific? Hence, we are studying the effect of these HDACi on multiple additional NPC1 human fibroblasts from the patients carrying different type of mutations. Initial results on cells from four patients indicate that two HDACi's (LBH589 and SAHA) used in this study correct the NPC1 phenotype with varying efficacy. We are in a process of screening ~50 additional NPC1 mutations found in patients. This work may help in providing targeted therapy to patients.

1643

Cellular and Organismal Consequences of Defects in NPC1 Membrane Function.

K. L. Huegel[1], A. Brumfield[2], P. Vaughan[2], D. R. Hyde[2], K. T. Vaughan[2]; [1]Department of Biological Sciences, University of Notre Dame, Notre Dame, IN, [2]University of Notre Dame, Notre Dame, IN

Niemann Pick Type C (NPC) disease is a cholesterol transport disorder induced by defects in the NPC1 and NPC2 genes. Focusing on mutations in NPC1, which are responsible for 95% of human cases, we have identified a defect in the dynamic membrane tubulation of late endosomes and lysosomes (LE/Ls). This loss of tubulation correlates strongly with the accumulation of cholesterol and other lipids in LE/Ls and a loss of cholesterol sensing in ER membranes. To determine the basis of this loss of tubulation, we performed MS/MS analysis of purified NPC1 membranes and identified novel tubulation factors. STARD9 was identified as a multi-pass transmembrane protein containing an N-terminal kinesin motor domain. STARD9 is expressed prominently in Purkinje neurons, which are the most vulnerable neuronal cell type in NPC disease. STARD9 was found to be present in wild-type NPC1 membranes but absent from mutant NPC1 membranes. ShRNA analysis of STARD9 revealed a loss of tubulation of NPC1-containing membranes and evidence of cholesterol accumulation. Cholesterol sensing in the ER was also affected by STARD9 depletion. Live-cell imaging of tagged STARD9 constructs

reveals evidence of microtubule binding, strengthening the case for STARD9 to be involved in membrane tubulation. To evaluate zebrafish as a model system to study NPC disease, we have also prepared morpholinos directed against the 5'UTR of zebrafish NPC1. Morpholino injection affects brain development and induces accumulation of cholesterol in multiple brain areas. We observe a significance reduction in the size of the developing cerebellum and the number of Purkinje neurons in the morphant fish. These areas of the brain also display evidence of cell death. Interestingly, cholesterol accumulation is not restricted to Purkinje neurons, suggesting that something other than cholesterol accumulation itself is defective. These studies provide additional details of NPC1 membrane tubulation and suggest that zebrafish will be a powerful model system to study the etiology of NPC disease.

1644

A Novel Phosphoinositide Pathway Controls EGF Receptor Signaling, Lysosomal Trafficking and Degradation.

Y. Sun[1], A. C. Hedman[2], X. Tan[2], N. J. Schill[1], R. A. Anderson[1]; [1]Department of Pharmacology, University of Wisconsin-Madison School of Medicine and Public Health, Madison, WI, [2]Program in Molecular and Cellular Pharmacology, Department of Pharmacology, University of Wisconsin-Madison School of Medicine and Public Health, Madison, WI

The epidermal growth factor receptor (EGFR) plays pivotal roles in cell proliferation and differentiation. The modulation of EGFR endosomal trafficking and degradation is essential for proper signaling. Here, we show that type Igamma phosphatidylinositol phosphate kinase i5 (PIPKIγi5), an enzyme that synthesizes phosphatidylinositol-4,5-bisphosphate ($PI4,5P_2$) on the endosomes, controls EGFR lysosomal trafficking and degradation. Loss of PIPKIγi5 via siRNA results in a block of EGFR trafficking to the lysosome, resulting in endosomal retention of activated EGFR. This sorting failure resulted in enhanced and prolonged EGFR downstream signaling. However, loss of PIPKIγi5 did not impact the sorting and degradation of other receptors indicating that overall lysosome function was not impaired.

PIPKIγi5 controls EGFR trafficking by regulating sorting nexins (SNX) 5 and 6, both phosphoinositide effectors and interaction partners of PIPKIγi5. Loss of either SNX also blocked EGFR lysosomal trafficking and degradation similar to that of the PIPKI(i5 knockdown. PIPKIγi5 kinase activity regulates the interaction of SNX5/6 with Hepatocyte growth factor regulated tyrosine kinase substrate (Hrs), a key component of the ESCRT-0 complex that plays important role in EGFR trafficking into MVB. That indicates a role of PIPKIγi5 and SNX5/6 in EGFR MVB sorting. These finding reveal a novel pathway where PIPKIγi5, $PI4,5P_2$, and SNX5/6 form a novel phosphoinositide signaling nexus that controls EGFR signaling by modulating lysosomal trafficking. These results challenge the dogma that PI3P and $PI3,5P_2$ are the only phosphoinositides required for endosomal trafficking and lysosomal degradation.

1645

Endosomal Accumulation of the Activated EGFR Induces Apoptosis.

B. Ceresa[1], J. Rush[1], L. Quinalty[1]; [1]Cell Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK

Endocytosis both positively and negatively regulates cell surface receptor signaling by temporally and spatially controlling interactions with downstream effectors. Considerable evidence indicates the endocytic pathway controls the biochemistry of receptor:effector communication, however, there are less data indicating endocytosis regulates cell physiology. MDA-MB-468 cells are an excellent model for studying the endocytic regulation of EGFR signaling. In MDA-MB-468 cells, liganded cell surface EGFRs promote cell growth whereas intracellular, liganded EGFRs induce apoptosis. In contrast to most cells, in MDA-MB-468 cells

there is no appreciable decrease in EGFR levels following EGF stimulation [Hyatt and Ceresa (2008) Exp. Cell Res., 314(18):3415-25]. In this study, we report that in MDA-MB-468 cells defective endocytic trafficking causes the phosphorylated EGFR to accumulate in the early endosome up to 24 hours after ligand stimulation. These receptors are on the limiting membrane of the endosome and oriented with the carboxyl terminus in the cytoplasm and the amino terminus in the lumen of the endosome. To determine whether this perturbation in EGFR trafficking is sufficient to cause apoptosis, we used biochemical and pharmacological strategies to disrupt EGFR endocytic trafficking in cells that do not normally undergo EGF-dependent apoptosis. When HeLa cells are manipulated such that active EGF:EGFRs accumulate on the limiting membrane of endosomes, receptor phosphorylation is sustained and the cells undergo apoptosis. However, when cells were manipulated to accumulate the EGF:EGFR complex in the intraluminal vesicles of the late endosome, phosphorylation of the receptor was not sustained nor did the cells undergo apoptosis. The dose-dependent induction of apoptosis indicates that it is a function of the liganded receptor. These data demonstrate that the EGFR-mediated apoptosis is initiated from the limiting membrane of the endosome.

1646

The role of Arl8b and Rab7 GTPases in lysosome tabulation.

A. Saric[1], J. G. Kay[2], W. Furuya[2], S. Grinstein[2], R. J. Botelho[1]; [1]Chemistry and Biology, Ryerson University, Toronto, ON, Canada, [2]Cell Biology, Hospital for Sick Children, Toronto, ON, Canada

Lysosomes are essential for the catabolism of endocytic and biosynthetic cargo, phagosome maturation and autophagy. Therefore, we are interested in understanding the mechanisms that establish, maintain and/or change the properties and function of these organelles. In resting macrophages, lysosomes are predominantly small, globular organelles, appearing punctate under the fluorescence microscope. In contrast, activation of macrophages with phorbol esters or LPS was previously shown to convert lysosomes into tubular lysosomes (TLs). TLs are suggested to have a role in delivering V-ATPases to phagosomes for acidification and to help retain fluid-phase endocytic uptake in macrophages. However, very little else is known about how TLs form and function. To address this lack of knowledge, we investigated the molecular requirements for LPS-stimulated tubulation of lysosomes in RAW and J774 macrophages. We show that TLs are very dynamic relative to punctate lysosomes; not only did TLs fuse, fission, branch, and displayed bidirectional movement, they also moved at 0.35 µm/sec, which was significantly faster than 0.15 µm/sec for punctate lysosomes. Consistent with this, TL formation required microtubules and the kinesin and dynein motor proteins. The lysosomal Rab7 and Arl8b GTPases are regulators of motor proteins. Thus, we investigated if these GTPases were important for TL biogenesis. Not only did Rab7 and Arl8b GTPases colocalize to TLs, but importantly, expression of dominant negative mutants or siRNA against Rab7 and Arl8b potently blocked TL formation. Moreover, Rab7 anchors dynein and kinesin to membranes via the adaptor proteins RILP and FYCO1, respectively. Indeed, overexpression of RILP and FYCO1, which respectively hyperactivates dynein and kinesin, hindered TL formation. This suggests that dynein and kinesin activities must be balanced for TL biogenesis. Taken together, our data supports a model whereby Rab7 and Arl8b modulate dynein and kinesin motor proteins to transform punctate lysosomes into TLs. In turn, TLs are significantly more dynamic than punctate lysosomes.

1647

Arf-like GTPase, Arl8b interacts with HOPS complex and regulates lysosomal trafficking and antigen presentation.

M. Sharma[1], S. Garg[1], C. Ung[1], A. Tuli[1], D. C. Barral[1], D. L. Hava[1], N. Veerapen[2], G. S. Besra[2], N. Hacohen[3,4], M. B. Brenner[1]; [1]Brigham and Women's Hospital/Harvard Medical School, Boston, MA, [2]School of Biosciences, University of Birmingham, United Kingdom, [3]Broad Institute of MIT and Harvard, [4]Center for Immunology and Inflammatory Diseases, Massachusetts General Hospital

Lysosomes are membrane-bound organelles present in eukaryotes whose catabolic function is essential for maintaining general cellular homeostasis. They receive and degrade macromolecules from the endocytic, autophagic and phagocytic membrane trafficking pathways. A specialized function of lysosomes in antigen presenting cells is to serve as the key cellular compartment where antigen presenting molecules including CD1 and MHC class II intersect with, and bind microbial antigens for presentation to T cells. Thus, uncovering the host endocytic machinery that regulates delivery of antigen presenting molecules to lysosomes is critical to understanding host defense. To identify molecular mediators of CD1 trafficking to and from the lysosomes, we assembled a library of short hairpin RNAs targeting members of the endocytic regulatory protein families and used it to screen for loss of CD1 antigen presenting function. Here, using a lysosome-dependent immunological screen of a trafficking short hairpin RNA library, we identified the Arf-like GTPase, Arl8b as a critical regulator of cargo delivery to lysosomes. In addition to endocytic cargo, delivery of phagocytosed cargo to lysosomes was also impaired in Arl8b-depleted macrophages. To gain insight into the mechanism of Arl8b action, we conducted GST pulldown assays using purified GST-Arl8b and identified HOmotypic fusion and vacuole Protein Sorting (HOPS) complex members as effectors of Arl8b. HOPS complex is a six subunit complex conserved from yeast to humans and is considered to be the critical tethering complex that mediates the fusion of late-endosomes and lysosomes. A direct interaction of GTP-bound Arl8b with Vps41 subunit of the HOPS complex was observed using yeast-two-hybrid and purified proteins. Moreover, overexpression of Arl8b recruited Vps41 and other HOPS subunits to LAMP1 positive lysosomes. On the contrary, knockdown of Arl8b led to complete loss of HOPS complex subunits from lysosomes suggesting that like other small GTPases, Arl8b is critical for membrane association of its downstream effector proteins. Similar to Arl8b knockdown, depletion of HOPS complex subunits also led to delay in trafficking of cargo including CD1d to lysosomes. Together, these results define Arl8b and HOPS complex as key regulators of lysosomal cellular and immunological functions.

1648

Role of Arf-like GTPase Arl8b in Regulating Lysosome/Lytic Granule Motility and Exocytosis.

A. Tuli[1], M. Sharma[1], J. Thiery[2], A. Mentlik[3], S. Garg[1], J. S. Orange[3], J. Lieberman[2], M. B. Brenner[1]; [1]Brigham and Women's Hospital/Harvard Medical School, Boston, MA, [2]Immune Disease Institute/Harvard Medical School, Boston, MA, [3]Children's Hospital of Philadelphia/University of Pennsylvania, Philadelphia, PA

A key mechanism that immune cells including Natural killer (NK) cells and cytotoxic T-lymphocytes employ to kill infected or diseased target cells is through regulated exocytosis of lytic granule contents towards the target cell membrane. Although the mechanism by which lytic granules kill the target cells is well-understood, the preceding molecular steps including their movement on microtubules and polarization towards the immunological synapse (IS) is less clear. Previous studies of a small GTPase of the Arl family, Arl8b, had shown that its expression increases motility of lysosomes on microtubule tracks while its knockdown leads to clustering of

lysosomes at the microtubule organizing center (MTOC). Based on these observations, we hypothesized that Arl8b regulates motility and exocytosis of lysosome and lysosome-related organelles required to mediate various physiological events including target-cell killing and plasma membrane (PM) repair. We found endogenous Arl8b co-localized with perforin and granzyme containing lytic granules in both ex vivo NK cells and immortalized NK cell line, YT-Indy. Moreover, in a comparison of cell mediated cytotoxicity as measured using standard Cr(51) release assay, Arl8b-deficient NK cells clearly demonstrated a significant loss of cytolytic activity against 721.221 target cells compared with control cells. To gain insight into the mechanism of Arl8b action, we assessed which step during lytic granule exocytosis is impaired upon Arl8b knockdown. It was previously reported that the microtubule organizing centre (MTOC) translocates towards the IS as it matures. This reorientation is essential for the movement and polarization of the granules to the site of release. We examined the role of Arl8b in these processes using Arl8b-deficient cells. Interestingly, compared to the control knockdown, in NK cells lacking Arl8b, lytic granules and MTOC failed to polarize at the IS and remained almost at the opposite pole to that of the IS. Since Arl8b was first described to be a lysosomal small GTPase, we also analyzed its role in regulating the motility and exocytosis of conventional lysosomes during the process of PM repair. Similar to our findings with lytic granules, conventional lysosomes also showed significantly reduced exocytosis upon treatment with ionomycin, an ionophore commonly used to induce PM repair response. Our findings suggests Arl8b to be a critical factor required for motility and exocytosis of lysosomes and lysosomes-related organelles.

Glucose starvation regulates clathrin adaptors at the trans-Golgi Network and endosomes.

M. Duncan[1], L. Graves[2], Q. Aoh[1]; [1]Biology, University of North Carolina Chapel Hill, Chapel Hill, NC, [2]Department of Pharmacology, University of North Carolina Chapel Hill, Chapel Hill, NC

Glucose is a rich source of energy and the raw material for biomass increase. Many eukaryotic cells remodel their physiology in the presence and absence of glucose. The yeast Saccharomyces cerevisiae undergoes changes in transcription, translation, metabolism and cell polarity in response to glucose availability. Upon glucose starvation, translation initiation and cell polarity are immediately inhibited and then gradually recover. We demonstrate that like cell polarity and translation, traffic at the trans-Golgi network (TGN) and endosomes is regulated by glucose via an unknown mechanism that depends on Protein Kinase A (PKA). Upon glucose withdrawal, clathrin adaptors exhibit a biphasic change in localization: they initially delocalize from the membrane within minutes and later partially recover onto membranes. These changes are co-incident with changes in posttranslational modifications of adaptors. The clathrin adaptors Ent5 and Gga2 exhibit glucose dependent phosphorylation and dephosphorylation respectively. Ras and Gpr1 signaling pathways, which converge on PKA, are required for changes in adaptor localization and changes in posttranslational modifications. Acute inhibition of PKA demonstrates that inhibition of PKA prior to glucose withdrawal prevents several adaptor responses to starvation including changes in localization and phosphorylation. These findings suggest that membrane traffic at the TGN and endosomes is remodeled by glucose starvation and that PKA activity prior to glucose starvation primes this response.

Cortactin regulates Golgi size by controlling retrograde trafficking from late endosomes.

N. Hong[1], K. C. Kirkbride[1], L. C. Lynn[1], M. Micaroni[2], E. S. Clark[3], G. P. Morgan[2], B. J. Marsh[2], A. M. Weaver[1]; [1]Vanderbilt University medical center, Nashville, TN, [2]The University of Queensland, [3]University of Miami Medical School

Dynamic flow of membrane between cellular compartments is critical for maintenance of organelle size and function. While the actin cytoskeleton is known to regulate Golgi homeostasis and morphology, the mechanism is unclear. Here, we show that knockdown (KD) of the branched actin regulator cortactin leads to a dramatic reduction in Golgi size, dependent on binding the Arp2/3 actin-nucleating complex. Surprisingly, aside from Golgi volume changes, there was little effect of cortactin transient or stable KD on Golgi stack ultrastructure, anterograde trafficking of the constitutive cargo VSV-G, or Golgi assembly from ER membranes. However, 2D and 3D image analysis by electron microscopy revealed a notable expansion of prelysosomal organelles, suggesting an exit block from late endosomes. Inhibition of late endosomal trafficking by treatment of cells with Rab7 siRNA or the endosomal inhibitor chloroquine led to a similar compact Golgi morphology to that found in cortactin-KD cells. These data indicate that vesicular trafficking from late endosomes, regulated by cortactin-decorated branched actin networks, is a major mechanism for maintenance of Golgi homeostasis.

Antagonistic control of lysosomal fusion by Rab14 and the Lyst-related protein LvsB.

A. De Lozanne[1], K. Falkenstein[1], E. Kypri[1]; [1]Molecular Cell & Developmental Biology, University of Texas, Austin, TX

The function of the protein Lyst, defective in patients with the Chediak-Higashi Syndrome, is not known at the molecular level. We have shown that the Dictyostelium ortholog of Lyst, LvsB is a cytosolic protein that associates with lysosomes and postlysosomes. We found that LvsB acts as an antagonist to the activity of DdRab14, a protein that promotes homotypic fusion among lysosomes. DdRab14 is normally found on lysosomes and leaves those lysosomes as they mature into postlysosomes. On the other hand, LvsB binds to those lysosomes that are about to mature into postlysosomes. Interestingly, in the absence of LvsB, DdRab14 is found to colocalize with postlysosomal markers. Importantly, activation of DdRab14 phenocopies the loss of LvsB causing abnormal heterotypic fusion between lysosomes and postlysosomes and the great enlargement of those compartments. In contrast, inactivation of DdRab14 suppresses the phenotype of LvsB null cells restoring their lysosomal size and segregation from postlysosomes. This suppression effect is specific for LvsB function since DdRab14 inactivation does not suppress the phenotype of vacuolin B mutants. Our data suggest a model whereby LvsB binds to late lysosomes and promotes, by an unknown mechanism, the inactivation of DdRab14. This inactivation allows the lysosomes to mature into postlysosomes for eventual secretion. We propose that human Lyst may act in a similar way to promote the maturation of lysosome-related organelles.

1652

AP-1B and Arf6 cooperate in the maintenance of polarized membranes in epithelial cells.

*S-F. Ang[1,2], E. Shteyn[1], H. Folsch[1]; [1]Cell and Molecular Biology, Feinberg School of Medicine, Northwestern University, Chicago, IL, [2]Agency for Science, Technology and Research (A*STAR) Singapore, Singapore*

Apical-basolateral cell polarity is fundamental for the organization of epithelial tissues. It is well established that the epithelial cell-specific clathrin adaptor complex AP-1B is important for

basolateral sorting of transmembrane receptors from recycling endosomes to the basolateral plasma membrane. Here we show that the small GTPase Arf6 regulates AP-1B function. We found that interfering with Arf6 functions by overexpression of mutant Arf6 alleles or depleting Arf6 expression with shRNAs led to specific apical missorting of AP-1B-dependent cargos. Furthermore, we found that Arf6 could precipitate AP-1B in vitro, and that Arf6 and AP-1B partially colocalized in recycling endosomes. We hypothesize that Arf6 specifically recruits AP-1B onto recycling endosomes to initiate the generation of basolaterally-targeted vesicles. However, a functional interaction between Arf6 and AP-1B may not be restricted to recycling endosomes. Indeed, we also found specific colocalization of AP-1B, but not AP-1A, with Arf6 in membrane ruffles of epithelial cells. Because Arf6 is known to be involved in Rac-induced ruffling and cell migration[1-4], we are now investigating whether AP-1B has a functional role in these processes. So far, preliminary data indicate that exogenous expression of µ1B/AP-1B in µ1B-negative LLC-PK1 cells decreases the migration speed in a wound-healing assay. This was not because of a difference in the actin organization in the leading edges of the migrating cells, suggesting that the cytoskeleton may not be the cause of this speed change. In conclusion, Arf6 and AP-1B may cooperate in diverse cellular processes at multiple intracellular locations.

Trafficking of Late Endosomes and Secretion of Exosomes in Polarized Epithelial Cells are Regulated by Cholesterol and SNARE Proteins.

J. Xu[1], A. Lakkaraju[1]; [1]Ophthalmology & Visual Sciences, University of Wisconsin-Madison, Madison, WI

Late endosomes are important hubs for sorting proteins and lipids to lysosomes for degradation or recycling to the plasma membrane. Exocytosis of late endosomes results in the release of intraluminal vesicles or exosomes into the extracellular space. Exosomes are a novel mode of cell-independent communication and function in antigen presentation, immune responses, and stem cell and tumor biology. In polarized epithelia, apical and basolateral endocytic routes converge in late endosomes and polarized secretion of exosomes may participate in the establishment and maintenance of apico-basal polarity and in the epithelial-mesenchymal transition. However, little is known about late endosome trafficking or the machinery involved in exosome release in epithelial cells. Here, we investigated these phenomena in polarized Madin-Darby canine kidney (MDCK) and retinal pigment epithelial (RPE) cells. Live imaging using spinning disk confocal microscopy showed that late endosomal membrane proteins LAMP2, CD63 and Niemann-Pick C1 (NPC1) are present in tubules and vesicles that undergo rapid, bidirectional movement over long distances. In cells treated with U18666A or the retinal lipofuscin fluorophore A2E, both of which cause cholesterol accumulation in late endocytic compartments, there is a significant inhibition of tubulovesicular trafficking from late endosomes and lysosomes. Immunoprecipitation experiments showed that in RPE cells with A2E or excess cholesterol, the v-SNARE VAMP7 is sequestered with Vti1b on late endosomal/lysosomal membranes. This prevents VAMP7 from interacting with the t-SNARE syntaxin 4 at the plasma membrane and inhibits exocytosis of late endosomes. Exosomes released apically have different protein compositions than those released at the basolateral surface. Cholesterol loading and A2E also inhibit the release of exosomes. Accumulation of lipofuscin and A2E are hallmarks of age-related macular degeneration (AMD), the most common cause of vision loss in older adults. Histopathological analyses of eyes with AMD show cholesterol deposits in the RPE

basement membrane and allelic variants in cholesterol modulating proteins have been implicated in AMD. At the cellular level, cholesterol homeostasis and late endosome/lysosome function have emerged as hotspots in the pathogenesis of several diseases of aging such as atherosclerosis, Alzheimer's disease and AMD. Our data show that in the RPE, lipofuscin and cholesterol reorganize late endosomal-lysosomal membranes and interfere with the molecular machinery required for organelle motility and function. Over time, disturbed cholesterol homeostasis in the RPE can cause late endosomal traffic jams, impair lysosome function and lead to oxidative stress, inflammation and chronic RPE cell damage.

Rac and Rab GTPases Dual Effector Nischarin Facilitates Survival of Intracellular Bacteria.

C. P. Kuijl[1], M. Pilli[1,2], S. Alahari[3], H. Janssen[4], P. S. Khoo[1], K. Ervin[1], M. Calero[1], S. Jonnalagadda[2], R. H. Scheller[1], J. Neefjes[4], J. R. Junutula[1]; [1]Genentech, South San Francisco, CA, [2]Osmania University, [3]Louisiana State University Health Sciences Center, [5]The Netherlands Cancer Institute

Intracellular pathogenic bacteria, like Salmonella typhimurium, survive inside host cells by blocking the fusion of bacteria-containing endosomal vacuoles with lysosomes, thereby preventing degradation of the engulfed bacteria. The transport and fusion of membrane-bound compartments in a cell is regulated by small GTPases including Rac and members of the Rab GTPase family, and their effector proteins. However, the role of these components for survival of intracellular pathogens is poorly understood. Here, we identify Nischarin as a novel dual effector that can interact with members of Rac and Rab GTPase (Rab4, Rab14 and Rab9) families at different endosomal compartments. Sequential interaction of Nischarin with these GTPases, regulates the fate of Salmonella-containing vacuoles (SCV) produced after phagocytosis of the pathogen and prevent fusion of SCV with lysosomes.

Syndecans regulate the biogenesis of exosomes: a non-cell autonomous function in signaling.

M. F. Baietti[1,2], Z. Zhang[1,2], E. Mortier[1], G. Degeest[1,2], A. Geeraerts[1,3], A. Melchior[1,2], F. Depoortere[1,2], C. Coomans[1,2], E. Vermeiren[1], P. Zimmermann[1], G. David[1,2]; [1]Center for Human Genetics, K.U.Leuven, Leuven, Belgium, [2]Dept. of Molecular and Developmental Genetics, VIB, [3]Dept. of Chemistry, K.U.Leuven

Objectives:

Syndecans, heparan sulfate proteoglycans, are essential for fine-regulating signaling events between cells. The extracellular heparan sulfate chains of these membrane proteins attract several signaling molecules, such as morphogens, to cell surfaces, but the mechanisms of their regulatory functions remain largely unknown.

We have found that, through the PDZ protein syntenin, a well-known syndecan cytoplasmic adaptor, syndecans are connected to Alix, an auxiliary component of the ESCRT machinery, implicated in vesicular budding, and marker of small signaling vesicles released by cells known as ‘exosomes’.

Here, we explore whether the syndecan-syntenin-Alix connection might regulate the biogenesis of exosomes, impacting on the cellular release of morphogen signals.

Results:
Syndecan-1 is released in exosomes and co-fractionates, together with syntenin and Alix, with exosomal marker proteins such as CD63. While syntenin over-expression results, depending on Alix, in an increased release of exosomes, the depletion of syntenin (or Alix) by RNAi treatment blocks the exosomal accumulation of syndecan and marker proteins. Strikingly, syndecan RNAi markedly suppresses exosome production.
Syntenin has an effect on a subset of exosomes: while CD63 and syntenin largely reside in the same exosome population, as shown by immuno-fractionation and by fluorescence cross-correlation spectroscopy, flotillin-1 co-purifies mainly with CD63-negative vesicles and its release is not affected by syntenin.
Syntenin-exosomes are of endosomal origin and depend on endosomal trafficking, as shown by RNAi targeting Rab7, a small GTPase regulating late endocytic membrane traffic. Electron microscopy analysis of syntenin-depleted cells shows that MVBs are largely devoid of intraluminal vesicles, indicating that syntenin supports the intraluminal budding and then production of exosomes.
The molecular machinery responsible for the biogenesis of syntenin-exosomes is ESCRT-dependent, as depletion by RNAi of several components of the ESCRT complexes affects the formation of these exosomes. The presence of heparan sulfate chains on syndecans is necessary for producing exosomes, and the release of exosomes, impaired in HS-depleted cells, can be rescued by anti-syndecan antibody, suggesting that ligand-initiated syndecan oligomerization might be the driving force for the production of syntenin-exosomes.
Syndecan-syntenin exosomes contain HS-dependent signaling cargo, such as p-FGFR, and can transfer FGF-responsiveness to recipient cells, hinting at the functional relevance of these exosomes.
Conclusions:
The results obtained show that interfering with syndecan-syntenin-Alix reduces exosome production by affecting the biogenesis of MVBs and that syndecan-syntenin-Alix complexes control the composition of a specific population of exosomes, potentially transferring specific information between cells. The molecular connection of syndecan with exosomes might thus support a novel role for proteoglycans in vesicular trafficking and trans-cellular signaling, supporting the release of growth factors and signaling components into the extracellular space. The establishment of a direct link between syndecans and exosomes, as a novel mechanism of morphogen spreading, may help explain the role of HSPG in the diffusion of morphogenetic signals, in particular how lipid-modified morphogens travel long-range. Syndecan-syntenin exosomes might also participate in the biology of HS-associated pathological processes, including neurodegenerative and oncogenic diseases.

1656

Characterization of the Vac14 multimer and its role in regulating phosphatidylinositol-3,5-bisphosphate.

S. C. Ho[1], T. Alghamdi[1], R. Botelho[1]; [1]Chemistry and Biology, Ryerson University, Toronto, ON, Canada

Phosphatidylinositol-3,5-bisphosphate (PtdIns(3,5)P2) is an important regulator of endolysosome function. For example, PtdIns(3,5)P2 deficiency causes a striking enlargement of the yeast vacuole and swelling of endolysosomes in higher eukaryotes. Moreover, PtdIns(3,5)P2 defects is now linked to neuropathologies in humans. To understand PtdIns(3,5)P2 action, it is essential to define the mechanisms underlying the synthesis of PtdIns(3,5)P2. In yeast, PtdIns(3,5)P2 is synthesized by the Fab1 PtdIns(3)P 5-phosphatase Fab1 and degraded by the antagonistic Fig4 phosphatase. Interestingly, Fab1 and Fig4 form a common protein complex, along with Vac14. Although Vac14 binds and regulates both Fab1

and Fig4, we do not understand how Vac14 does this. Yeast two-hybrid assays, co-immunoprecipitation and in vitro protein interaction assays with recombinant Vac14 all indicate that Vac14 self-interacts – thus Vac14 likely is a core scaffold for Fab1 and Fig4. However, it is not known if what the multimeric state of Vac14 is and if its multimerization is necessary for interaction and regulation of Fab1 and/or Fig4. Therefore, to solve the importance of Vac14 multimerization, we set out to identify the multimeric state of recombinant Vac14 and the domain responsible for Vac14 self-interaction. Size-exclusion chromatography and ultracentrifugation with glycerol gradients were used to identify the molecular weight of the recombinant Vac14 multimer. The combined results of these two techniques suggest that the Vac14 multimer is non-globular and exists as a homodimer and/or homotrimer. Moreover, using sequential Vac14 truncations and co-immunoprecipitation from yeast lysates, our data suggests that residues 550-880 in the C-terminus of Vac14 are necessary for Vac14 self-interaction. We are now using analytical ultracentrifugation to obtain a precise multimeric state of Vac14 and developing point mutants in conserved residues of the C-terminus to better characterize Vac14 multimerization. Ultimately, these point mutants will be used in functional assays.

1657

The Endosomal Rab Cascade is Dependent on ESCRT Activity.

M. Russell[1], T. Shideler[1], D. Nickerson[2], M. West[1], G. Odorizzi[1]; [1]MCDB, Univ Colorado-Boulder, Boulder, CO, [2]Department of Biochemistry, Univ Washington, Seattle, WA

Maturation of early endosomes into late endosomes is marked by replacement of Rab5 with Rab7 at endosomal membranes, making them competent for fusion with lysosomes (vacuoles in yeast). Maturation also involves the budding of intralumenal vesicles (ILVs), leading to the multivesicular body (MVB) morphology of late endosomes. The switch in fusion properties driven by Rab5-Rab7 conversion coincides with the activity of the endosomal sorting complexes required for transport (ESCRTs), which mediate the budding of ILVs. However, it is unclear if Rab conversion and ESCRT activity are mechanistically coordinated. To address this issue, we examine how loss of ESCRT activity leads to formation of enlarged endosomal structures known as class E compartments. We show in yeast that the loss of ESCRT function disables Rab conversion to result in the chronic localization of Rab5 and its guanine nucleotide exchange factor at class E compartments, leading to the accumulation of membrane destined for the vacuole. More than twice the amount of membrane at an average MVB is found in a single class E compartment cisterna, and restoring ESCRT function causes a burst in MVB formation. Moreover, class E compartment biogenesis requires Rab5 activity, and dominant-active Rab5 expression can drive class E compartment morphology without ESCRT disruption. However, neither Rab5 activity nor Rab5-Rab7 conversion are required for ESCRT-mediated ILV budding. We conclude that Rab conversion at endosomes occurs downstream of ILV budding and requires ESCRT function.

1658

Intralumenal Vesicle Formation at Multivesicular Endosomes requires Ubiquitinated Cargo.

C. MacDonald[1], D. Stringer[1], R. C. Piper[1]; [1]Molecular Physiology & Biophysics, University of Iowa, Iowa City, IA

Degradation of post-Golgi membrane proteins is regulated by their ubiquitination, which serves as a signal for their internalization and subsequent delivery into lysosomes. Ubiquinated membrane proteins travel to endosomes where the Endosomal Sorting Complex Required for Transport (ESCRT) machinery incorporates them into intralumenal vesicles (ILVs), which bud into the endosomal lumen to form multivesicular bodies (MVBs). ILVs are then transported to

the lysosome / vacuole for degradation. How cargo itself coordinates the activity of the ESCRTs and whether it can regulate the formation of its own ILV carrier are unknown. By fusing a deubiquitnating (DUb) enzyme to ESCRT-0 we have created an environment where all cargo is deubiquinated at the endosome. Under these conditions we show ILV formation is completely ablated. ILV formation was restored when cells expressed cargo fused translationally to a single ubiquitin, which was resistant to ESCRT-DUb activity. These data indicate that vesicle formation is fostered by a cascade of interactions between cargo and the Ub-binding domains within the ESCRT apparatus, helping to organize the sorting machinery into a productive pathway. Finding that ubiquitinated cargo was critical for ILV formation led us to re-examine the integral membrane protein Sna3, which has been reported to follow the MVB pathway in a ubiquitin-independent manner. We have further characterized Sna3 and show it acts as an adaptor protein for the methionine transporter Mup1. This role of Sna3 is induced in conditions distinct from the previously described Mup1 adaptor, Art1, which specifically induces internalization in response to substrate. Furthermore, we have clarified the role of ubiquitin in Sna3 internalization and show that ubiquination plays a crucial role in Sna3 trafficking to the vacuole. Specifically, Sna3 undergoes ubiquitin-dependent MVB sorting either by becoming ubiquitinated itself or associating with other ubiquitinated membrane protein substrates.

1659

Spongiform neurodegeneration-linked E3 ligase, Mgrn1, regulates endosome-to-lysosome trafficking in neurons.

D. Fallaize[1], P. Reynolds[1], L. Li[1], L-S. Chin[1]; [1]Pharmacology, Emory University, Atlanta, GA

A null mutation in the gene encoding the novel protein Mahogunin RING finger 1 (Mgrn1) causes prion disease-like spongiform neurodegeneration in mice. Moreover, depletion of Mgrn1 by the pathogenic forms of prion protein has been implicated in human prion disease pathogenesis. Despite the critical importance of Mgrn1 in maintaining neuronal survival, the mechanism and sites of Mgrn1 action remain mostly undefined and the pathogenic mechanism by which loss of Mgrn1 function causes spongiform neurodegeneration is unknown. We have recently shown that Mgrn1 regulates endosome-to-lysosome trafficking by ubiquitinating TSG101 and that siRNA-mediated depletion of Mgrn1 in HeLa cells results in enlarged endosomes and lysosomes. Western blot analysis reveals that endogenous Mgrn1 protein is expressed in multiple brain regions, including cerebral cortex. Immunofluorescence confocal microscopic studies show that endogenous Mgrn1 protein is localized in axons, dendrites, and synapses of mouse cortical neurons, suggesting that Mgrn1 may play a functional role in neuronal and synaptic physiology. We found that a pool of endogenous Mgrn1 protein is associated with early endosomes in cortical neurons. Furthermore, consistent with our findings in Mgrn1-depleted HeLa cells, primary cortical neurons from Mgrn1 null mutant mice exhibit swollen endosomes and lysosomes. Our results support a role for Mgrn1 in regulation of neuronal endosome-to-lysosome trafficking and have important implications for understanding and combating spongiform neurodegeneration.

1660

ALIX interacts with a YPX_3L motif of Protease-Activated Receptor 1 and mediates MVB/Lysosomal sorting through an ESCRT-III-dependent pathway independent of ubiquitination.

M. Dores[1], B. Chen[1], H. Lin[1], U. Soh[1], M. Paing[2], W. Montagne[1], T. Meerloo[3], J. Trejo[1]; [1]Pharmacology, University of California San Diego, La Jolla, CA, [2]Molecular Microbiology, Washington University, [3]Cellular and Molecular Medicine, University of California San Diego

The sorting of signaling receptors to lysosomes is an essential regulatory process. During degradation, receptors are modified with ubiquitin and sorted by ESCRT-0, -I, -II and -III complexes into intralumenal vesicles (ILVs) of multivesicular bodies (MVBs). However, it remains unclear whether a single universal mechanism mediates MVB sorting of all receptors. We previously showed that protease-activated receptor-1 (PAR1), a G protein-coupled receptor for thrombin, is internalized after activation and sorted to lysosomes independent of ubiquitination and the ubiquitin-binding ESCRTs, Hrs and Tsg101. Here, we now report that PAR1 sorts to ILVs of MVBs through an ESCRT-III-dependent pathway independent of ubiquitination. We further demonstrate that ALIX, a CHMP4/ESCRT-III interacting protein, mediates PAR1/ESCRT-III interaction. ALIX binds directly to a YPX_nL motif localized within the PAR1 second intracellular loop via its central V-domain and directs the lysosomal degradation of PAR1. This study reveals a novel MVB/lysosomal sorting pathway for signaling receptors that bypasses the requirement for ubiquitination and ubiquitin-binding ESCRTs.

Receptors, Transporters, and Channels

1661

Measuring receptor dimerization using proximity biotinylation.

A. P. Liu[1], S. L. Schmid[1]; [1]Cell Biology, The Scripps Research Institute, La Jolla, CA

G-protein couple receptors (GPCRs) represent the largest class of signaling receptors and play an essential role in virtually all cellular processes. In recent years, there is increasing evidence that homo- and hetero-dimerization of activated GPCRs is a means to control the specificity and increase the diversity of signaling events. Several methods have been developed to determine if specific GPCRs would homo-dimerize or hetero-dimerize. In particular, resonance energy transfer techniques have been used to show receptor dimerization. A drawback of such strategies is that dimerization is measured not only on the cell surface, but also for receptors inside the cell. Furthermore, because of the nature of energy transfer, signal is only attained when two receptors are in close proximity and transient dimers that associate and dissociate quickly would yield lower energy transfer than stable dimers, thus hindering the interpretation of data. To address these limitations, we have developed a new strategy for measuring receptor dimerization based on enzyme-based proximity biotinylation. The bacterial biotin ligase BirA catalyzes biotinylation on a lysine residue within a specific motif encoded in an acceptor peptide (AP) fused to the GPCR of interest. In the presence of biotin, receptors conjugated to BirA will biotinylate receptors conjugated to AP when the receptors dimerize. Importantly, biotinylated receptors would remain biotinylated even after receptor dissociation. As a test case, we have focused on three chemokine receptors, CXCR4, CCR2, and CCR5. Here we use CXCR4-BirA as ‘donor’ and CXCR4-AP, CCR2-AP, and CCR5-AP as ‘acceptors’. Using proximity biotinylation, we have shown that CXCR4 homo-dimerizes and hetero-dimerizes with CCR2 and CCR5. Future work will focus on characterizing the dependence of receptor expression levels

on the extent and kinetics of receptor dimerization as well as whether and how agonists/antagonists for CXCR4, CCR2, and CCR5 alter receptor dimerization.

1662

Single molecule study of Thrombospondin receptors in endothelial cell plasma membrane.

A. Chanda[1], J. M. Githaka[2], N. Touret[2], G. Danuser[1], K. Jaqaman[3]; [1]Cell Biology, Harvard Medical School, Boston, MA, [2]Department of Biochemistry, University of Alberta, Edmonton, AB, Canada, [3]Systems Biology, Harvard Medical School, Boston, MA

Thrombospondin-1 (TSP-1) is a potent anti-angiogenic factor downregulated in many tumors. CD36 and integrin β-1 are two of its key receptors, mediating its anti-angiogenic activity by initiating signaling cascades that inhibit endothelial cell migration and promote apoptosis. Receptor clustering on the plasma membrane is thought to be important for initiating these signaling cascades. However, little is known about the mechanisms that contribute to CD36 and integrin β-1 clustering and how they lead to downstream signals. In this study, we used quantitative single molecule live cell imaging to measure the dynamics of CD36 in primary human microvascular endothelial cells (HMVECs). To monitor CD36 motion at the single molecule level, we labeled CD36 with primary fab fragments followed by secondary fab fragments conjugated to dyLight 549 fluorophores, and recorded 100ms time-lapse image sequences using total internal reflection fluorescence microscopy (TIR-FM). We also used fixed-cell TIR-FM imaging to study the spatial organization of CD36 and integrin β-1 on the cell surface. Using the two approaches, we compared receptor dynamics and spatial organization between unstimulated cells and cells exposed to TSP-1 or 3TSR, a small subdomain of TSP1 which primarily binds to CD36 and integrin β-1. We found that treatments with either TSP-1 or 3TSR, at doses that lead to HMVEC apoptosis, result in a significant increase in CD36 clustering and mobility and in a differential spatial organization of integrin β-1. Based on our data we propose that the 3TSR domain of TSP-1 results in a change in CD36 dynamics, potentially mediated in part by integrin β-1, that facilitates CD36 clustering and signaling.

1663

Dectin-1, an Innate Immune Receptor, is Endocytosed upon Ligand Binding.

A. Locke[1], A. Fitieh[1], S. Ungarian[1], N. Touret[1]; [1]Department of Biochemistry, University of Alberta, Edmonton, AB, Canada

Dectin-1 is a receptor expressed in macrophages and dendritic cells that plays a key role in anti-fungal immunity. It recognizes ß-glucans, polymers of glucose found in the fungal cell wall. Upon ligand binding, Dectin-1 triggers signaling cascades that lead to phagocytosis of fungal pathogens and the release of pro-inflammatory mediators. Interestingly, soluble ß-glucans themselves have been found to have immunomodulatory effects, suggesting Dectin-1 can bind and internalize soluble ß-glucans to trigger an immune response. The goal of our research is to develop tools to visualize Dectin-1 endocytosis and to characterize the endocytic pathway responsible for ß-glucan internalization.

We stably expressed Dectin-1 in RAW 264.7 murine macrophage cells. Surface Dectin-1 was labeled with antibodies and allowed to internalize into the cells in the presence of the soluble ß-glucans phospho-curdlan and laminarin. Immunofluorescence staining revealed surface Dectin-1 localized to multiple punctate structures inside the cell only upon stimulation with these ligands. This uptake was dependent on the GTPase dynamin, as the intracellular puncta were not observed in cells transiently expressing a dominant-negative dynamin mutant. In addition, total internal reflection fluorescence microscopy showed that at early timepoints, Dectin-1

puncta greatly co-localized with GFP-tagged clathrin. Further dual-fluorescence confocal analysis found Dectin-1 localized to Rab5+ early endosomes by 15 minutes of ligand stimulation, and to recycling endosomes and lysosomes by 30 minutes. We have also observed the recruitment of GFP-tagged Spleen Tyrosine Kinase (Syk), a key player in Dectin-1 signaling, to Dectin-1 puncta.

To quantify Dectin-1 uptake, cell surface biotinylation was performed prior to treatment of the cells with soluble ß-glucans for various times. After the timepoints, non-internalized receptors were stripped of the biotin label with a reducing agent. Subsequent streptavidin pull-down of internalized biotinylated proteins and immunoblotting confirmed that the rate of Dectin-1 uptake increased dramatically upon binding the ß-glucans. Upon treatment with dextran, a sugar that is not a Dectin-1 ligand, the rate of uptake remained only at a constitutive level. By performing the same assay in the presence of pharmacological inhibitors of endocytosis, we determined that ligand-stimulated Dectin-1 endocytosis is also a clathrin- and actin-dependent process.

We conclude that Dectin-1 is internalized rapidly upon binding of soluble ß-glucan ligands, and that several molecular players and events involved in its endocytosis have been identified. Future studies will examine the role of endocytic trafficking in the regulation of Dectin-1 downstream signaling and vice versa.

1664

Activation of the Innate Immune Receptor Dectin-1 by Clustering.

A. Fitieh[1], A. Locke[1], S. Ungarian[1], N. Touret[1]; [1]Biochemistry, University of Alberta, Edmonton, AB, Canada

Dectin-1 is a pattern-recognition receptor that plays a key role in anti-fungal immunity. It specifically recognizes beta-glucans, polymers of glucose found on the fungal cell wall. Upon ligand binding, dectin-1 triggers signaling cascades that lead to various cellular responses, including phagocytosis and the release of pro-inflammatory mediators, which all culminate in the generation of an effective immune response and eradication of the pathogen. The molecular mechanisms underlying dectin-1 activation and signal transduction are not fully understood. The aim of this study is to elucidate such mechanisms. We propose that upon binding of fungal particles, dectin-1 receptors cluster and assemble into multimeric complexes. In these clusters, dectin-1 becomes activated and promotes the recruitment and activation of Syk (spleen tyrosine kinase), which in turn triggers subsequent signaling cascades. To test our hypothesis, we stably expressed human dectin-1 in RAW 264.7 cells. Various levels of dectin-1 clustering were induced using antibody cross-linking or beta-glucans of different sizes. The corresponding activation of dectin-1 was detected by determining the activation of several downstream effectors (Src, Syk, NF-kB). We demonstrate that antibody cross-linking and larger ligands are able to induce more Syk phosphorylation than smaller ligands. To quantify the level of dectin-1 clustering, single molecule analysis was employed. Antibody cross-linking of dectin-1 formed clusters of approximately 50 dectin-1 molecules in nanodomains of 500 nm, which were identified as the nucleation site for intracellular signaling. Additionally, the phosphorylation and recruitment of Syk to regions of the plasma membrane rich in dectin-1 clusters was observed using confocal microscopy. Together, our results suggest that receptor clustering is the mechanism by which dectin-1 is activated.

Investigation of the presence of a Basigin-mediated lactate metabolon in the brain.

J. D. Ochrietor[1], P. Gambon[2], L. N. Little[2], E. Stotz-Potter[2]; [1]Biology, University of North Florida, Jacksonville, FL

It is generally accepted that plasma membrane-associated expression of monocarboxylate transporters (MCTs) 1, and 4 requires an association with Basigin (CD147), whereas MCT2 does not. In the neural retina, Basigin gene products associate with MCT1 and MCT4 to form a lactate metabolon between Müller glial cells and photoreceptor neurons. The Basigin gene products hold the two halves of the metabolon together and the MCTs transport lactate via facilitated diffusion. It is thought that the metabolon transfers lactate from the highly glycolytic Müller cells to photoreceptor neurons to fuel rapid ATP synthesis in those neurons. In contrast, MCT2 likely plays a minor role in metabolite transfer in the neural retina. Therefore, the purpose of this study was to determine if a similar metabolon exists between neurons and glial cells within other parts of the nervous system as well. The authors believe that such a metabolon could account for the astrocyte-neuron coupling mechanism proposed to exist in the brain. Paraffin-embedded sections of mouse olfactory bulb and midbrain were subjected to immunohistochemical analyses using antibodies specific for Basigin, MCT1, MCT2, and MCT4. In the olfactory bulb, MCT2 is the predominant MCT and is expressed in the granule cell layer, whereas MCT1 and MCT4 are restricted to blood vessel endothelial cells. Basigin expression in the olfactory bulb was observed in the mitral cells and on blood vessel endothelial cells. In the midbrain, MCT1, MCT4, and Basigin are again expressed on blood vessel endothelial cells, but Basigin and MCT4 are also expressed on cell bodies. MCT2 expression was observed on cell bodies as well. The data suggest that a lactate metabolon like that observed in the neural retina does not exist in the regions of the brain tested. It is likely that while neurons within the midbrain and olfactory bulb use lactate as a metabolite based on MCT expression patterns in those regions, rapid delivery from glial cells to neurons is not required like it is in the neural retina.

MCSF Controls Phagocytosis in Macrophages by Stimulating Cytoskeletal Rearrangements.

J. W. Debelius[1], D. M. Kapperman[1], A. D. Hoppe[1]; [1]Department of Chemistry and Biochemistry, South Dakota State University, Brookings, SD

Phagocytic engulfment of particles requires the engagement of multiple phagocytic receptors. The principle macrophage growth factor, macrophage colony stimulating factor (MCSF or CSF-1) stimulates phagocytosis within seconds of addition. This enhancement is independent of changes in receptor expression. We demonstrate that the mechanism for this enhancement results from cytoskeleton rearrangements, ruffling and local exploration by extensions of plasma membrane. Drugs that interfere with actin function as well as fixation with paraformaldahyde inhibit the binding of particles. Fluorescence Recovery after Photobleaching demonstrate that net rate of receptor diffusion increased upon MCSF administration and the immobile fraction decreases. These results suggest that perturbations in the local actin cytoskeleton by MCSF allow increased receptor mobility.

1667

Characterization of the Basigin binding domain of Basigin-2 and L1cam.

D. Patel[1], J. Selfridge[1], J. Ochrietor[1]; [1]Biology, University of North Florida, Jacksonville, FL

The Basigin gene codes for two proteins in the neural retina by splice variation. Basigin and Basigin-2, members of the immunoglobulin superfamily (IgSF) are identical in amino acid

sequence, with the exception of an additional Ig domain in the extracellular portion of the Basigin-2 molecule (Ochrietor *et al*., 2003, *IOVS*). The Basigin-2-specific loop is highly conserved throughout evolution, suggesting it has a specific, conserved role, most likely as a binding domain in the retina. Basigin-2 also contains significant amino acid sequence identity (50%) in its amino terminal Ig loop with an extracellular domain of L1cam, an IgSF neural cell adhesion molecule that is a known binding partner for Basigin in the brain (Heller *et al*., 2003, *J Neurochem*). Therefore, the purpose of this study was to determine whether the regions of significant amino acid sequence identity in both Basigin-2 and L1cam serve a common function as binding domains for Basigin. The cDNA sequences for the potential Basigin binding domains of Basigin-2 and L1cam were each cloned into the pET102 bacterial expression vector (Invitrogen Corporation) and recombinant proteins were generated and purified. ELISAs were then performed to assay the ability of each recombinant protein to bind endogenous mouse Basigin. The data indicate that the conserved regions within Basigin-2 and L1cam do indeed bind to Basigin. In addition, it was determined that the binding affinities of each protein for Basigin were similar, in the □M range, which is consistent with Ig cell adhesive binding affinities. The data suggest that Basigin-2 and L1cam share a common motif: the Basigin-binding domain. Future studies will investigate exactly which amino acids within the motif are involved in the interaction.

1668

Characterization of the interactions between the cell adhesion molecules Basigin and Embigin and monocarboxylate transporters in neural tissues.

K. Fletcher[1], N. Little[1], J. Ochrietor[1]; [1]University of North Florida, Jacksonville, FL

Basigin and Embigin are classified within the same subset of the Immunoglobulin (Ig) superfamily. Both glycoproteins have been implicated in MCT expression at the plasma membrane. The two molecules diverge, however in that Basigin works with more than one MCT (1, 3, and 4) while Embigin is only thought to interact with MCT2. It is known that Basigin and MCT1 must associate for membrane-associated expression in many tissues. Indeed, the MCT1 glycoprotein is not expressed at the plasma membrane in the Basigin null mouse retina. The association utilizes hydrophobic interactions via the transmembrane domain of Basigin. Due to the striking similarities between Basigin and Embigin, including 50% amino acid sequence identity in their transmembrane domains, the purpose of this study was to determine whether Embigin interacts with MCT2 in a similar manner to that of Basigin and MCT1. To answer this question, recombinant versions of the Basigin and Embigin transmembrane domains were generated for ELISA binding assays using endogenous mouse MCT2. The data indicate that neither Embigin nor Basigin transmembrane domains interact with MCT2. This finding suggests that Basigin does not interact with MCT2 due to differences in amino acid sequences of MCT1 and MCT2. The data also raise questions about the validity of naming Embigin as the accessory molecule for MCT2 expression. If it is an accessory protein then it must use a domain other than the transmembrane region. Future studies by this laboratory will examine the other domains of the Embigin glycoprotein to determine if the extracellular or intracellular domains, rather than the transmembrane domain, associate with MCT2.

1669

Enrichment of inositol 1,4,5-trisphosphate receptors and chromogranins in secretory granules of pancreatic β- and α- cells.

Y. S. Hur[1], C. K. Suh[2], S. H. Yoo[1]; [1]Department of Biochemistry, Inha University School of Medicine, Incheon, Korea, [2]Department of Physiology, Inha University School of Medicine, Incheon, Korea

Secretory granules are signature organelles of all secretory cells, and contain not only the largest amounts of calcium in the cell but also function as the major IP_3-dependent intracellular Ca^{2+} store of secretory cells (reviewed Yoo, S.H., *FASEB J.* (2010) 24, 653). Typically, secretory granules contain high concentrations of all three IP3R isoforms and of calcium storage proteins chromogranins and secretogranins. Chromogranins A and B, and secretogranin II are three major members of the granin protein family, and are high-capacity, low-affinity Ca^{2+} storage proteins. Pancreas contains several types of secretory cells such as acinar cells, β- and α- cells along with large numbers of secretory granules in each cell. Yet, there is very little information on the distribution of the IP_3Rs and chromogranins in these cells. Therefore, we have here investigated the distribution and the relative concentrations of IP_3R isoforms and of chromogranin B and secretogranin II in subcellular organelles of rat pancreatic β- and α- cells using immunogold electron microscopy. The IP_3Rs were shown to localize in secretory granules, the endoplasmic reticulum (ER), and the nucleus of rat pancreatic β- and α- cells, and the IP_3R concentrations in secretory granules were shown to be ~2-fold higher than those of the ER or the nucleus. Generally agreeing with pancreatic acinar cells, chromogranin B and secretogranin II were also shown to localize in secretory granules, the ER, and the nucleus of pancreatic β- and α- cells, and their concentrations were also ~2-fold higher than those of the ER or the nucleus. Taken together, these results suggest that secretory granules of pancreatic β- and α- cells also function as the major IP_3-sensitive Ca^{2+} store of these cells as is the case with other secretory cells.

1672

Elevated Levels of Saturated Fatty Acids Disrupt Calcium Homeostasis and Affect Atrial Fibrillation Dynamics in the Ovine Heart.

R. P. OConnell[1], H. Musa[2], M. Yamazaki[2], K. Bandaru[2], M. Klos[2], T. J. Herron[2], U. R. Avula[2], J. Kalifa[2], J. M. Anumonwo[1,2]; [1]Molecular and Integrative Physiology, University of MIchigan, Ann Arbor, MI, [2]Internal Medicine, University of MIchigan, Ann Arbor, MI

Introduction: There is increasing evidence linking obesity and atrial fibrillation (AF). It has been suggested that an excess of myocardial fat can induce ectopic activity and may underlie the arrhythmogenicity associated with an elevated risk for AF. Fat cells (adipocytes) are known to secrete bioactive factors that can modulate cardiac function. The implications of these bioactive factors on myocyte electromechanical function are largely uninvestigated. A major component of these biofactors are free fatty acids (FFA). These FFAs are composed of both saturated Fas (palmitic acid (PA) and stearic acid (SA)) and several unsaturated FAs. We hypothesized that saturated fatty acids detrimentally modulate cardiac electromechanical function. Methods: We have used a combination of optical as well as the whole-cell patch-clamp techniques to examine the effects of saturated and unsaturated fatty acids on the electromechanical function of left atrial ovine myocytes and atrial fibrillation dynamics. Our FFA concentrations were chosen to reflect the elevated levels found in obese sheep (Veiga-Lopez et al, 2010). Results: First, we tested the effects of chronic (24 hr) exposure of left atrial myocytes to 10 μM SA. Treated cells demonstrated an abbreviation of action potential duration at 80% repolarization (APD80) (as a % of control: 63.56 ± 8.39, $p \leq 0.006$), and reduced the density of peak L-type calcium currents (ICa-L) by approximately 50% without significantly affecting voltage-dependent activation or

inactivation. Similarly, chronic exposure to 10 μM PA exposure abbreviated APD80 values (as a % of control 63.68 ± 4.35, p≤0.004) and significantly reduced ICa-L current density. Additionally, 10 μM PA induced a depolarizing shift in voltage- dependent activation of the L-type calcium channel and altered time-dependent inactivation resulting in increased persistent ICa-L. Acute (15 min) exposure of up to 50 μM PA did not significantly affect ICa-L. Furthermore, FA treated myocytes demonstrated reduced calcium transient amplitudes (0.35 ± 0.05 vs. 0.18 ± 0.04 ΔF/Fo, p≤0.007; CTL vs. PA) and the half widths (292.3 ± 19.8 vs. 225.8 ± 11.5 msec, p≤0.007; CTL vs. PA). Importantly, chronic exposure of atrial myocytes to 10 μM oleic acid, a monounsaturated FFA, had no discernable effects on ICa-L. Finally, in optical mapping experiments we examined the effects of 20 μM PA on AF dynamics.PA was perfused into the coronary circulation of isolated ovine hearts. Average APD80 values were abbreviated by 20% (p=0.07). However, dominant frequency maps demonstrated a marked increase in the frequency of fibrillatory activity (17 Hz vs 7.9 Hz; p<0.05; CTL vs PA). Significant recovery was observed after washout. Conclusions: The electrophysiological properties of the left atrium in the whole heart and in isolated cells exposed to elevated levels of saturated, but not monounsaturated FFAs, demonstrate electromechanical alterations consistent with conditions favoring AF. These results may provide insight into the mechanism linking AF with excess adiposity seen in obesity.

1673

Membrane transport activity and dynamics of the ABC transporter, P-glycoprotein.

P. P. Cheney[1], H. Assoudani[2], M. Stachler[2], M. K. Knowles[2]; [1]Chemistry and Biochemistry, University of Denver, Denver, CO

ATP binding cassette (ABC) transporters regulate the lipid asymmetry of the plasma membrane by exporting a wide variety of lipids to the outer leaflet. P-glycoprotein (PGP) is an ABC transporter responsible for the efflux of a large number of hydrophobic small molecules, such as drugs and fluorescent dyes. The interactions of PGP with its local environment on the plasma membrane are studied here using confocal and total internal reflection fluorescence microscopy (TIRFM). A fusion protein of PGP with enhanced green fluorescent protein (EGFP) and several rhodamine-derivative and cyanine fluorescent dyes make the transporter and its substrates visible. Here we use fluorescence recovery after photobleaching (FRAP) techniques to assess bulk protein mobility on the membrane. To complement this technique, TIRFM is used to track single PGP molecules and PGP clusters across the surface of the plasma membrane. Using these microscopic methods, the localization and dynamics of PGP on the membrane in the inactive, active, and inhibited states are determined and a preliminary mechanistic model is proposed.

1674

Developmental tradeoffs: endocytosis leads to the down-regulation of ABC-efflux in the sea urchin small micromere lineage.

J. P. Campanale[1], A. Hamdoun[1]; [1]Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA

Embryos use ATP-binding cassette (ABC) transporters to establish gradients of morphogens and to reduce intracellular accumulation of toxins. We used confocal microscopy to assess ABC-transporter activity in micromeres of sea urchin embryos. Micromeres give rise to the small micromeres, which are essential for the production of germline. As the micromeres divided to produce small micromeres they accumulated 2.2 times more of the ABC-transporter substrate calcein-AM, than other cells in the embryo. Reduced ABC-transporter activity persists in small micromeres, which accumulate an array of ABC-transporter substrates including, CellTrace

RedOrange, BoDipy-verapamil and BoDipy-vinblastine. The reduction in transport activity is mediated by a pulse of endocytosis that occurs 20-60 min after the appearance of the micromeres. Down regulation of efflux is prevented by phenylarsine oxide (PAO), an inhibitor of endocytosis. Micromeres of early 16-cell embryos treated with PAO have a 15% reduction of efflux activity, whereas controls have a decline of 36%. In contrast, 50 min after the start of the 16-cell stage, PAO treatment results in a 31% decrease in efflux activity, roughly equivalent to that measured in controls. Tetramethylrhodamine dextran and cholera toxin B were used to measure endocytosis of apical micromere membrane. During the down regulation of transport, measurements of rhodamine positive endosomes indicated that micromeres retrieve an average of 0.8% of their cellular volume, while the macromeres retrieve only 0.2 %. The removal of raft-associated ganglioside peaks at 6% of cell volume in the micromeres and 2.7% in the macromeres. These results suggest the loss of transport is mediated by selective retrieval of either ABC-transporters or the lipid rafts with which they are associated. The down-regulation of efflux in small micromeres represents a paradox; critical germline precursor cells accumulate more toxins. We hypothesize that a loss of transport may be required for the detection of developmental signaling molecules. If cells in embryos down-regulate ABC-transporter activity to receive signals during development, then this may generate specific windows of germline susceptibility.

1675

A Role for TRPM7's Control of Magnesium Homeostasis in Conferring Resistance to Cell Stress.

H-C. Chen[1,2], L-T. Su[3], O. González-Pagán[1,2], L. W. Runnels[1,2]; [1]Pharmacology, UMDNJ-RWJMS, Piscataway, NJ, [2]Graduate School of Biomedical Science, UMDNJ, Piscataway, NJ, [3]Medicine, University of California, San Diego, San Diego, CA

TRPM7, a member of the transient receptor potential melastatin-like (TRPM) ion channel subfamily, is a unique bifunctional protein with ion channel and kinase activities. This Ca^{2+} and Mg^{2+} permeant ion channel is ubiquitously expressed and has been linked to various physiological roles, including magnesium homeostasis, melanopore formation, cell proliferation and early development. Recent studies have demonstrated that depletion of the TRPM7 protein in neurons reduces cell death caused by oxygen-glucose deprivation, however, the mechanism(s) involved remains unclear. We've been investigating how TRPM7 contributes to the demise of cells using HEK-293 cells and Swiss-3T3 fibroblasts as model systems. Our research has revealed that overexpression of TRPM7 in HEK-293 cells increases production of reactive oxygen species (ROS) and the activation of the stress-activated protein kinases (SAPKs), p38 MAP kinase and c-Jun N-terminal kinase (JNK). Conversely, knockdown of TRPM7 in HEK-293 as well as Swiss 3T3 fibroblasts, lessened cell death caused by a wide range of apoptotic stimuli. Inhibition of TRPM7 channel activity using novel TRPM7 channel blockers that we have identified was similarly protective. Consistent with a role of the channel in apoptosis, knockdown of TRPM7 in Swiss 3T3 fibroblasts reduced apoptotic signaling in response to cell stress, as assessed by cleavage of PARP and caspase-3. In addition, TRPM7-knockdown fibroblasts have lower levels of ROS than in control cells, both in the absence of cell stress as well as in response to apoptotic stimuli. Surprisingly, re-expression of the magnesium transporter SLC41A2 was able to restore the concentration of ROS in TRPM7 knockdown cells as well as their sensitivity to apoptotic stimuli. Together these findings underscore a critical role for the TRPM7 channel and its control of magnesium homeostasis in the cellular response to cell stress.

1676

Acid production in Cystic Fibrosis airway cells measured by flow cytometry.

E. Wunderlich[1], C. Lewis[2], H. Fischer[1]; [1]Children's Hospital Oakland Research Institute, Oakland, CA, [2]Samuel Merritt University

Airway pH and bicarbonate transport across CFTR are changed in CF and affect airway epithelial function. Intracellular pH in airway cells is generally measured using wide-field fluorescent microscopy on whole cells with a pH reporter dye. Here we measure intracellular airway cell pHc using flow cytometry and calculate acid production using cell buffer capacity. We used two airway cell lines, one containing the CFTR (CFBE41o- bronchial cells expressing recombinant wt-CFTR), and one without the CFTR (JME CF nasal surface cells). We then compare flow cytometry measurements to both confocal and wide-field microscopy values. Flow cytometry was performed on resuspended (scraped) cells preloaded with the pH reporter dye 5 uM SNARF-1 in HEPES-buffered, nominally bicarbonate-free Ringers and calibration solutions. Confocal microscopy experiments were performed on adherent cells preloaded with 5 uM SNARF-5. Wide-field microscopy was performed on cells on glass preloaded with 5 uM BCECF. All techniques were calibrated using the high K+/ nigericin method and a 2-5 point pH calibration. Flow cytometry data fit a calibration curve derived from 4 to 5 datasets, each dataset containing 30,000 cells set to a unique pH ranging from 6 to 8. Using flow cytometry, CFBE41o-wt cells in Ringers had median pH values of 7.26 +/- 0.01 (n = 3). JME cell pH was 7.41 +/- 0.07 (n = 3). In both cell types, intracellular pH was comparable to wide-field microscopy values. Confocal measurements were variable, possibly due to variable dye localization to intracellular organelles, which were resolved by this technique. When 500 uM amiloride and 10 uM ZnCl2 were added to the cells to prevent acid extrusion, pHc decreased. In CFBE41o-wt cells, pH fell to 6.93 +/- 0.06 (n = 3), corresponding to an initial acid production of 860 +/- 160 fmols / cell hour based on the cell buffer capacity (separately determined). JME pH fell to 7.09 +/- 0.08 (n = 3), corresponding to an initial acid production of 410 +/- 60 fmols / cell hour. By microscopy, we measured an initial acid production of 1620 +/- 730 fmols / cell hour (n = 6) in CFBE41o- cells and 1360 +/- 620 fmols / cell hour (n = 5) in JME cells. We conclude (1) that CFBE41o- and JME airway cells produce substantial, but not significantly different levels of basal acid, and (2) that airway cell pH can effectively be measured by flow cytometry of scraped adherent cells. We suggest that this technique would allow for functional pH analyses on small subpopulations of cells. For comparison, confocal microscopy appears appropriate for measuring subcellular pH compartments. Funded by NIH/NHLBI HL86323, CF Foundation (FISCHE10G0), and the Beverly M. Folgers Foundation.

1677

Regulation of the expression and cellular localization of aquaporin-3, 9 and 10 in human skin epidermis keratinocytes.

E. Vodouhé[1], M. Boury-Jamot[1], M. Juan[2], E. Noblesse[2], S. Schnebert[2], E. Perrier[2], M. Dumas[2], J-M. Verbavatz[3]; [1]CNRS URA2096, IBITEC-S, CEA/Saclay, Gif-sur-Yvette, France, [2]LVMH Recherche, Saint Jean de Braye, France, [3]MPI-CBG, Dresden, Germany

Skin epidermis is a multi-layered epithelium which undergoes continuous renewal by proliferation and differentiation of keratinocytes. Aquaporins (AQP) are a family of 13 water channels and glycerol transporters in humans. Aquaporin-3 (AQP3) is expressed in skin epidermis keratinocytes in humans and rodents. Aquaporin-9 (AQP9) was also found in mouse skin epidermis. Our objectives were to investigate the expression and regulation of AQP during differentiation in normal human keratinocytes (NHK) and human epidermis. Results: by RT-PCR, AQP3 and aquaporin-10 (AQP10) mRNA and protein were detected in NHK in culture. After 72h calcium-induced differentiation of NHK (with 1.5 mM Ca2+), AQP3 expression was

preserved but AQP10 was replaced by AQP9. In human skin, using immunofluorescence with specific anti- AQP3, AQP9 and AQP10 antibodies on human skin sections, the expression of AQP3 in plasma membranes was confirmed in basal and suprabasal keratinocytes, while AQP10 was localized in keratinocyte intracellular compartments. AQP9 was found only in the stratum granulosum, the epidermis layer prior to terminal differentiation of keratinocytes into corneocytes. In contrast to skin epidermis, AQP3 in proliferative NHK was localized in the endoplasmic reticulum, but AQP3 was targeted to plasma membranes after calcium-induced differentiation of NHK. Interestingly, this behavior was recapitulated in MDCK cells transfected with AQP3-GFP. In these cells, AQP3 trafficking to the plasma-membrane was rapidly reversed by: - lowering extracellular [Ca2+] from 1.5mM to 0.15 mM - the PLCß inhibitor U73343 (2 µM) – the PKC inhibitor Rho320432 (10µM). In conclusion, we show that: - AQP expression is regulated by differentiation in human epidermis keratinocytes: AQP10 is expressed only in proliferative keratinocytes, AQP3 is found in proliferative and differentiated keratinocytes and AQP9 is expressed only in terminally differentiated keratinocytes. Results in MDCK cells suggest that the calcium-sensitive PLC-PKC pathway is directly involved in AQP3 trafficking from the intracellular compartment to plasma membranes during calcium-induced differentiation of keratinocytes.

1678

The Mitochondrial TIM23 Protein Transport Complex Undergoes Conformational Dynamics Coupled to the Energized State of the Inner Membrane.

K. Malhotra[1], J. Landin[1], A. Johnson[2], N. Alder[1]; [1]Molecular and Cell Biology, University of Connecticut, Storrs, CT, [2]Molecular and Cellular Medicine, Texas A&M Health Science Center, College Station, TX

The TIM23 complex of the mitochondrial inner membrane (IM) is a multi-component assembly that mediates the translocation of matrix-targeted precursor proteins as well as the integration of membrane proteins. This complex is energetically coupled to both an ATPase motor and the electrochemical proton potential ($\Delta\tilde{\mu}_{H+}$) across the IM. The central subunit of this complex, Tim23, forms a voltage-gated channel and contains a large soluble domain in the intermembrane space that functions as a substrate receptor. The central objective of this study is to investigate the coupling between the energized state of the membrane and conformational dynamics of the Tim23 channel subunit. To this end, we utilize a newly-developed a fluorescence-based experimental strategy that allows us to explore the structure and function of mitochondrial membrane proteins. In this approach, Tim23 is synthesized with fluorescent probes at specific sites by conducting cell-free translation reactions in the presence of aminoacyl-tRNA analogs that allow for the incorporation of non-natural (probe-bearing) amino acids. Labeled Tim23 is then post-translationally imported into the IM of isolated mitochondria where it properly assembles with native subunits to form TIM23 complexes, allowing for high-resolution fluorescence mapping of the fully operational channel by both steady-state and time-resolved fluorescence measurements [Alder et al. (2008) *Cell* 134: 439-450]. By monitoring the spectral characteristics of environment sensitive probes at key sites within Tim23, we can examine the conformational dynamics of specific regions in response to changes in the energized state of the membrane as they occur in real time. Our results show that the Tim23 subunit undergoes major structural rearrangements in response to changes in the $\Delta\tilde{\mu}_{H+}$, not only within the membrane-bound channel domain but also within the soluble receptor region. Moreover, the kinetics of these conformational changes indicate that they are tightly coupled with changes in the energized state of the membrane. Hence, we conclude that ion gradients drive conformational changes in key sites of Tim23 that are coupled to its function in driving polypeptide translocation and integration. This work provides novel insights into how proteins

within energy-conserving membranes can utilize the $\Delta\tilde{\mu}_{H+}$ to perform work. Moreover, it provides a system for analyzing: (i) how the different components of the $\Delta\tilde{\mu}_{H+}$, the membrane potential and the proton gradient, may differentially drive conformational changes, and (ii) how voltage-gated proteins may sense changes in membrane potential.

1679

Expression of the Genes Encoding Multidrug Resistance-Associated Proteins (MRPs) and Distribution of MRP1-4 Proteins in Human Skin Cells and Epidermis.

W. Khazen[1], J-M. Verbavatz[1], K. Lazou[2], E. Noblesse[2], S. Schnebert[2], M. Dumas[2], E. Perrier[2], M. Garrigos[1]; [1]CEA-Saclay, iBiTec-S, F-91191 Gif-sur-Yvette Cedex, France, Gif-sur-Yvette Cedex, France, [2]LVMH Recherche, F-45804 St Jean de Braye Cedex, France, St Jean de Braye Cedex, France

The nine human multidrug resistance–associated proteins (MRP1-9), which possess an ATP-binding consensus motif, are involved in cellular detoxification processes. Their physiological roles in the human epidermis are unknown. The aim of this study was to characterize the expression, location and functionality of these proteins in normal proliferating human epidermis keratinocytes (NHEK) and melanocytes (NHEM) and in normal human skin samples under various conditions. Judging from reverse transcription-polymerase chain reaction experiments, the genes encoding MRP1, MRP4, MRP5 and MRP7 are similarly expressed in NHEK and NHEM. In contrast, MRP2 gene expression is mainly observed in NHEM and the MRP3 gene is exclusively expressed in NHEK. The expressed proteins were visualized by immunofluorescence. MRP1-4 proteins were found in the intracellular compartment of NHEM and NHEK cell lines. MRP2 was immunodetected around the nuclei of NHEM cells. MRP4 was restricted to the dendrites. Unexpectedly, we found that MRP2 forms a barrier-like structure in the *stratum granulosum* region of the epidermis of normal human skin. We demonstrate that MRPs are functional in NHEK and NHEM cell lines and show that MRP1 and MRP2 are implicated in the sensitivity of both cell lines to doxorubicin, probably by sequestering doxorubicin within the cell. We conclude that these transporters might help protect epidermis cells against xenobiotics.

Mitochondria, Chloroplasts, and Peroxisomes

1680

ER tubules mark sites of mitochondrial division.

J. Friedman[1], L. Lackner[2], M. West[1], J. DiBenedetto[1], J. Nunnari[2], G. Voeltz[1]; [1]Molecular, Cellular, and Developmental Biology, University of Colorado-Boulder, Boulder, CO, [2]Molecular and Cellular Biology, University of California-Davis

Mitochondrial structure and distribution are regulated by division and fusion events. Mitochondrial division is regulated by Dnm1/Drp1, a dynamin-related protein that forms helices around mitochondria to mediate fission. Little is known about what determines sites of mitochondrial fission within the mitochondrial network. Given that ER and mitochondria exhibit tightly coupled dynamics and have extensive contacts, we tested whether ER plays a role in mitochondrial division. We show that mitochondrial division occurs at positions where ER tubules contact mitochondria and mediate constriction prior to Drp1 recruitment. These data demonstrate that ER tubules play an active role in defining the position of mitochondrial division sites.

1681

The function of the Mmm1 protein in *Neurospora crassa*.

J. G. Wideman[1], F. E. Nargang[1]; [1]Department of Biological Sciences, University of Alberta, Edmonton, AB, Canada

Both mitochondria and the endoplasmic reticulum (ER) are essential sites of phospholipid biosynthesis. The recently discovered ER-Mitochondria Encounter Structure (ERMES) complex which comprises the Mdm10, Mdm12, Mmm1 and Mmm2 proteins is thought to function in the exchange of phospholipids between the two organelles. In yeast, the absence of any ERMES complex member causes several phenotypes including the alteration of mitochondrial steady-state lipid ratios, enlarged mitochondria, impaired mitochondrial protein assembly, as well as defects in mitochondrial motility, inheritance and DNA stability. In *Neurospora crassa* we have previously shown that strains lacking Mmm1 contain enlarged mitochondria and are deficient in the assembly of mitochondrial β-barrel proteins. We now demonstrate that mitochondria isolated from *N. crassa* strains lacking Mmm1 do not exhibit obvious alterations in lipid ratios. We also show that HA tagged Mmm1 fractionates with both gradient purified mitochondria and the post-mitochondrial pellet. We demonstrate that Mmm1 forms a dimer with an unknown protein via disulfide bonding. In a cysteine-less mutant, inability to dimerize has no effect on the localization of the protein, but Tom40 is less efficiently assembled into the mature TOM complex. The import and assembly of other outer membrane proteins (Tom22 and Porin) remains unaffected. These results suggest that Mmm1 is directly involved in the late assembly of Tom40 and may not be involved in mitochondrial lipid homeostasis in *N. crassa*. Focusing on a highly conserved region of Mmm1, we constructed another mutant *N. crassa* strain. This mutant is impaired in the assembly of the β-barrel proteins Tom40 and porin, whereas Tom22 assembly remains unaffected. Taken together our results suggest that Mmm1 plays a direct role in mitochondrial protein assembly in *N. crassa* and different domains of the protein appear to be involved in the assembly of specific mitochondrial proteins.

Live-cell imaging of the association of STAT6-GFP with mitochondria.

J. Lee[1], Y-M. Yang[1], P. Sehgal[2]; [1]Cell Biology and Anatomy, New York Medical College, Valhalla, NY, [2]Cell Biology and Anatomy and Medicine, New York Medical College

STAT6 has been implicated in regulating energy metabolism in cell types such as the hepatocyte. However, all prior discussion of the mechanisms involved have centered on the genomic/transcriptional effects of STAT6. We carried out a survey of all seven STAT proteins (STAT1, 2, 3, 4, 5a, 5b and 6) for their possible association with mitochondria in human Hep3B hepatocytes by first washing out bulk soluble STAT proteins using a low concentration digitonin-sucrose buffer followed by paraformaldehyde fixation and immunofluoresence using respective anti-STAT pAbs. The possible co-localization was evaluated quantitatively using Manders' and Pearson's metrics with mitochondria marked using a mAb to F1-ATPase. STAT6 was observed to be strongly associated with mitochondria; this immunofluoresence was inhibited by STAT6-blocking peptide and reduced by transfecting Hep3B cells with STAT6 siRNA. Following transient transfections of an expression vector, STAT6-GFP, but not N1-GFP, was observed to colocalize with MitoTracker- and TMRE-positive mitochondria in live cells and with F1-ATPase mAb assayed by immunofluoresence after fixation. In contrast, using the same techniques we were unable to detect any association of STAT3-GFP or STAT5a-GFP with mitochondria based on GFP fluoresence. Immunogold EM confirmed the association of STAT6 within the mitochondrial matrix in human pulmonary arterial endothelial and smooth muscle cells. The present data showing the association of STAT6-GFP with mitochondria in live cells represents

the first visible evidence of the association of a STAT protein family member with mitochondria. Supported by NIH grants R01HL087176 and F31HL107013.

Human MIEF1 Recruits Drp1 to Mitochondrial Outer Membranes and Promotes Mitochondrial Fusion Rather than Fission.

J. Zhao[1], T. Liu[1], S. Jin[2], X. Wang[1], M. Qu[1], N. Tomilin[3], O. Shupliakov[3], U. Lendahl[2], M. Nister[1]; [1]Oncology-Pathology, Karolinska Institutet, Stockholm, Sweden, [2]Cell and Molecular Biology, Karolinska Institutet, Stockholm, Sweden, [3]Neuroscience, Karolinska Institutet, Stockholm, Sweden

BACKGROUND: Mitochondrial morphology is controlled by two opposing processes: fusion and fission. Drp1 (dynamin-related protein 1) and hFis1 are two key players of mitochondrial fission, but how Drp1 is recruited to mitochondria and how Drp1-mediated mitochondrial fission is regulated in mammals is poorly understood.
METHODS: This work used a number of cell biological techniques, eg cell culture, generation of expression constructs, mutational analysis, subcellular fractionation, immunoblotting, double and triple immunofluorescence stainings, confocal microscopy, transmission electron microscopy, RNAi silencing, in vivo protein cross-linking, co-immunoprecipitation and cell fusion assays.
RESULTS: We have identified the vertebrate-specific protein MIEF1 (mitochondrial elongation factor 1; independently identified as MiD51), which is anchored to the outer mitochondrial membrane. Elevated MIEF1 levels induce extensive mitochondrial fusion, whereas depletion of MIEF1 causes mitochondrial fragmentation. MIEF1 interacts with and recruits Drp1 to mitochondria in a manner independent of hFis1, Mff (mitochondrial fission factor) and Mfn2 (mitofusin 2), but inhibits Drp1 activity, thus executing a negative effect on mitochondrial fission. MIEF1 also interacts with hFis1 and elevated hFis1 levels partially reverse the MIEF1-induced fusion phenotype. In addition to inhibiting Drp1, MIEF1 also actively promotes fusion, but in a manner distinct from mitofusins.
CONCLUSIONS: Our findings uncover a novel mechanism, which controls the mitochondrial fusion–fission machinery in vertebrates. As MIEF1 is vertebrate-specific, these data also reveal important differences between yeast and vertebrates in the regulation of mitochondrial dynamics.

1684

Fast oscillations of NAD(P)H in the salivary glands epithelium of live rats imaged by intravital two-photon microscopy.

N. Porat-Shliom[1], A. Masedunskas[1], R. Weigert[1]; [1]Intracellular Membrane Trafficking Unit, Oral and Pharyngeal Cancer Branch,NIDCR, NIH, Bethesda, MD

Several endogenous small molecules have been described to emit upon two-photon excitation. Among them is the reduced form of nicotinamide adenine dinucleotide (NADH) and the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) [1]. NAD(P)H molecules are present both in the cytosol and mitochondria and provide the optical contrast to reveal the architecture of various organs. Here we focus on imaging NAD(P)H endogenous fluorescence in the salivary glands (SGs) of live rats by using intravital two-photon microscopy, and show how details of the structure of acini and ducts can be easily resolved. Furthermore, we show that in resting conditions NAD(P)H fluorescence propagates across the salivary epithelium in waves that exhibit a characteristic frequency. By using different experimental approaches we show that these waves are not the result of motion artifacts. Interestingly, the waves seem to be originated from specific foci, most likely the nerve terminals. Stimulation of the β2 adrenergic receptor by

its agonist isoproterenol (ISO), leads to a sharp increase in endogenous fluorescence, whereas the muscarinic agonist Carbachol (Carb) has no effect on the oscillating fluorescence. Moreover, when SGs were labeled with cationic dyes, such as TMRM and Rhodamin123, which are sensitive to the mitochondrial membrane potential, we observe waves that overlaps those revealed by exciting NAD(P)H emission. This finding suggests that the oscillations of the NAD(P)H pool may be linked to mitochondrial metabolism. Although further experiments are required, we speculate that: 1) NAD(P)H oscillations and propagation may be originated from the neurotransmitters originated from nerve terminals, 2) the waves may be used as an indicator of SGs functionality ,raising the possibility of using two-photon stimulated endogenous emissions as a diagnostic tool, and 3) the increase of NAD(P)H upon agonist stimulation may be associated with the regulation of stimulated protein secretion.

1685

The role of a dual specificity phosphatase on alternative oxidase production in *Neurospora crassa.*

A. B. Desaulniers[1], F. Nargang[1], K. Adames[1]; [1]Biological Sciences, University of Alberta, Edmonton, AB, Canada

Various inhibitors and mutations result in blockage of the standard electron transport chain. In many organisms, including *Neurospora crassa*, this leads to the expression of alternative oxidase (AOX). AOX is a single protein enzyme that carries electrons from ubiquinol to molecular oxygen. Single gene knockout (KO) strains, available from the Fungal Genetic Stock Centre, were screened for their ability to grow in the presence of Antimycin A, an inhibitor of the standard electron transport chain. KO strains that were unable to grow were selected for further investigation. One KO was found to affect a gene encoding a protein with homology to *Saccharomyces cerevisiae* Yvh1p, a dual specificity phosphatase. The protein contains a HCX_5R phosphatase domain in the N-terminal region and a redox sensing zinc-binding domain in the C-terminal region. The KO has a slow growth phenotypye and under inducing conditions, a low level of AOX. We have shown that the levels of the phosphatase are similar in cultures grown under both non-inducing conditions and conditions that induce AOX. Cell fractionation experiments have revealed that the majority of the protein localizes to the nuclear and microsomal fractions and not to the cytosolic or mitochondrial fractions. Mutational analysis of the two domains has shown that both the phosphatase and zinc binding domains need to be functional to rescue AOX induction.

1686

Cell-free Reconstitution and Spectral Analysis of the ADP/ATP Carrier within Proteoliposomes.

A. R. Long[1], N. N. Alder[1]; [1]Molecular and Cell Biology, University of Connecticut, Storrs, CT

The ADP/ATP carrier (AAC) of the mitochondrial inner membrane (IM) transports ADP into the mitochondrial matrix and exports ATP into the cytosol after its synthesis; hence, it is central to cellular energy balance. The AAC contains six transmembrane helices and three matrix-facing loops and represents the only member of the mitochondrial carrier family for which crystal structures are available. Previous work suggests that cardiolipin, the signature phospholipid of mitochondria in eukaryotic cells, is critical for the assembly and function of the AAC. The objective of this work is to investigate the conformational dynamics and lipid interactions of key regions (matrix loops) of the AAC reconstituted into model membrane systems using a fluorescence-based approach. Membrane proteins are innately difficult to analyze because they are not amenable to solution-based studies. We therefore use AAC reconstituted into proteoliposomes for spectroscopic analyses. To synthesize proteoliposomes containing AAC,

we have adapted a novel but well-characterized cell-free translation system whereby polypeptides are integrated directly into preformed liposomes of desired lipid composition. In agreement with previous work with other membrane proteins, AAC is properly integrated as judged by carbonate extraction and proteolysis. Further, we provide evidence that insertion occurs co-translationally by monitoring the interaction of ribosome-bound integration intermediates with liposomes. To synthesize full length AAC with the fluorescent probe NBD at specific sites, we program translation reactions with mRNA encoding AAC bearing unique nonsense (UAG) codons and include suppressor tRNA analogs that allow for the incorporation of non-natural (probe-bearing) amino acids. This has provided evidence for secondary structural elements with membrane interacting surfaces within the matrix loops. In support of this work, synthetic peptides corresponding to matrix helices were used to investigate the innate propensity of these regions to interact with the bilayer. These peptides have been shown to interact with model membranes in a cardiolipin dependent manner by solvent effects, collisional quenching, and resonance energy transfer. In conclusion, we have developed a novel experimental method for the synthesis of proteoliposomes containing AAC site-specifically labeled with fluorescent probes. This technique allows us to monitor structural dynamics of key locations on AAC in relation to the bilayer. Taken together, this work shows that matrix helices of the AAC interact dynamically with the bilayer in a manner dependent on lipid content and conformational state.

1687

Assembly and Activity of Respiratory Complex II in Reconstituted Membrane Systems.

C. T. Schwall[1], N. N. Alder[1]; [1]Molecular and Cell Biology, University of Connecticut, Storrs, CT

Mitochondrial respiratory complex II (succinate:quinone oxidoreductase) is comprised of a soluble catalytic dimer (Sdh1p and Sdh2p in *Saccharomyces cerevisiae*; SdhA and SdhB in mammals) and a membrane-bound heterodimer (Sdh3p and Sdh4p in *S. cerevisiae*; SdhC and SdhD in mammals). The membrane bound subunits coordinate a heme, making complex II a *b*-type cytochrome. As the only membrane-bound complex of the tricarboxylic acid cycle, this complex oxidizes succinate to fumarate and passes the electrons to quinone as part of the electron transport chain of the inner mitochondrial membrane. The primary objective of this work is to investigate the role of the phospholipid environment in: a) the assembly of the membrane subunits, and b) the enzymatic activity of the holoenzyme. Membrane proteins and complexes are traditionally refractory to standard biochemical and biophysical analyses. In order to overcome this technical challenge we have employed the following technically innovative approaches: a) detergent-free proteoliposome synthesis for studying dimerization of membrane-bound Sdh3p/C and Sdh4p/D subunits, and b) reconstitution of active complex II from native membranes into nanolipoprotein particles (nanodiscs) to study isolated function in a lipid bilayer environment. In relation to membrane subunit assembly within proteoliposomes, we have unexpectedly observed that Sdh3p/C form homodimers in a manner that is promoted by heme and also by cardiolipin, the signature phospholipid of mitochondria in eukaryotes. In addition, the Sdh3p/C homodimer is disrupted by Sdh4p/D, suggesting heterodimer formation that can then lead to the assembly of the functional complex. But, interestingly, Sdh4p/D homologs Tim18 and YLR164w appear to interact even more strongly with Sdh3/C, judged by their disruption of the homodimer. Taken together, these results suggest dynamic interaction among complex II membrane subunits and their homologs. By reconstituting the holocomplex into nanodiscs of different lipid composition, we analyzed the effects of phospholipid environment on catalytic activity and complex stability as well. We observed a strong effect of acyl chain length on activity and that maximal activity requires the native-like lipid composition that contains cardiolipin. In conclusion, complex II membrane protein subunit assembly involves multiple

potentially-interacting proteins whose interactions are mediated by lipids and cofactors. Further, complex II catalysis is greatly affected by lipid properties and the presence of cardiolipin.

MARCH5, a mitochondrial E3 ligase, degrades mitochondrial targeted HBx viral oncoprotein.

Y. Yoo[1], Y. Park[1], H. Cho[1]; [1]Ajou University, Suwon, Korea

The hepatitis B virus X protein (HBx), oncogenic protein, plays an important role in HBV replication and development of hepatocellular carcinoma.HBx localizes to the mitochondrial outer membrane, which induces mitochondrial dysfunction, oxidative stress and cell death. MARCH5, a mitochondrial E3 ubiquitin ligase localizes to the mitochondrial outer membrane. We here showed that MARCH5 binds HBx and promotes its degradation whereas the MARCH5H43W mutant lacking ubiquitin ligase activity did not, indicating that MARCH5 serves as a protein quality controller on viral oncoprotein. Accordingly, overexpression of MARCH5 alleviated the HBx-induced ROS generation. In addition, HBx-mediated transactivation activity on the COX-2 promoter was weakened in the presence of MARCH5. Thus, the data indicate that MARCH5 contributes to protecting the cells from HBx-mediated cytotoxic effects.

1689

Reconstitution of the Minimal Mitochondrial Fission Machinery in Yeast and Humans.

S. Koirala[1], Q. Guo[1], J. M. Shaw[1]; [1]Biochemistry, University of Utah, Salt Lake City, UT

Mitochondrial fission regulates organelle copy number and mitochondrial function in metabolism, development and apoptosis. The dynamin-related GTPases Dnm1 and Drp1 are required for mitochondrial fission in yeast and human, respectively. Dnm1/Drp1 assembles into spirals that encircle and divide mitochondria. In yeast, a tail-anchored protein called Fis1 and an adaptor protein called Mdv1 recruit Dnm1 to the membrane, where Mdv1 co-assembles with Dnm1 and stimulates Dnm1 GTPase activity. Whether Fis1 participates in Dnm1 assembly or post-assembly membrane scission events is unknown. Although Fis1 is conserved in humans (hFis1), an Mdv1 homolog is absent. Instead, humans have at least two different membrane anchored proteins (hFis1 and hMff) whose roles in fission are poorly defined.

Using yeast cells expressing only Dnm1 and a mitochondrial-tethered form of Mdv1, we demonstrated that Fis1 is dispensable for Dnm1 recruitment, assembly, and mitochondrial membrane scission in vivo. Importantly, the absence of Fis1 did not affect distribution of fission complexes on the mitochondrial membrane. Thus, Fis1 acts to direct essential fission components to the correct cellular membrane but does not determine the site of complex assembly. Similar tethering studies reveal that hDrp1 and hMff (but not hFis1) are sufficient to reconstitute mitochondrial fission in yeast. We postulate that the hMff protein combines the hDrp1 GTPase recruitment and effector functions that are carried out separately by Fis1 and Mdv1 in yeast. To test this model, we are using biochemical methods to determine how the cytoplasmic domain of hMff affects the assembly and GTPase activities of hDrp1. Our findings suggest that the conserved role(s) of Fis1 in yeast and human is yet to be identified.

The Caf4p Adaptor is a Component of Active Mitochondrial Fission Complexes.

Q. Guo[1], S. Koirala[1], N. Perkins[2], M. McCaffery[2], J. M. Shaw[1]; [1]Biochemistry Department, University of Utah, SLC, UT, [2]Integrated Imaging Center, Department of Biology, Johns Hopkins University, Baltimore, MD

Mitochondrial fission in eukaryotes is mediated by protein complexes that assemble around the cytoplasmic surface of mitochondrial tubules. In budding yeast, fission requires the tail-anchored protein Fis1 and the dynamin-related GTPase Dnm1. Mdv1 and Caf4 are adaptor proteins that interact with both Fis1 and Dnm1 and have redundant functions in Dnm1 recruitment to mitochondria (Griffin et al., 2005). Although Mdv1 is required after Dnm1-recruitment for mitochondrial fission, a role for Caf4p in fission has not been established.
Using time-lapse imaging studies, we established that GFP-Caf4 is present at mitochondrial fission sites and is able to rescue mitochondrial fission defects when Mdv1 is absent. In addition, Caf4 and Mdv1 co-localize in a subset of fission complexes *in vivo*, which also carry out mitochondrial fission. When over expressed 2.5 fold relative to endogenous levels, only Caf4 causes dominant negative fission defects. Experiments are underway to determine whether Caf4 expressed from the genomic MDV1 promoter is sufficient to support wild-type levels of fission *in vivo*. (supported by NIH-RO1-GM053466)

Discovery of NOL11, a Metazoan-Specific SSU Processome Protein That Is Required For Pre-rRNA Transcription And Processing.

E. Freed[1], J-L. Prieto[2], B. McStay[2], S. Baserga[1]; [1]Yale University, New Haven, CT, [2]NUI Galway

Ribosome biogenesis is among the most fundamental of cellular processes. Pre-rRNA transcription and processing occur in the subcellular compartment called the nucleolus. The majority of the hundreds of nucleolar proteins involved in ribosome biogenesis were discovered in yeast. While most of these proteins and their functions are conserved to humans, it is becoming clear that important differences exist in how ribosome biogenesis is regulated between yeast and humans. In particular, some essential proteins are not conserved between these two organisms, raising the possibility that they are replaced by functional analogs. Our objective was to identify non-conserved interaction partners for the human ribosome biogenesis protein, hUTP4/Cirhin, since a mutation in the C-terminus of hUTP4/Cirhin is reported to cause North American Indian childhood cirrhosis (NAIC). By screening a yeast two-hybrid cDNA library and through affinity purification followed by mass spectrometry, we identified an uncharacterized nucleolar protein, NOL11, as an interaction partner for hUTP4/Cirhin. Bioinformatic analysis revealed that NOL11 is conserved throughout metazoans, but is not found in any other phylogenetic groups. Co-immunoprecipitation experiments show that NOL11 is in the human ribosomal small subunit (SSU) processome. Using siRNAs to knock-down NOL11 revealed that NOL11 is involved in the cleavage steps that are required to generate the mature 18S rRNA, and further suggested that NOL11 may be required for optimal pre-rRNA transcription. Directed one-by-one yeast two-hybrid analysis shows a complex interaction network between NOL11, other SSU processome subcomplex members, and the RNA polymerase I transcription machinery supporting a role for NOL11 in both pre-rRNA processing and transcription. Finally, yeast two-hybrid analysis using truncated forms of hUTP4/Cirhin shows that NOL11 interacts with the C-terminus of hUTP4/Cirhin, allowing us to propose that NOL11 is the functional analog

of the yeast protein, Utp8. Further study of NOL11 and its interaction with hUTP4/Cirhin may shed light on the etiology of North American Indian childhood cirrhosis.

1692

Spatio-temporal organization of transcription factories within living cells.

S. Maharana[1,2], G. Shivashankar[3]; [1]Mechanobiology Institute, National University of Singapore, Singapore, [2]National Centre for Biological Sciences, Bangalore, India

Recent studies have shown that transcriptional activity in the nucleus is organized in distinct sites called transcription factories (TFs), where genes either loop out or are co-clustered to form active chromatin hubs. In addition, our studies are beginning to reveal that gene-active chromosomes share physical proximity within the 3D architecture of the cell nucleus. However the spatio-temporal organization of TFs and its functional implications are unclear. Using high-resolution live-cell fluorescence imaging and spectroscopy, we analyze the dynamic organization of TFs. For this we labeled TFs using fluorescent UTPs which co-localize with active RNA Pol-II antibody in a transcription dependent manner. Dual color labeling methods revealed that TFs are specialized foci. Further, the local chromatin structure, mapped using fluorescence anisotropy measurements, in vicinity of TFs showed a transcription dependent compaction state. Interestingly TFs exhibited a dynamic behavior with runs, pauses and steps. This dynamic organization of TFs was dependent on ATP, lamin B1, histone acetylation levels and cytoplasmic to nuclear anchorage. Importantly during runs, TFs are mobile within the inter-chromosome territories. The spatio-temporal organization of TFs that we observe may provide possible mechanisms to alter gene expression programs upon integration of physico-chemical signals to the nucleus.

Digitor, a Novel Zinc-finger Protein Interacts with the Nuclear Spindle Matrix Protein Skeletor as well as with the Dynein Light Chain Ddlc1 in *Drosophila.*

S. Sengupta[1], C. Yao[1], U. Rath[2], J. Girton[1], K. M. Johansen[1], J. Johansen[1]; [1]Biochemistry, Biophysics & Molecular Biology, Iowa State University, Ames, IA, [2]Physiology and Biophysics, Albert Einstein College of Medicine, Bronx, NY

In *Drosophila* we have used yeast two-hybrid interaction assays to identify a novel zinc-finger protein (CG14962) that we have named, Digitor, which interacts with the COOH-terminal of the spindle matrix protein Skeletor. Skeletor localizes to interband regions of polytene chromosomes during interphase but redistributes during mitosis to form a spindle matrix complex together with Chromator, Megator, and EAST that is distinct from the microtubule-based spindle apparatus. The interaction between Skeletor and Digitor was subsequently confirmed by pull-down assays. Digitor is a 44 kD protein that contains four NH_2-terminal zinc-

finger domains in addition to six TQT motifs in the COOH-terminal domain. Since the TQT motif has previously been identified in dynein light chain binding proteins we made His- and MBP-tagged versions of Digitor and the *Drosophila* dynein complex light chain Ddlc1 (LC8), respectively. Pull-down assays performed with these constructs strongly supported the existence of a direct physical interaction between Digitor and Ddlc1. Furthermore, transient expression studies in S2 cells revealed that GFP-tagged Digitor localizes to the nucleus. Interestingly, it has previously been demonstrated that the spindle matrix protein Megator homolog Tpr in mammalian cells associates with the dynein complex during mitosis (Nakano et al., J. Biol. Chem. 285:10841, 2010). Experiments are in progress to determine whether Skeletor, Digitor, and Ddlc1 all are present in the same complex and to how the interactions between these proteins are coordinated during the cell cycle. Supported by NSF grant MCB0817107.

1694

The "PcG body" established by correlative light electron microscopy.

J. Smigova[1,2], P. Juda[1,2], D. Cmarko[1,2], I. Raska[1,2]; [1]Institute of Cellular Biology and Pathology, Charles University in Prague, First Faculty of Medicine, Prague, Czech Republic, [2]Department of Cell Biology, Institute of Physiology AS CR v.v.i., Prague, Czech Republic

Polycomb group (PcG) proteins are a set of conserved, essential regulatory factors, that through the assembly on key regulatory DNA elements, repress the transcription of their target genes. Proteins of the Polycomb repressive complex 1 (PRC1) are found to be diffusely distributed in nuclei of cells from various species. However, they can be also localized in intensely fluorescent foci, whether imaged using GFP fusions to proteins of PRC1 complex, or by conventional immunofluorescence microscopy. Such foci are termed PcG bodies, and are believed to be situated in the nuclear interchromatin compartment. However, an ultrastructural description of the PcG body has not been reported to date.

To establish the ultrastructure of PcG bodies in human U-2 OS cells stably expressing recombinant polycomb BMI1-GFP protein, we used correlative light electron microscopy (CLEM) implemented with high-pressure freezing, cryosubstitution and on-section labeling of BMI1 protein with immunogold. CLEM approach allowed us to clearly identify fluorescent PcG bodies, not as distinct nuclear bodies, but as nuclear domains enriched in separated heterochromatin fascicles. Importantly, high-pressure freezing and cryosubstitution allowed for a high and clear-cut imunogold BMI1 labeling of heterochromatin structures throughout the nucleus. The density of immunogold labeled BMI1 in the heterochromatin fascicles corresponding to fluorescent "PcG bodies" did not differ from the density of labeling of heterochromatin fascicles outside of the "PcG bodies."

Further, we focused on compaction aspect of the chromatin accumulated into PcG foci and the behaviour of the foci in hyperosmotic environment. Our preliminary data show that with increasing hypertonic load and incubation time the PcG foci reduce their size gradually up to total disappearing and when the cells are washed, the PcG foci appear again. The treated cell reacts within its physiological realms and BMI1 protein undergoes the changes in post-translational modifications.

1695

Characterization of the function of a novel nuclear protein, JC1V2, an interaction partner of Dictyostelium discoideum SUN-1.

B. Burgute[1], R. Müller[1], B. Gassen[1], L. Eichinger[1], A. Noegel[1]; [1]Center for Biochemistry, Medical Faculty, University of Cologne, Cologne, Germany

Dictyostelium SUN-1 is the homolog of mammalian Sun proteins. Sun proteins are inner nuclear membrane proteins and are essential components of the LINC complex which connects the nucleus and the cytoskeleton. For the Dictyostelium protein we reported that it connects the centrosome to chromatin and ensures genome stability. However the role of SUN-1 in general is still poorly understood. Here we introduce a novel nuclear protein as an interacting partner of SUN-1, JC1V2, which has a role in gene regulation, aggregation and chemotaxis of D. discoideum. The N-terminus of SUN-1 is important for this interaction. JC1V2 protein is divided in to two domains. The N-terminal domain is highly basic, containing segments of low compositional complexity and C-terminal has a DUF926 domain (Domain of Unknown Function #926 in the NCBI Conserved Domain Database). During interphase JC1V2 is localised in the nucleus in a punctuated pattern, during mitosis it redistributes to the cytosol. Upon ectopic expression of JC1V2 the cells show a severe growth defect, a delay in stream formation, aggregation and chemotaxis. Overexpression of the N-terminus only also led to a growth defect, however streaming and aggregation were enhanced when compared to wildtype cells. This was paralleled by enhanced chemotactic speed and increased motility. To better understand the function of JC1V2, we performed gene expression profiling using microarray studies, which revealed up-regulation of genes involved in stress response whereas genes involved in translation were found to be down-regulated. In conclusion Dictyostelium JC1V2, a SUN-1 interacting protein, is involved in gene regulation, growth and aggregation.

1696

Son is Important for Cell Cycle Progression.

K. N. Torres-Munoz[1], A. Sharma[2], P. A. Bubulya[3]; [1]Master of Science Program, Wright State University, Dayton, OH, [2]Biomedical Sciences Program, Wright State University, Dayton, OH, [3]Biological Sciences, Wright State University, Dayton, OH

The organization of pre-mRNA processing factors into nuclear speckles is important for coordinating pre-mRNA transcription and splicing in mammalian cells. Pre-mRNA processing factors disassemble from these nuclear compartments at the onset of mitosis and assemble into mitotic interchromatin granules clusters (MIGs) in the cytoplasm until they enter nuclei in telophase. A large repeat-rich splicing factor called Son is required for proper organization of pre-mRNA processing factors in nuclear speckles during interphase. Because Son is also required for mitotic progression through metaphase, we analyzed localization of Son in human cells during mitosis. We found Son in MIGs, consistent with the possibility that Son may seed MIG assembly at metaphase to promote normal cell cycle progression. Our recent results revealed that Son is required to maintain the organization and integrity of the mitotic spindle. Son-depleted cells exhibited disorganized spindles with longer interpolar distances than controls. Exon array analysis points toward changes in mRNA levels and alternative splicing of transcripts encoding mitotic regulators as a key mechanism for mitotic defects in Son-depleted cells. Our study also provides a comprehensive view of human transcription and splicing targets for Son in fundamental cellular pathways such as integrin-mediated cell adhesion, cell cycle regulation, cholesterol biosynthesis, apoptosis, and epigenetic regulation of gene expression.

1697

A novel role for β-dystroglycan as a nuclear scaffolding protein required for nuclear domains organization and function.

I. A. Martínez-Vieyra[1], R. Gonzalez-Ramirez[2], S. L. Morales-Lázaro[3], A. Ortega[1], B. Cisneros[1]; [1]Departamento de Genética y Biología Molecular, CINVESTAV-IPN, México DF, Mexico, [2]Departamento de Biología Molecular e Histocompatibilidad, Hospital General Dr. Manuel Gea González, México, DF, Mexico, [3]Departamento de Neurodesarrollo y Fisiología Celular, UNAM, México, DF, Mexico

β-dystroglycan is a widely expressed transmembrane protein belonging to the dystrophin-associated protein complex. β-dystroglycan anchors α-dystroglycan to the cell membrane via its the N-terminus domain, and binds to dystrophin via its C-terminus domain, providing by this way a tight link between the extracellular matrix and the intracellular cytoskeleton. Nuclear localization of β-dystroglycan has been revealed recently; however, its functional relevance remains unknown. The nucleus of eukaryotic cells is a highly dynamic organelle organized into different specialized domains that perform specific functions, including replication, transcription, RNA processing, and ribosome biogenesis. Therefore, to make an inference concerning the nuclear role of β-dystroglycan, we analyzed its potential association with different nuclear compartment markers, by immunofluorescence and immunoprecipitation assays. We found that β-dystroglycan associates with protein markers from nuclear envelope (lamin A/C, -B1, and emerin),splicing speckles (SC35), Cajal bodies (p80 coilin), and nucleoli (Nopp140). Interestingly, β-Dystroglycan knock-down resulted in mislocalization and decreasing levels of lamin B1, emerin, nopp140 and coilin. Altogether, our data revealed that β-dystroglycan works as nuclear scaffolding protein required for nuclear domains organization and function.

1698

Quantification of Water and Ions in the Nucleus by Cryo-Correlative Light and Scanning Transmission Electron Microscopy.

D. Ploton[1], F. Nolin[1], L. Wortham[1], G. Balossier[1], P. Tchelidze[1], V. Banchet[1], N. Lalun[1], H. Bobichon[1], J. Michel[1]; [1]Université de Reims Champagne Ardenne, Reims Cedex, France

The cell nucleus contains the highest concentration of macromolecules in the cell. Thus, in mammalian cells, mean concentration of macromolecules varies from 65 to 180 mg/ml for whole nuclei and from 75 to 200 mg/ml for interphase chromatin and nucleolus respectively as measured by using different approaches such as chemical assays, interference microscopy or quantitative Scanning and Transmission Electron Microscopy (STEM). Such high concentrations induce macromolecular crowding which predicts that a small variation in the water content could produce strong variations in the activity of numerous macromolecules. Data dealing with water content and ions concentration in hydrated nuclear compartments are unknown. This is limiting for a detailed knowledge of the cell nucleus function because water is recognized as a crucial player in the organization of proteins and nucleic acids.
The objective of our study was to quantify water and ions concentration in the main nuclear domains at nanoscale both within control and stressed cells.
For this, we developed a new correlative light and electron microscopy imaging approach combining observation of the same cryo-ultrathin section first by fluorescence microscopy (localization of GFP in HeLa cell-line expressing H2B-GFP) and then by cryo-STEM. As fluorescence and STEM images were perfectly aligned, nuclear compartments containing chromatin were clearly identified in order to perform simultaneous water quantification and elementary analysis (N, P, K^+, Cl- , Mg^{2+} and S) by STEM with a resolution of 20 nm and expressing data in mmol/L.

We found that nucleoplasm contained more water than clumps of interphase condensed chromatin and than chromatin of mitotic chromosomes (75.7 %, 64.8 % and 63.2% respectively). In the nucleolus, fibrillar centers contained more water than other nucleolar components (dense fibrillar and granular components) (82.9% and 68.8% respectively). Concentration of ions ranged from 128 to 462 mmol/L for K^+, from 23 to 85 mmol/L for Cl- and from 13 to 55 mmol/L for Mg^{2+}. Interestingly, a nucleolar stress induced by actinomycin D increased water content in all the nuclear compartments.
In conclusion, this study simultaneously quantified water and elements in the main nuclear components for the first time. We found that water content is lower than previously estimated in control cells and that it increased after a nucleolar stress.

Coilin implicated in U snRNA 3' end processing: nucleic acid interaction studies point to additional functions of the Cajal body marker protein.

H. J. Broome[1], M. D. Hebert[1]; [1]Biochemistry, University of Mississippi Medical Center, Jackson, MS

Coilin is a nuclear protein known primarily as the marker for Cajal bodies, subnuclear domains present in cells with high transcriptional demands and important in the biogenesis of small nuclear ribonucleoproteins (snRNPs), the primary component of the pre-mRNA splicesome. However, the majority of coilin is nucleoplasmic and the function of this fraction has yet to be fully elucidated. In HeLa cells, Cajal bodies have been found to associate with both U1 and U2 gene loci that yield the RNA component of U1 and U2 snRNPs, respectively. The primary transcripts for both U1 and U2 snRNA, products of RNA polymerase II, have been shown to be longer than the mature transcript that is incorporated into the snRNP and must undergo 3' end processing. Both the RNA polymerase II C-terminal domain and the Integrator complex are involved in the processing of U2 snRNA. We hypothesize that coilin can bind nucleic acid and plays a role in the processing of these primary U snRNA transcripts as an additional function to its known role in Cajal body formation. In this study, we seek to characterize the nucleic acid interaction properties of coilin and determine in what capacity it may be involved in snRNA 3' end processing. Using electroelution, we purify bacterially expressed coilin to homogeneity. We then incubate purified coilin with DNA, RNA, and double-stranded RNA. Following incubations, we analyze DNA/dsRNA binding and global RNA degradation by agarose gel electrophoresis and specific RNA degradation by qRT-PCR. We have also targeted coilin for knockdown with siRNA in HeLa cells, and analyzed the effect of this knockdown on U snRNA processing by qRT-PCR. Here, we show purified coilin can bind double-stranded DNA and double-stranded RNA in vitro. Surprisingly, purified coilin degrades HeLa RNA in a concentration-dependent manner, and this activity seems to arise from the N terminus as purified coilin C-terminal fragments have relatively diminished RNase activity. Upon incubation with a U2 snRNA primary transcript in vitro, coilin displays RNase specificity to the CU region, which is downstream of the mature 3' terminus. In HeLa cells with 70-80% coilin mRNA knockdown, we show a significant increase in the level of 3' pre-processed U1 and U2 snRNA by qRT-PCR analysis. Taken together these results support additional functions of coilin, including U snRNA processing, and suggest a more direct role for Cajal bodies in the biogenesis of snRNPs.

Coilin Levels Modulate Cell Cycle Progression and Gamma H2AX Levels in Etoposide Treated U2OS Cells.

V. Velma[1], Z. I. Carrero[1], C. J. Beck[1], M. D. Hebert[1]; [1]Biochemistry, Univ Mississippi Med Ctr, Jackson, MS

Background: Cajal bodies (CB) are subnuclear domains that participate in small nuclear ribonucleoprotein (snRNP) biogenesis. Coilin is the CB marker protein, but its localization changes in response to various types of cellular stress. Cisplatin induced DNA damage causes nucleolar accumulation of coilin whereas UV-C induced DNA damage fragments CBs and facilitates the interaction of coilin with proteosomal proteins. The main objective of this study was to investigate the role of coilin in the DNA damage response, with specific emphasis on the relationship between coilin and the formation of gamma H2AX, a biomarker for certain types DNA damage.
Results: siRNA mediated depletion of coilin correlated with significantly high levels of gamma H2AX in etoposide treated U2OS cells. We have investigated the role of coilin in the induction of gamma H2AX and found that coilin directly interacts with RNF8, which plays a major role in ubiquitination of gamma H2AX. Further, we have observed that transiently transfected coilin inhibits the nucleolar localization of endogenous coilin in etoposide treated U2OS cells. Modulation of coilin levels in etoposide treated cells is associated with alterations in cell proliferation, with the depletion of coilin levels causing an increased cell proliferation rate and the increase in coilin levels causing a decrease in cell proliferation rates compared to their respective controls. This observation indicates that the coilin has a direct or indirect role in cell cycle check points and may influence the stalling of cells at a specific phase of the cell cycle. To test this, we conducted FACS analysis on etoposide treated U2OS cells transiently transfected with coilin. We found that coilin overexpression increases the percent of cells in S and G2/M and reduces the number of cells in G1 compared to controls.
Conclusion: Coilin reduction increases gamma H2AX levels in etoposide treated U2OS cells. This increase in gamma H2AX levels may be attributed to the reduced activity of RNF8, which we have found to interact with coilin. In U2OS cells treated with etoposide, alteration of coilin levels, either increased or decreased, is associated with changes in proliferation rates. FACS analysis demonstrates that the over expression of coilin arrest cells in the S and G2/M phases of cell cycle in etoposide treated U2OS cells. Collectively, these data further indicate a role for coilin and CBs in the DNA damage response.

Investigation of Functional Diversity within the Ribosomal Protein L22e family in Drosophila melanogaster: Evidence for SUMOylation of RpL22.

M. G. Kearse[1], V. C. Ware[1]; [1]Department of Biological Sciences, Lehigh University, Bethlehem, PA

Duplicated ribosomal proteins are found throughout eukaryotic genomes, at times encoding highly similar or identical proteins. Whether these paralogues are functionally redundant or provide a unique cellular role, not limited to translation, remains largely unknown and unexplored. Using *Drosophila* as a model, we have focused on the two members of the eukaryotic-specific ribosomal protein L22e family, RpL22 (ancestral) and RpL22-like (duplicated). Within the reproductive system, RpL22 is ubiquitously expressed, but RpL22-like expression is confined to the testis. Using paralogue-specific C-terminal peptide-derived polyclonal antibodies, Western analysis of fly tissues shows immunodetection for RpL22 at its expected molecular weight (MW) of 33kD as well as a predominant higher MW product at ~50kD, suggestive of post-translational modification. Within the testis, RpL22-like is

predominantly detected at its predicted MW and is a component of ribosomes (Kearse *et al.*, 2011). In this report, we investigate the possible SUMOlyation of RpL22. Computational probing predicts a SUMOylation consensus motif, localized at different sites within the fly-specific N-terminal extension of both family members. Results from tissue culture (S2 cells)-based experiments replicate the electrophoretic pattern when FLAG-tagged RpL22, but not a K39R mutation within the proposed SUMOylation site, is co-expressed with HA-SUMO. These results confirm the *in silico* prediction and demonstrate that RpL22 can be SUMOylated, likely with two SUMO moieties. Interestingly, Western analysis shows that SUMOylated RpL22 is more predominant in adult testis than in S2 cells. Western analysis of RpL23a-FLAG-affinity purified complexes from S2 cells shows that SUMOlyated RpL22 is only a minor component of complexes containing RpL23a or RpL9. Furthermore, whole-mount testis immunohistochemistry reveals distinct nucleoplasmic, but not nucleolar localization within the male germline. These data suggest that within the male germline, RpL22 and RpL22-like have distinct roles. Current efforts are devoted toward elucidating the role of RpL22e paralogues in the male germline using an *in vivo* tissue-specific RNAi approach.

Cells Exhibit a Threshold Dependant Nuclear Reorganization Response to Shear Stress.

E. A. Booth-Gauthier[1], S. Spagnol[1], K. N. Dahl[1,2]; [1]Chemical Engineering, Carnegie Mellon University, Pittsburgh, PA, [2]Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA

Endothelial cells respond to shear stress by altering gene and protein expression. The mechanisms by which these cells respond to shear stress have not been fully elucidated. Since the probability of gene expression correlates to the position of the genes in the nucleus, we examined reorganization of the nucleus of cells under shear stress by tracking fluorescent intranuclear markers. By studying large scale nuclear response under physiological shear stress conditions, we are able to show that there is a shear-stress threshold dependence to the nuclear response. At high levels of shear stress we observed a shift from random reorganization to a directed reorganization. Additionally, we stiffened the nuclei of cells by overexpressing a mutant nuclear structural protein associated with aging called progerin and considered the effects of chemical stimulation with vascular endothelial growth factor (VEGF). Progerin stiffened nuclei show little response to shear, potentially from altered mechanotransductive response. Stimulation of cells with VEGF also shows increased intranuclear movement in HUVECs. Although not gene specific, these large scale organizational responses across the nucleus could correspond to substantial changes in gene expression. HUVECs and HeLa cells both showed a threshold response to shear stress. At high shear stress cells show a directed reorganization in response to shear stress. The expression of progerin more than doubles the continuum stiffness of the nucleus as shown by micropipette aspiration. However, in progerin expressing cells, there is increased intranuclear movement in cells under shear stress and altered nuclear response. Here, we show that the nucleus responds to extracellular shear stress with both increasing levels of shear stress and with time under shear. Thus, in addition to force-sensitive elements in the plasma membrane, extracellular adhesions and cytoskeleton, the nucleus itself may be a mechanosensitive element of the cell. The introduction of progerin results in an interruption of these responses that could be either from stiffening of the nucleoskeleton, from damage to other underlying nuclear structures or from altered nucleoskeletal-cytoskeletal connections. These nucleus-wide mechanical studies show that there is a materials response of the nucleus to shear stress in addition to an active biological response; by changing the material mechanical properties of the nucleus the biological activities of the nucleus are also altered.

1703

Characterization of the Enlargement of Speckles of SF2/ASF due to Loss of Function of Smu1 in the Mammalian Temperature-Sensitive Mutant.

K. Sugaya[1], Y. Ishihara[1], K. Sugaya[1]; [1]National Institute of Radiological Sciences, Chiba, Japan

A temperature-sensitive (ts) CHO-K1 mutant cell line, tsTM18, exhibits chromosomal instability with decreased DNA synthesis at the nonpermissive temperature, 39°C. An amino acid substitution in Smu1 underlying the ts phenotypes of tsTM18 cells was identified previously. We also found a ts defect in splicing of the *unc52/perlecan* gene. In the present study, we have generated cell lines expressing Smu1 tagged with green fluorescent protein (GFP) to study the dynamics of Smu1 in living cells. The hybrids complement deficiencies in tsTM18 cells and allow them to grow normally at 39°C. GFP-tagged Smu1 is found in speckles in many discrete nucleoplasmic sites, and most of these also contained SF2/ASF. SF2/ASF is a member of the serine/arginine (SR)-rich splicing group of factors that are necessary for spliceosome assembly and can influence alternative splicing. SF2/ASF is also involved in the integrity of genome maintenance. In tsTM18 cells cultured at 39°C, the Smu1 ts defect appears to alter SF2/ASF localization, suggesting a physiological association of Smu1 with SF2/ASF. The significant decrease of Smu1 may lead the enlargement of speckles of SF2/ASF. These data show the importance of Smu1 as a regulator of splicing and genome maintenance.

1704

Visualization of Eukaryotic DNA Mismatch Repair Reveals Distinct Recognition and Repair Associated Intermediates.

C. S. Campbell[1], H. Hombauer[2], C. Smith[2], A. Desai[2], R. Kolodner[2]; [1]Cellular and Molecular Medicine, Ludwig Institute for Cancer Research, San Diego, CA, [2]Ludwig Institute for Cancer Research

DNA Mismatch Repair (MMR) increases the fidelity of DNA replication by eliminating mispaired bases resulting from replication errors. MMR proteins are conserved from bacteria to humans and people with defective mismatch repair develop cancers at much higher rates due to an increased accumulation of mutations. In eukaryotes, Mispaired bases are recognized by two partially redundant heterodimer complexes, Msh2-Msh6 or Msh2-Msh3. After the mismatch recognition factors bind a mispaired base, accessory factors including the Mlh1-Pms1 complex are recruited, ultimately targeting repair to the daughter DNA strand. We used high-resolution microscopy to visualize functional fluorescent-tagged versions of the Msh2-Msh6 and Mlh1-Pms1 MMR complexes in living S. cerevisiae cells. Msh2-Msh6 forms foci in S-phase that colocalize with nuclear foci composed of the DNA replication machinery, often called replication factories. This localization was independent of mispair recognition. The association of Msh2-Msh6 with replication factories is completely dependent on the interaction of Msh6 with the DNA polymerase clamp PCNA (Pol30). Replication factory-association accounts for 10 to 15% of MMR in wild-type cells but is essential for MMR in the absence of the exonuclease Exo1. Mlh1-Pms1 forms nuclear foci that are dependent on mispair recognition by Msh2-Msh6 or Msh2-Msh3. Surprisingly, these foci rarely colocalize with Msh2-Msh6 foci. Mlh1-Pms1 foci increase in frequency in response to increased levels of mispaired bases. These foci also increase in response to the disruption of processes downstream of mispair recognition, indicating an accumulation of foci that cannot be efficiently processed. Based on these data, we conclude that Mlh1-Pms1 foci are sites of active mismatch repair; this is the first time mismatch repair intermediates have been observed in eukaryotes. These results suggest that (I) mispair recognition involves either the concentration of Msh2-Msh6 at replication factories or a second distinct pathway that depends on both Msh2-Msh6 and Exo1, and that (II) accumulation of Mlh1-Pms1 triggered by Msh2-Msh6-dependent mispair recognition defines sites of active MMR.

1705

Involvement of p32, fibrillarin, and Nop52 in pre-90S particle separation during human ribosome biogenesis.

H. Yoshikawa[1,2], W. Komatsu[1,3], T. Hayano[1,4], Y. Miura[1,2], K. Homma[6], K. Izumikawa[1,2], H. Ishikawa[1,2], N. Miyazawa[1], H. Tachikawa[1,6], Y. Yamauchi[7], T. Isobe[2,7], N. Takahashi[1,2]; [1]Department of Agricultre, Tokyo Univ of Agriculture and Technology, Fuchu, Japan, [2]CREST, JST, Tokyo, Japan, [3]Dokkyo Medical Univ, [4]Ritsumeikan Univ, [5]National Institute of Genetics, [6]Tokyo Univ, [7]Tokyo Metropolitan Univ

Ribosome biogenesis, which takes place in the nucleolus, is fundamental cellular metabolism to produce ribosomes. It is coordinated by cell growth and proliferation, and its aberrant regulation causes some human diseases and cancer. Ribosome biogenesis starts with the transcription of a large ribosomal RNA precursor (47S pre-rRNA in human cells), which soon combines with numerous factors to form 90S preribosome (pre-90S). This pre-90S undergoes further processing and modification of pre-rRNAs, and association with ribosomal proteins before splitting into pre-40S and pre-60S particles. Despite that this splitting step is one of the most important processes to produce small and large ribosome subunits in ribosome biogenesis, its molecular mechanism remains to be determined even in yeast cells that have been analyzed extensively.
In this report, we present evidence that p32, fibrillarin (FBL; a human homolog of yeast Nop1p), and Nop52 (a human homolog of yeast Rrp1p) involves in this splitting step. We first isolated and analyzed the nuclear p32-associated protein complex by mass-based proteomic approaches, and showed that p32 associated with 31 pre-rRNA processing factors including not only an early pre-rRNA processing factor FBL but also a late processing factor Nop52. Both FBL and Nop52 interacted directly with p32. Using immunofluorescence microscopy, we next showed that p32 co-localized with FBL or Nop52 in the nucleolus and Cajal bodies. p32 was also present in the pre-ribosomal fractions prepared by cell fractionation or separated by ultracentrifugation of the nuclear extract. In addition, we showed that p32 associated with pre-rRNAs including 47S/45S and 32S pre-rRNAs. We then found that knockdown of p32 with a siRNA slowed the early processing from 47S/45S pre-rRNAs to 18S rRNA and 32S pre-rRNA. Furthermore, we found that Nop52 competes with FBL for binding to p32 probably in the nucleolus. Given the fact that FBL and Nop52 were associated with preribosome particles distinctly different from each other, we suggest that p32 is a new rRNA maturation factor involved in the remodeling from pre-90S particles to pre-40S and pre-60S particles that requires the exchange of FBL for Nop52.

RNA Localization and Transport

1706

The hnRNP protein CBF-A, a novel transacting factor for mammalian mRNA transport and localization.

N. Fukuda[1], C. Raju[1], T. Fukuda[1], P. Percipalle[1]; [1]Department of Cell and Molecular Biology, Karolinska Institute, Stockholm, Sweden

Upon export certain mRNAs are assembled into granules and transported to subcellular compartments for localized translation through mechanisms that require interplay of cis-acting elements and transacting factors. The A2RE or RNA trafficking sequence (RTS) in the 3' untranslated region (UTR) of the myelin basic protein (MBP) mRNA is recognized by the A/B type hnRNP proteins hnRNP A2 and CBF-A. In oligodendrocytes RTS recognition by CBF-A is

necessary for transport and localization of MBP mRNA to the myelin compartment. CBF-A has a conserved role in RTS-mediated transport and localization of Arc, CaMKIIα and BDNF mRNAs at neuronal synapses. In the nucleus of brain cells CBF-A is excluded from dense chromatin and localizes to nascent pre-mRNPs within the perichromatin region. Since CBF-A does not bind to transcripts without RTSs, co-transcriptional RTS-recognition by CBF-A de facto provides a sorting mechanism for transport-competent mRNAs at an early stage in RNP biogenesis. Recently we discovered that the role of CBF-A is conserved in spermatogenic cells where CBF-A is involved in transport and localization of protamine 2 mRNA. Here we show that CBF-A binds to the conserved RTS in the protamine 2 mRNA 3' UTR and in round spermatids, both CBF-A splice variants p37 and p42 associate with protamine 2 mRNA and accompany the transcript to chromatoid body. The p42 isoform appears in protamine 2 mRNA-containing polysomes and interacts with the 5' mRNA cap structure. We conclude that in elongating spermatids when a distinct protamine 2 mRNP emerges in the cytoplasm to engage the translation machinery, p42 remains associated with the transcript, facilitating targeting to the translation machinery.

1707

Cotranslational transport of ABP140 mRNA to the distal pole of S. cerevisiae.

C. Kilchert[1], A. Spang[1]; [1]Biozentrum, University of Basel, Basel, Switzerland

In budding yeast, several mRNAs are selectively transported into the daughter cell in an actin-dependent manner. This directional transport involves a specialized myosin system, the SHE machinery. With ABP140 mRNA, we now describe the first mRNA that is transported in the opposite direction and localizes to the distal pole of the mother cell, independent of the SHE machinery. Distal pole localization is not observed in mutants devoid of actin cables and can be disrupted by latrunculin A. Furthermore, expression of Abp140p is required for localization of its mRNA; more specifically, the N-terminal actin-binding domain of Abp140p is necessary for distal pole localization of the mRNA. By replacing the N-terminal localization motif, ABP140 mRNA can be retargeted to different subcellular structures. In addition, accumulation of the mRNA at the distal pole can be prevented by inhibition of protein translation. We therefore propose a model of translational coupling, in which ABP140 mRNA is tethered to actin cables via its nascent protein product and is transported to the distal pole, possibly by actin retrograde flow.

1708

Endoplasmic Reticulum (ER) Resident Protein-Encoding mRNAs Undergo Translation-Independent Localization to Subdomains of the ER Membrane.

S. Jagannathan[1], Q. Chen[1], C. Nicchitta[1]; [1]Department of Cell Biology, Duke University Medical Center, Durham, NC

mRNAs encoding secretory and integral membrane proteins are localized to the ER membrane via the SRP pathway, a translation- and topogenic signal-dependent mechanism for segregating the synthesis of topogenic signal-encoding proteins to the ER, the gateway to the secretory pathway. In a recent report, we demonstrated that topogenic signal-encoding mRNAs sequence display cohort-specific patterns of enrichment on the ER as well as distinct modes of attachment to the ER membrane (1). Resident endomembrane protein-encoding mRNAs are the most highly enriched class of mRNA on the ER membrane; secretory pathway cargo (secretory and membrane protein)-encoding mRNAs, in contrast, display diverse subcellular distributions, ranging from cytosol-enriched to highly ER-enriched. These subcellular distribution patterns were mirrored in distinct modes of mRNA association with the ER membrane, where resident endomembrane protein-encoding mRNAs undergo direct, ribosome-independent binding interactions with the ER and secretory cargo protein-encoding mRNA are bound to the ER via

their functional association with membrane-bound ribosomes. These findings demonstrate that topogenic signal-encoding mRNAs undergo hierarchical, cohort-specific modes of localization to the ER. In current studies, we extend these findings in studies of the subcellular localization of newly synthesized mRNAs. By tracking the subcellular distributions of metabolically labeled, newly synthesized mRNA as a function of time after nuclear export and in the presence or absence of the protein synthesis inhibitor cycloheximide, we demonstrate that secretory cargo protein-encoding mRNAs rapidly accumulate in the cytosol when translation is inhibited whereas resident endomembrane protein-encoding mRNAs localize to the ER in a translation-independent manner. Furthermore, in cell fractionation studies, we report that cargo- and resident endomembrane protein encoding-mRNAs bind to distinct subdomains of the ER. Using Brij 35 in combination with buffer conditions that release ribosomes from the ER, secretory cargo-encoding mRNAs (β-2-microglobulin) were efficiently released from the ER membrane whereas endomembrane protein-encoding mRNAs (GRP94) were retained in a Brij 35-resistant ER membrane domain. We speculate that translation- and ribosome-independent mRNA localization to the ER represents a previously unexplored mechanism for establishing the intrinsic self-organization capacity of the endomembrane system.

1709

Genome-scale survey of subcellular mRNA translation reveals compartment-specific regulation of cellular protein synthesis.

D. W. Reid[1], C. V. Nicchitta[1,2]; [1]Department of Biochemistry, Duke University Medical Center, Durham, NC, [2]Department of Cell Biology, Duke University Medical Center, Durham, NC

In eukaryotic cells, protein synthesis is primarily catalyzed by two populations of ribosomes, cytosolic and endoplasmic reticulum (ER)-bound, which catalyze the synthesis of distinct cohorts of proteins, cytosolic and nucleoplasmic in the case of cytosolic ribosomes and secretory and integral membrane, in the case of ER-bound ribosomes. The signal recognition particle (SRP) pathway, which directs the co-translational recruitment of topogenic signal-encoding mRNAs to the ER, is an established mechanism for regulating mRNA partitioning between the cytosol and ER. Recent genomic studies of subcellular mRNA partitioning have demonstrated that cytosolic protein-encoding mRNAs are also represented and in some cases enriched on the ER, suggesting both a broad role for the ER in cellular protein synthesis and the existence of additional, SRP-independent mechanisms trafficking mRNAs to the ER. We have investigated the genomic and biochemical patterns of mRNA partitioning to the ER and report that topogenic signal-encoding mRNAs are partitioned to the ER in a hierarchical, cohort-specific manner where mRNAs encoding resident proteins of the endomembrane system displayed high ER enrichment and mRNAs encoding secretory pathway cargo were represented on free and ER-bound ribosomes, though biased to the ER. In agreement with previous studies, mRNAs encoding cytosolic and nucleoplasmic proteins were represented on the ER, with small cohorts displaying substantial ER enrichment. To assess the consequences of bi-compartmental mRNA partitioning on mRNA translation, we performed a genome-wide interrogation of subcellular mRNA translation profiles by ribosome footprinting. Cytosolic and ER-bound polyribosomes were treated with nuclease and the ribosome-protected mRNA fragments subjected to deep sequencing. By this technique, the position of ribosomes on each mRNA, in either compartment, can be determined at single nucleotide resolution. These studies demonstrate that the cytosol and ER target specific subsets of biologically related mRNAs for translation. Additionally, the biochemical properties of translation are divergent, with ER-bound ribosomes displaying greater processivity and more efficient termination, as compared to cytosolic ribosomes. On the basis of these data, we speculate that mRNA localization to the ER

serves as a novel mechanism for the post-transcriptional regulation of gene expression, and operates on a genome-wide scale to regulate steady-state cellular protein levels. (Supported by NIH GM077382, C.V.N.)

1710

The human enhancer of mRNA decapping, Hedls, regulates the decapping enzyme, Dcp2, protein levels and activity.

S. Erickson[1], E. Corpuz[1], C. Fillman[2], J. Maloy[1], J. Lykke-Andersen[1]; [1]UCSD, La Jolla, CA, [2]University of Colorado at Boulder

mRNA decay is a key step in the regulation of gene expression. A critical step in several mRNA decay pathways is decapping. A major decapping complex consists of the decapping enzyme Dcp2 as well as several decapping enhancers. An outstanding question is what role does each of these enhancers play in regulating the activity of Dcp2. We have identified a role for the metazoan specific decapping enhancer Hedls (also called Ge-1/Edc4) in the regulation of Dcp2 protein stability and activity. We observed that knockdown of Hedls results in the accumulation of deadenylated mRNA using a beta globin reporter containing the AU-rich element from the 3'UTR of granulocyte-macrophage colony-stimulating factor mRNA. This suggests that Hedls is required for the efficient 5'-3' decay of the message following deadenylation. We also observed that endogenous Dcp2 levels were reduced dramatically upon Hedls depletion. In addition exogenously expressed Dcp2 protein is highly unstable but can be stabilized by Hedls co-expression or by deletion of or five point mutations within the C-terminal Hedls interaction domain of Dcp2. Thus Hedls promotes Dcp2 activity at least in part by interacting with and preventing the activity of a C-terminal Dcp2 instability domain. These results provide novel insights into the regulation of mRNA decay mediated by the Dcp2 decapping complex.

1711

A subset of axonally transported RNAs associates with Myosin Va in ribonucleoprotein complexes.

A. Calliari[1], A. Puppo[2], J. Mercer[3], D. Munroe[4], J. Sotelo[1], J. R. Sotelo-Silveira[5,6]; [1]DPAN, Instituto Inv. Biologicas Clemente Estable, Montevideo-Uruguay, Montevideo, Uruguay, [2]Telethon Institute of Genetics and Medicine, Italy, [3]McLaughlin Research Institute, MT, [4]SAIC-National Cancer Institute at Frederick, NIH, MD, Frederick, MD, [5]Genetics, Instituto Inv. Biologicas Clemente Estable, Montevideo, Uruguay, [6]Cell and Molecular Biology, School of Sciences, UdelaR, Montevideo-Uruguay, Montevideo, Uruguay

Sorting of specific messenger RNA to particular cytoplasmic locations and regulated translation has been demonstrated to occur in multiple systems. While mature axons have been shown to contain specific ribosomal and messenger RNAs, their origin and roles are still unclear. RNA trafficking by means of kinesins and dyneins moving along microtubules has been clearly established in several cell types, including neurons. Since the highly processive myosin Va (MVa) has been described as a component of ribonucleoprotein particles (RNPs) in the rat nervous system, we characterized myosin Va-associated RNPs in rat adult brain and spinal root axons. Using fluorescence microscopy, we show that myosin Va colocalizes with RNA and with RNA binding proteins in discrete structures present in spinal cord root axons. We also show that the axonal structures known as periaxoplasmic ribosomal plaques are enriched in RNPs, some of which are equipped with a dual kinesin and myosin Va molecular motor complex and MVa mRNA. Immunoprecipitation of myosin Va-associated messenger RNAs and microarray analysis demonstrated that myosin Va associates with a specific subpopulation of neuronal mRNAs both in brain and ventral/dorsal root axons. In conclusion, our data suggest that myosin Va is involved in mRNA trafficking within axons.

1712

Schwann cells as local supply of axonal RNA in regenerating mammalian.

J. Sotelo[1], A. E. Kun[1], L. Canclini[1], J. R. Sotelo-Silveira[2], J. Mercer[3]; [1]Dept. Proteins & Nucleic Acids, Instituto Inv. Biologicas Clemente Estable, Montevideo-Uruguay, Montevideo, Uruguay, [2]Genetics, Instituto Inv. Biologicas Clemente Estable, Montevideo, Uruguay, [3]McLaughlin Research Institute, MT

The existence and extent of axonal protein synthesis has been a contentious issue for decades, but evidence supporting it has steadily accumulated. In turn, this raises the question of whether axonal mRNAs are transcribed in the cell body, glia, or both? Here we show that proximal segments of transected sciatic nerves, in which newly synthesized RNA was labelled in the absence of neuronal cell bodies in vitro, accumulate labelled RNA in axons. We show that myosin-Va function is required for this cell-to-cell transfer, as segments from null mutant mice have no detectable labelled axonal RNA. We also demonstrate that the integrity of the actin cytoskeleton is necessary for RNA transference from glia to axon, since latrunculin impairs such transference in a dose dependent way. Our results demonstrate cell-to-cell transfer of RNA (including neurofilament mRNA and ribosomal RNA) and suggest that its mechanism may be similar to the mechanism of transfer of melanosomes, which also is disrupted in myosin-Va-deficient mice. The enhancement of cell-to-cell transfer by injury suggests that interventions following injury or degeneration, particularly gene therapy, may be accomplished by applying them to nearby glial cells (or implanted stem cells) at the site of injury to promote regeneration.

1713

Expression of a Putative miR, Lb-miR-1 in Leishmania braziliensis.

J. M. Porter-Kelley[1], M. J. Woodard[1], J. O. Odera[1], S. R. Best[1]; [1]Life Sciences, Winston-Salem State University, Winston Salem, NC

MicroRNAs have been described in most organisms from worms to human and more recently in protozoans. MicroRNAs are a group of small RNAs that regulate gene expression post-transcriptionally in a complex process of binding to mRNA in a perfect complement or almost perfect complement that cleave mRNAs or inhibit their translation. Gene expression in *Leishmania* is not well understood, however, it is known to be post-transcriptionally regulated. Argonaute-like and Dicer-like protein, the machinery needed for the processing of miRNAs have been shown to exist computationally in *Leishmania braziliensis.* Our hypothesis is that microRNAs may regulate gene expression in *L. braziliensis*. Here we show our results of computational data analysis showing potential MicroRNAs in *L. braziliensis.* We also show that Lb-miR-1 is expressed in *L. braziliensis* promastigotes.

Epigenetics and Chromatin Remodeling

1714

Generation of a Novel Chromatin E-map in a Mammalian Cell Line.

D. Talbot[1], A. Roguev[2], G. Negri[2], N. Krogan[2], B. Panning[1]; [1]Department of Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA, [2]Department of Cellular and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA

Quantitative epistasis mapping (E-MAP) is a powerful method for identifying synergistic or antagonistic functional relationships between genes. E-MAPs have been successfully generated in two yeast species, *E. coli*, and *Drosophila* S2 cells, but until now, this approach has not been

utilized in mammalian cell lines. In this presentation, we report a method for generating an E-MAP using GFP labeled mouse fibroblast cell lines and a highly efficient transient knock-down (KD) approach with esiRNA (endoribonuclease-prepared siRNA).

Interrogation of pair-wise combinations of approximately 160 genes focused on chromatin regulation and epigenetics was carried out post-transfection using an Acumen® eX3 plate laser scanning image cytometer. This approach allowed us to rapidly and accurately enumerate whole wells for cell proliferation, at multiple time points, without further sample manipulation. Using this data, a mammalian E-MAP based on more than 12,000 unique combinations of double KDs was generated using hierarchical clustering algorithms. As expected, functionally related genes exhibited similar phenotypes and members of known multi-protein complexes were clustered together. Two complexes, Ccr4-Not and Paf1, were also seen to be located near each other in a common sub-tree and in addition, we observed buffering interactions between the complexes. This synergistic mode of action has also been debated in the literature. Further screening studies analyzing cell cycle and apoptosis with additional components for these complexes will provide further information about the interactions of these complexes.

This presentation demonstrates the power and utility of generating E-MAPs in mammalian cells and is applicable to many cell types and genes of interest or gene and drug combinations.

1715

Centromere maintenance is dynamic throughout the cell cycle.

J. Dorn[1], L. Anaick[1], V. De Rop[1], P. Maddox[1]; [1]Univ Montreal, Montreal, QC, Canada

The centromere is a defining feature of chromosomes. On mitotic chromosomes, it determines the primary constriction where it templates kinetochore assembly, thus linking chromosomes to the mitotic spindle. It is thus surprising that centromeres are specified epigenetically in most model organisms. The epigenetic mark is widely considered to be the substitution of histone H3 for the variant CENP-A in centromere nucleosomes.

Epigenetic marks are dynamic throughout the cell cycle, changing with transcriptional activation for instance. CENP-A was thought to be an exception since maintaining centromere identity is critical for survival. This hypothesis is supported by evidence that during replication, CENP-A from the mother centromere is evenly distributed among the daughter centromeres, and that newly synthesized CENP-A is only loaded after mitotic exit. Furthermore, FRAP experiments have shown that CENP-A does not turn over at centromeres. This suggested that once incorporated into the centromere, CENP-A would remain stable for many cell cycles.

We hypothesized that specific mechanisms regulate the stability of centromere identity throughout the cell cycle. Using a novel high-resolution live cell microscopy assay, we find that centromere levels of CENP-A are dynamic throughput interphase in HeLa cells. Loading of new CENP-A to centromeres persists throughout G1, repopulating centromere CENP-A levels to that seen pre-replication with first-order kinetics (time-constant ~2.5h). Continued analysis of CENP-A levels in control cells revealed that centromeric CENP-A levels increase to greater than pre-replication levels, and that the excess CENP-A is lost during S/G2. Taken together these results suggest that CENP-A levels at centromeres is dynamic throughout the cell cycle.

Depletion of CENP-A or its chaperone HJURP simply abolished new CENP-A loading, but did not affect pre-assembled centromeric CENP-A. Thus these data support recent findings that HJURP is required for the physical assembly of CENP-A nucleosomes. On the contrary, depletion of the licensing factor KNL-2 lead to a loss of centromeric CENP-A, suggesting that

KNL-2, which is recruited to the centromere in early G1 and remains bound until S-phase, is important for the maintenance of centromere identity. Co-immunoprecipitation of KNL-2 and subsequent mass spectrometry identified MgcRacGAP, which has been previously reported to play a role in centromere function. We find that MgcRacGAP localizes transiently to centromeres at the end of G1 and is required to stabilize newly incorporated CENP-A at the centromere. We propose a model where KNL-2 acts as the epigenetic mark for the centromere during G1 via three mechanisms. First, KNL-2 is required to protect preexisting CENP-A from removal during G1. Second, it targets the CENP-A loading machinery to replenish CENP-A levels. Finally KNL-2 recruits MgcRacGAP at the end of G1 to protect newly incorporated CENP-A from removal in G2. In sum, centromere epigenetic identity is dynamic and this may represent a mechanism for error correction of the epigenetic mark.

1716

CENP-C recruits M18BP1 to centromeres to promote CENP-A chromatin assembly.

B. Moree[1], C. B. Meyer[1], C. J. Fuller[1], A. F. Straight[1]; [1]Stanford University Medical School, Stanford, CA

Eukaryotic chromosomes segregate by attaching to microtubules of the mitotic spindle through a chromosomal microtubule-binding site called the kinetochore. Kinetochores assemble on a specialized chromosomal locus termed the centromere, characterized by the replacement of histone H3 in centromeric nucleosomes with the essential histone H3 variant centromere protein A (CENP-A). Understanding how CENP-A chromatin is assembled and maintained is central to understanding chromosome segregation mechanisms. CENP-A nucleosome assembly requires the Mis18 complex and the CENP-A chaperone HJURP. These factors localize to centromeres in telophase/G1, when new CENP-A chromatin is assembled. The mechanisms that control their targeting are unknown. Here we identify a mechanism for recruiting the Mis18 complex protein M18BP1 to centromeres. We show that depletion of CENP-C prevented M18BP1 targeting to metaphase centromeres and inhibited CENP-A chromatin assembly. We find that M18BP1 directly bound CENP-C through conserved domains in the CENP-C protein. Thus, CENP-C provides a link between existing CENP-A chromatin and the proteins required for new CENP-A nucleosome assembly.

1717

Function of HP1 proteins as a component in kinetochore formation and its relation with chromosome instability.

R. Gonzalez Barrios de la Parra[1], E. Soto Reyes[1], J. R. Mendoza Perez[1], C. Castro Hernandez[1], L. A. Herrera Montalvo[1]; [1]Biomedical Research, National Cancer Institute Mexico, Mexico City, Mexico

HP1 Family of proteins are involved in the formation and maintenance of chromatin higher order structure. In mammals there are known three isotypes (HP1α, HP1β and HP1γ). Recently, it has been proposed that HP1 may play an important roll in inner centromere establishment, generated by its interaction with HMis12 complex, (HMis12C) which is relevant in kinetochore formation and microtubule recognition which ensure correct chromosomal segregation. However, alterations in chromatin structure or loss in H3K9 methylation lead to a reduction of the protein presence and changes of HP1 proteins localization to heterochromatin followed by chromosome instability. It has not been studied if this is mediated by loss of recruitment of HMis12C to the kinetochore and which is it relation with chromosomal instability generation. Thus, the aim of this study is to determine if alteration of HP1 proteins is capable of reducing HMis12C recruitment to the kinetochore. We elaborated transfected of constructions of HP1-GFP for each isotype in HCT116 cells and performed time-lapse to observe localization along

cell cycle by confocal microscopy; in addition, we treated cells with TSA 1uM to analyze changes in HP1 localization. We used ChIP assay in satellite alpha and satellite 2 to determine presence of HP1, and HMis12 in HCT116 transfected cells with HP1-GFP and with Jmjd2b to observe the effect of the loss of H3K9me3 to HMis12C incorporation. We found that each isotype present a different localization at interphase, this localization is highly dynamic in mitosis where HP1α is removed and HP1β is enriched at the chromosomes centromere. Treatment with TSA generates a 70% relocalization of HP1 proteins to pericentromeric chromatin and an increase of chromosome instability. Jmjd2b over-expression reduces HP1 presence at chromatin and also reduces HMis12 in mitosis. These results support another function of HP1 as a kinetochore partner leading incorporation of HMis12 during cell division.

USP22 Mediates Puripotency, Differentiation and Sox2 Transcriptional Repression.

R. T. Sussman[1], S. B. McMahon[1]; [1]Cancer Biology, Thomas Jefferson University, Philadelphia, PA

USP22 is a ubiquitin hydrolase that we and others have recently shown cleaves mono-ubiquitin moieties from histones H2A and H2B. We have reported that USP22 is a stable component of the hSAGA transcription co-activator complex. (We have also shown that USP22 is required for cell cycle progression in differentiated cells, with USP22 depletion causing G1 arrest). A number of lines of evidence suggest a potential role for USP22 in stem cell function. USP22 was included in an 11-gene polycomb/cancer stem cell signature identified through a translational genomics analysis of metastases and primary tumors from both human patients and a mouse model of prostate cancer. The histone H2B deubiquitnase activity of nonstop, the drosophila ortholog to USP22, is required for early glial development and migration in flies. USP22 increases as mouse embryonic stem cells (mESCs) differentiate, either spontaneously through embryoid body formation, or forcibly through treatment with retinoic acid. We report that USP22 is important for mediating mammalian differentiation programs through transcriptional regulation. USP22 depleted mESCs exhibit a defect in differentiating upon embryoid body formation, as measured by alkaline phosphatase expression. This correlates with retention of a more stem-like morphology in these cells. Furthermore, after embryoid-body induced differentiation, USP22-depleted mESCs show decreased expression of markers for all three germ layers. These cells show no change in their cell-cycle profile or BrdU incorporation. Before induction of differentiation, USP22-depleted mouse and human ESCs display increased expression of the Sox2 transcription factor. Sox2 is a core transcription factor involved in the maintenance of pluripotency and one of four transcription factors needed to induce pluripotency in somatic cells. This coincides with increased RNA Polymerase II recruitment across the Sox2 locus and enhancer region, as well as a loss of histone H2B. Interestingly, ubiquitylated H2B levels increase across the Sox2 locus and enhancer region upon USP22 depletion, which is consistent with a decrease in the ability to remove ubiquitin from H2B when USP22 is depleted. Following Sox2 induction, the cells show increased transcription of Sox2 target genes including Nanog and TDGF1. These data suggest a model in which USP22 is important in maintaining steady-state Sox2 levels in ESCs and upon depletion of USP22, ESCs are defective in differentiation, potentially due to an overabundance of Sox2. These findings propose a role for the SAGA deubiquitylase activity in maintaining pluripotency and executing differentiation programs. The SAGA complex is traditionally though to act as a co-activator complex and we report a novel co-repressor function of the SAGA member USP22.

1719

Epigenetic status of cardiac master genes in native adipose derived stem cells.

A. Pasini[1,2], F. Bonafè[2], E. Fiumana[2], M. Govoni[2], C. Guarnieri[2], P. G. Morselli[3], C. M. Caldarera[4], C. Muscari[2], E. Giordano[1,2]; [1]Laboratory of Cellular and Molecular Engineering - University of Bologna, Campus of Cesena, Cesena (FC), Italy, [2]Department of Biochemistry "G. Moruzzi", University of Bologna, Bologna, Italy, [3]School of Plastic Surgery – University of Bologna, Bologna, Italy, [4]National Institute for Cardiovascular Research (INRC), Bologna, Italy

Adipose derived stem cells (ADSCs) are mesenchymal stem cells that can be easly isolated from lipoaspirates. They show multilineage differentiative capacities, including the cardiac phenotype. Therefore they represent a promise for regenerative medicine (Zuk 2001), for the treatment of those diseases affecting organs with extremely low potential of repair and regeneration, such as the heart. The knowledge of the molecular mechanisms that control development and differentiation - such as epigenetic DNA promoter methylation at CpG sites and histone modifications inducing chromatin remodelling and changes in DNA accessibility (Bernstein 2007) - will help to understand their potential in this regard.
Aim of this study was to evaluate the epigenetic status of cardiac specific transcription factors, such as GATA-4, MEF-2C and Nkx2.5 (Brand 2003) in undifferentiated human ADSCs. The analysis of DNA promoter methylation, using Methylation Specific PCR (MSP), revealed the unmethylated status of the promoters of the above cardiac master genes. This finding suggested that ADSCs are not prevented to differentiate towards the cardiac phenotype by DNA methylation, as otherwise reported for myogenic genes (Sørensen 2010).
Chromatin immunoprecipitation (ChIP) showed association of a well known transcriptional repressive mark [trimethylation of Lys27 in H3 (H3K27me3)] with GATA-4 and Nkx2.5 promoters. On the other hand, an enrichment in acetylation of histone 3 (acH3), hallmark of transcriptional potential, was detected for MEF-2C promoter. These results are in agreement with those of the gene expression analysis, showing the presence of only MEF-2C transcript in total mRNA extracted from undifferentiated human ADSCs of three different donors.
In conclusion our results suggest that the epigenetic signature of ADSCs represents a level for intervention to address their differentiation towards the cardiac lineage.

Regulation of Gene Expression on Mouse PAD4 in vivo.

T. Nara[1], D. Kamei[1], T. Sato[1], M. Sato[1], M. Yamada[1], Y. Nishina[1]; [1]Graduate School of Nanobioscience, Yokohama City University, Yokohama, Japan

Peptidylarginine deiminase (PAD) is a Ca^{2+}-dependent enzyme that catalysis the conversion of protein arginine residues to citrulline, and classified five different types of human PADs encoded by the genes PAD1-PAD4 and PAD6 in those characters. Human PAD4 (hPAD4) is localized in the cell nucleus, and has been shown to target multiple arginine sites in histons H3 and H4 including those sites methylated by coactivator-associated arginine methyltransferase and protein arginine methyltransferase1. It is thought that hPAD4 participates in transcriptional regulation of gene expression by antagonizing protein arginine methylation by methltransfelase. The expression of hPAD4 has been reported in human granulocytes/monocytes, synovial membranes, and some tumor cell lines such as MCF-7, but tissue-specific expression in vivo have not been studied in detail.
In this study, we investigated PAD4 gene expression and it's regulation in various tissues of mouse. Mouse PAD4 (mPAD4) is highly expressed in the estrogen responsive tissues, such as vagina, uterus and pituitary. It is speculated that mPAD4 expression may be controlled by estrogen in vivo. To further analysis, we use the ovary ectomized (OvX) mouse in order to exclude the endogenous estrogen. In the OvX mouse, the mPAD4 expression in vagina and

uterus were down regulated both at the mRNA and protein levels. Moreover, we stimulated the OvX mouse by injection of 17-beta-estradiol (E_2), the expression of mPAD4 mRNA and protein were up regulated in those tissues. These results suggested that the expression of mPAD4 is regulated by estrogen in the mouse tissues in vivo.
To investigate whether mPAD4 participates in transcriptional regulation as histone demethyltransferase, we examined the cellar localization of mPAD4 in vagina, at first. As a result of immunohistochemistry, mPAD4 was expressed in the epithelium of vagina. Furthermore, mPAD4 was existed in the cytoplasm of proliferating layer neighboring basement membrane, on the other hand, in the nucleus of differentiated layer. And then, we are examining whether mPAD4 is functional in vagina by using anti histone citrullination antibody.
Now, we attempt to analyze immunologically cellular localization of mPAD4 in the OvX and E_2 injected mouse, in order to study the relationship between proliferation, differentiation, and cellular localization of mPAD4 in vaginal epithelium by the treatment of E_2.

Conservation of the SIR complex in fission yeast.

S. D. Pilon[1], R. Gerson[1], K. Harding[1], A. N. Kettenbach[2], S. A. Gerber[2], A. D. Rudner[1]; [1]Ottawa Institute of Systems Biology, University of Ottawa, Ottawa, ON, Canada, [2]Department of Genetics, Dartmouth Medical School, Hanover, NH

In the budding yeast, *Saccharomyces cerevisiae*, heterochromatin contains nucleosomes that are hypoacetylated and are bound by a complex of three proteins, Sir2, Sir3 and Sir4 (Silent information regulator), named the SIR complex. Sir2 is the founding member of a conserved family of NAD-dependent protein deacetylases and creates the hypoacetylated domains of nucleosomes within heterochromatin. Sir3 and Sir4 are histone-binding proteins that appear conserved only in related budding yeasts, not larger eukaryotes. Current models for SIR complex assembly of heterochromatin propose that after initial recruitment to a DNA element, iterative rounds of histone deacetylation and SIR complex recruitment lead to spreading of heterochromatin. Although the role of histone deacetylation by Sir2 has been well established, the precise role of Sir3 and Sir4 in the establishment and spreading of heterochromatin is not fully understood.

Although Sir2 is highly conserved through evolution and is required for heterochromatin assembly in many eukaryotes, Sir3 and Sir4, and the SIR complex, are thought to be present only in budding yeasts. Recent work has suggested that Sir3 arose from a duplication of Orc1, a component of the Origin Recognition Complex (ORC). In budding yeasts that did not duplicate Orc1, Orc1 plays a role in replication and heterochromatin assembly. Orc1, which is highly conserved, therefore may be part of a SIR complex in larger eukaryotes. Work on budding yeast has pioneered the understanding of heterochromatin, and demonstrating that the SIR complex is conserved through evolution will alter current models for how heterochromatin is assembled and regulated in vertebrates.

We have purified Orc1-TAP in the fission yeast, *Schizzosaccharomyces pombe*, and found that in addition to purifying the other five ORC components, it also co-purifies Sir2 and a protein that may be analogous to Sir4. We are currently testing if this complex is distinct from ORC, if it localizes to sites of heterochromatin, and if mutants in the Sir4-like protein have defects in heterochromatin formation. We are also curious how the spSIR complex interacts with the other conserved components of heterochromatin.

1722

C/EBP[beta]-LAP* mediated recruitment of SWI/SNF modulates Ric-8B gene repression during osteoblast differentiation.

R. Aguilar[1], A. Arce[1], B. Henriquez[1], H. Sepulveda[1], R. Grandy[1], J. Olate[2], M. Montecino[1];
[1]Centro de Investigaciones Biomedicas, Universidad Andres Bello, Santiago, Chile,
[2]Departamento de Bioquimica y Biologia Molecular, Universidad de Concepcion, Concepcion, Chile

The Ric-8B gene is essential for cell proliferation and is down-regulated during osteoblast differentiation by a mechanism involving C/EBP[beta]-LAP*-mediated repression and SWI/SNF-dependent chromatin remodeling. Interaction of SWI/SNF and C/EBP[beta] has been previously demonstrated as a principal regulatory mechanism in myeloid gene promoters. Here, we address whether C/EBP[beta]-LAP* mediates the recruitment of SWI/SNF during Ric-8B gene repression in osteoblastic cells. C/EBP[beta] silencing in osteoblastic cells was achieved by specific siRNAs or lentiviral-mediated expression of specific shRNAs. Binding of SWI/SNF and C/EBP[beta] to the Ric-8B gene promoter was determined by chromatin immunoprecipitation (ChIP). Changes in gene transcription were evaluated by qPCR. The analyses were also carried out in stable osteoblastic cell lines expressing dominant-negative forms of SWI/SNF subunits. To evaluate Ric-8B gene promoter activity, undifferentiated pre-osteoblastic cells were co-transfected with constructs carrying the Ric-8B promoter fused to a Luciferase reporter gene together with vectors coding for mutated C/EBP[beta] proteins that impair interaction with SWI/SNF. Interaction between C/EBP[beta] and SWI/SNF was evaluated by co-immunoprecipitation. We find that silencing of C/EBP[beta] impairs SWI/SNF binding to the Ric-8B promoter and increases Ric-8B expression levels. This increased Ric-8B transcription is also observed in cell lines expressing dominant negative forms of SWI/SNF. Over-expression of a C/EBP[beta]-LAP* isoform carrying a mutation that impairs interaction with SWI/SNF is unable to repress the Ric-8B promoter activity. Co-immunoprecipitation studies show that C/EBP[beta] and SWI/SNF interact in nuclear extracts from osteoblastic cells. Together, our results support a model where C/EBP[beta]-LAP* recruits SWI/SNF to the Ric-8B promoter leading to Ric-8B gene repression during osteoblast differentiation.

1723

The Complete Chemical Synthesis of Histones H3 and H4 Containing Epigenetic Modifications and Their Use in Characterizing Arginine Methylated Histone Antibodies.

J. B. Fishman[1], A. D. Homon[1], E. N. Lamsa[1], J. R. Merlino[1], J. D. Sullivan[1], M. A. Shia[1], E. Neeley[2], M. Shipps[2], E. A. Berg[1]; [1]21st Century Biochemicals, Inc., Marlborough, MA, [2]Novus Bioloigcals, LLC, Littleton, CO

Arginine methylation occurs on numerous cytoplasmic and nuclear proteins including histones (H2A, H2AX, H2B, H3 and H4). In the case of histone modification, arginine methylation is known to play role in chromatin's accessibility to the enzymes that control transcription. Arginine methylation is catalyzed by a family of 9 enzymes called protein arginine methyl transferases (PRMTs). All PRMTs catalyze the addition of monomethyl arginine (MMA) onto a nitrogen within the guanidinium side-chain of arginine. Class I PRMTs further catalyze the formation of asymmetric dimethyl arginines (ADMA) where both methyl groups are on the same nitrogen whereas Class II PRMTs catalyze the formation of symmetric dimethyl arginines (SDMA) where each methyl group is on a different nitrogen. Critical to unraveling the role of arginine methylation and other epigenetic modifications (e.g., lysine methylation, acetylation, serine or threonine phosphorylation) are the availability of well characterized antibodies and peptides that

can be used in a variety of applications (western blotting, ICC/IHC, ChIP). One of the issues with antibodies that detect the specific methylation of arginine (MMA, ADMA or SDMA) is the difficulty in their characterization using short synthetic peptides and dot blots, competition ELISAs or similar methods. To better characterize various epigenetic antibodies, we have successfully synthesized numerous epigenetically modified forms of histones H3 and H4 in mg quantities. Peptide synthesis was affected using a combination of standard Fmoc amino acid building blocks, pseudoproline dipeptides to minimize inter-chain aggregation, and differing solvent mixtures to affect difficult couplings, followed by a variety of HPLC methods to isolate the full length peptides. The epigenetically modified histone proteins were characterized by HPLC, nanospray MS, and the sequence confirmed by CID MS/MS. The full length proteins were then used to characterize antibodies manufactured to specific MMA, ADMA or SDMA sites on histones (e.g., H3R8, H4R3 and H4R17) by western immunoblotting and dot blots. Antibodies that had appeared to cross-react to varying degrees with non-target modifications using short peptides were in fact shown to be specific using full length, epigenetically modified H3 and H4 protein. These proteins can also be used for the assembly of artificial nucleosomes and biotinylated forms of these proteins can be used for pull downs and other biochemical experiments. Thus synthetic histones containing defined epigenetic modifications are valuable tools for characterizing the specificity of epigenetic antibodies.

1724

The SCF^{Slimb} ubiquitin-ligase regulates Cap-H2 levels to control interphase chromosome condensation and spatial organization.

S. Daniel[1], S. L. Windler[2], D. W. Buster[3], M. Roberts[1], J. Meserve[1], D. Bilder[2], G. Bosco[1], G. C. Rogers[3]; [1]Molecular & Cellular Biology, University of Arizona, Tucson, AZ, [2]Molecular & Cell Biology, University of California at Berkeley, [3]Cellular & Molecular Medicine, University of Arizona

Chromosome condensation is essential during mitosis, however little is known about how or if interphase chromosome compaction is also modulated. Two conserved complexes (condensins I and II) facilitate chromosome condensation in mitosis. Recent work has revealed that condensin II also functions as an anti-pairing factor, preventing polytene chromosome assembly in non-dividing *Drosophila* nurse cells and inhibits homolog pairing essential for transvection. These interphase functions suggest that condensin is regulated throughout the cell cycle and, at present, it is not clear how interphase condensin is different from its mitotic activities. Since control of protein turnover is a prominent mechanism cells use to regulate cell cycle-dependent events, we examined whether the ubiquitin machinery could play a role in chromosome condensation. By examining a previous RNAi screen of the Cullin-based E3 ubiquitin-ligase family, we found that depletion of the SCF components (Cullin-1 or SkpA) or the F-box protein, Slimb, resulted in a chromosome hyper-condensation phenotype in cultured *Drosophila* S2 cells. Specifically, SCF^{Slimb} RNAi causes a dramatic change in the morphology of chromatin in non-mitotic cells; compacting chromosomes into a cluster of 8-12 spheres per nuclei that we call the ‘gumball’ phenotype and are likely to be individualized chromosome territories. Strikingly, we find that double RNAi of Slimb and either SMC-2, Cap-D3, or Cap-H2 completely rescues the gumball phenotype, suggesting that condensin II activity is negatively regulated by SCF^{Slimb}. Indeed, we also find that the non-SMC subunit, Cap-H2, is a novel Slimb ubiquitin-target, as Cap-H2 possesses a conserved Slimb-binding domain, co-immunoprecipitates with Slimb, and is stabilized upon Slimb depletion. Furthermore, mutation of the Slimb-binding domain stabilizes Cap-H2 and expression of this mutant in S2 cells is sufficient to induce the hyper-condensation gumball phenotype. Here, we also present *in vivo* evidence supporting a Slimb/Cap-H2 genetic interaction in modulating polytene chromosome assembly and pairing. Our results reveal a previously unknown mechanism for regulating condensin that utilizes ubiquitin-mediated

proteolysis of a key regulatory subunit to attenuate chromosome compaction and spatial organization during interphase of the cell cycle. We propose a model where SCF^{Slimb} controls Cap-H2 proteins levels thereby linking mitotic exit and chromosome decondensation to interphase specific compaction and chromosome organization.

Cytokinesis II

1725

Microtubule and actin cytoskeleton rearrangements within intracellular bridge mediates terminal cytokinesis.

J. Schiel[1], C. Wu[2], D. Castle[3], R. Prekeris[1]; [1]Cell and Developmental Biology, University of Colorado Denver, Aurora, CO, [2]University of Pittsburgh School of Medicine, [3]University of Virginia

Abscission, the final event during cytokinesis consists of orchestrated events of membrane and cytoskeleton reorganization, yet the exact mechanisms and timing of these events are unknown. Previously, we have shown that recycling endosomes are required for cytokinesis and their trafficking to, and fusion with, the intracellular bridge connecting the two daughter cells is necessary prior to abscission. We have also demonstrated that before endosome fusion, microtubules undergo a dramatic reorganization allowing for localized microtubule clearance from the intracellular bridge. Other labs have shown that the ESCRT complexes are also required for cytokinesis and abscission, but the construction of ESCRT filaments and the actual abscission step, is still a mystery. While recycling endosome and the ESCRT based abscission models are not mutually exclusive, their cohesiveness has not been investigated and remains unknown. Here we investigate the timing of recycling endosome secondary ingression and CHMP-4B, an ESCRT-III member responsible for forming ESCRT filaments, localization in respect to abscission. Our data show that the endosome-induced secondary ingression precedes and is likely required for ESCRT-III-mediated abscission. What remains unclear, is how endosomes induce secondary ingression and ESCRT-III recruitment during abscission. Proteomic analysis of recycling endosome cargo delivered to the intracellular bridge identified several actin cytoskeleton regulators that have not been studied in the context of cell division. We also show that endosome fusion with the furrow plasma membrane is required for the localized disassembly of cortical actin cytoskeleton, resulting in the formation of the secondary ingression, and the recruitment of the ESCRT-III protein complex during the terminal step of cytokinesis.

1726

Cyclin B1* expression and endopolyploidization during flower development in *Phalaenopsis aphrodite* subsp. *Formosana.

Y-L. Kao[1], Y-C. Weng[1], J-W. Wu[2], P-F. Wu[3], W-H. Chen[1,4]; [1]Department of Life Sciences and Institute of Biotechnology, National University of Kaohsiung, Kaohsiung, Taiwan, [2]Department of Life Sciences and Institute of Biotechnology, National University of Kaohsiung, [3]Department of Kinesiology, Health, and Leisure Studies, National University of Kaohsiung, Taiwan, [4]Orchid Research Center, National Cheng Kung University, Taiwan, Taiwan

Endopolyploidy has been found in various organs and tissues during plant development and flower development in *Phalaenopsis* orchids. Endopolyploidy is caused by endoreduplication / endomitosis, in which cytokinesis is not completed after one or several rounds of DNA replication and results in more amount of DNA content. Flower is the major attraction in

Phalaenopsis industry. Not only flower color and shape, flower size is also an important issue. In sepal and petal of different floral development in *Phalaenopsis aphrodite* subsp. *formosana*, the proportion of 2C nuclei decreased, the polyploidy proportion of 4C and 8C increased. There were 4C nuclei after one round of endoreduplication and 8C nuclei after twice endoreduplication existed simultaneously. The 8C nuclei had been detected at 1.1 cm sepal and 1.2 cm petal or larger flower bud. In pedicel, polyploidy levels and percentage were higher and more than sepal and petal, 8C nuclei had been showed in pedicel from 0.6 cm flower bud. However, ploidy degree in ovary remains monoploid because of germline stability. These results indicate that different endopolyploidy regulated-mechanisms might be existed in different floral tissues. *Cyclin B1* gene expression was detectable in sepal, petal and pedicel. In sepal and petal, *Cyclin B1* displayed abundantly among 0.5-1.1 cm and 1.4-1.8 cm of floral bud. The peak of *Cyclin B1* gene expression is highly correlated with endopolyploidization during floral development because of similar timing and pattern. To identify the regulatory role of this gene, three constructs were created. The first one contains the full length of *Cyclin B1* (Wild Type, abbreviated as WT). The second one includes two point mutations located on destruction box (Mutation, abbreviated as Mut). The third one excludes 5'-sequence deletion of destruction box (ΔDbox). All constructs were transient expression in the flower buds of diploid *P. aphrodite* by *Agrobacterium*-mediated transformation, respectively. Construct containing empty vector was also transferred as control (MOCK). GUS staining revealed that MOCK, WT, Mut, and ΔDbox gene did transient express. *Cyclin B1* gene expressions were amplified via RT-PCR. All of WT, Mut, and ΔDbox showed abundant exogenous *Cyclin B1* gene expression. All transient over-expression of WT, Mut, and ΔDbox appeared higher and faster endopolyploidy percentage and endoreduplication cell cycle (endocycle) index than MOCK. These results suggested that *Cyclin B1* may involve in endoreduplication and manipulate endopolyploidy in *P. aphrodite* during flowering.

Phosphorylation of NudC by Aurora B regulates cytokinesis.

K. N. Weiderhold[1], C. Chuang[2], M. Fadri-Moskwick[3], J. Pan[3], S-H. Lin[4], L-Y. Yu-Lee[5,6];
[1]Interdepartmental Program in Cell and Molecular Biology, Baylor College of Medicine, Houston, TX, [2]Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX, [3]Immunology, Baylor College of Medicine, Houston, TX, [4]Molecular Pathology, M.D. Anderson, Houston, TX, [5]Medicine, Baylor College of Medicine, Houston, TX, [6]Interdepartmental Program in Cell and Molecular Biology, Baylor College of Medicine

Nuclear distribution protein C (NudC) is a highly conserved protein that plays a role in mitosis and cytokinesis. We recently discovered that NudC is phosphorylated by the mitotic kinase Aurora B. Whether NudC phosphorylation by Aurora B plays a role in cytokinesis is not known. We found that NudC and Aurora B associate in the late stages of mitosis, from anaphase to cytokinesis. In vivo labeling showed that NudC is phosphorylated by Aurora B, as evidenced by reduced phosphorylation in the presence of the Aurora B inhibitor ZM447439. Using a series of GST-NudC truncation proteins in IP kinase assays, we mapped a site within the N-terminus of NudC at residue T40 as an Aurora B phosphorylation site. An anti-phospho-T40 (pT40) NudC peptide antibody was generated and used to show that pT40 NudC localizes to the midbody where Aurora B is localized during cytokinesis.

To determine the potential function of pT40 NudC in cytokinesis, we knocked down NudC in HeLa cells and rescued with wild-type NudC or NudC containing a T40A (phospho-defective) or

T40D (phospho-mimetic) mutation. NudC knockdown increased the percentage of cells exhibiting elongated intercellular bridges up to 30 µm in length, demonstrating a lack of cell abscission and failure in cytokinesis. Furthermore, Aurora B was found to be mislocalized along the elongated bridges instead of being concentrated at the midbody. Both wild type and T40A NudC rescued the cytokinesis phenotype and Aurora B localization. In contrast, T40D NudC was unable to rescue the cytokinesis defect and Aurora B remained diffused along the elongated bridges, indicating that a function of pT40 NudC is to prevent the completion of cytokinesis. Our studies suggest that phosphorylation/dephosphorylation of NudC plays a role in cytokinesis regulation, and that dephosphorylation of pT40 NudC is required for timely cell abscission.

1728

F-actin assembly at the cell division ring in fission yeast.

Y. Huang[1], J. Huang[2], A. Padmanabhan[3], D. Subramaniam[3], J. Yu[4], E. Tao[5], X. Tang[3], R. Wedlich-Soldner[4], M. Balasubramanian[6,7]; [1]Mechanobiology Institute, [2]Department of Biological Sciences, National University of Singapore, [3]Temasek Life Sciences Laboratory, [4]Max Planck Institute Martinsreid, [5]National University of Singapore, [6]Cell Division, Temasek Life Sciences Laboratory, Singapore, Singapore, [7]Department of Biological Sciences, Mechanobiology Institute, Singapore, Singapore

Cytokinesis in many eukaryotes involves the function of an actomyosin based contractile ring. One of the key steps in the assembly of the actomyosin ring is the polymerization / accumulation of actin filaments at the division site. In recent years, the fission yeast Schizosaccharomyces pombe has emerged as an attractive model for the study of cytokinesis, since it divides using an actomyosin ring. Here we investigate the mechanism of actin filament assembly at the division site in fission yeast using the recently developed lifeact-peptide, as a probe for studying actin dynamics. Although previous work had shown that actin filaments for the actomyosin ring assemble exclusively at the division site, we find that cable-like actin filaments are also assembled away from the division site, in a manner dependent on the formin-related protein Cdc12p. Non-medially assembled actin filaments accumulate at the division site and contribute to the assembly of actomyosin ring in a myosin II and myosin V-dependent manner. Our studies taken together with some studies in animal cells establish that overlapping mechanisms, of de novo actin filament assembly at the division site and of transport of preexisting actin filaments to the division site, may facilitate actomyosin ring assembly in many organisms.

1729

The condensation of actomyosin network into a contractile ring depends on actin cross-linkers alpha actinin and fimbrin during fission yeast cytokinesis.

D. Laporte[1], N. Ojkic[2], D. Vavylonis[2], J-Q. Wu[1,3]; [1]Department of Molecular Genetics, Ohio State University, Columbus, OH, [2]Physics Department, Lehigh University, Bethlehem, PA, [3]Department of Molecular and Cellular Biochemistry, Ohio State University, Columbus, Ohio State

Quantitative studies of the assembly of the contractile ring in the fission yeast S. pombe provides insights of how actin, myosin motors, and cross-linkers self-organize into contractile structures in cells. The fission yeast contractile-ring assembles through the condensation of a broad band of membrane-bound nodes containing myosin-II and formin. In the Search, Capture, Pull, and Release (SCPR) model, formins nucleate actin filaments from nodes and establish transient actomyosin connections among them. Myosin pulls and condenses the band of nodes into a ring. However, the role of actin cross-linkers in ring assembly is unclear. To dissect their

roles we mutated them and modified the concentrations of α-actinin Ain1 and fimbrin Fim1 in vivo. We also extended the SCPR model to account for actin filament flexibility, representing filaments as beads connected with springs and cross-linking as connections among actin filaments. Both Ain1 and Fim1 localize to the division site during node condensation. Ain1 localizes between nodes. Nodes collapse into clumps instead of a ring in *ain1Δ* cells. Surprisingly, in *fim1Δ* cells, condensation is not affected. However, reducing the level of both Ain1 and Fim1 severely affects node condensation, suggesting that they cooperate for ring formation. By titrating Ain1 and Fim1, we find that node condensation rates depend on their concentration, with meshworks forming instead of rings at high concentrations. The Kd of Ain1 with the ring is in the µM range. Using the in vivo parameter values, the model reproduces many of the observed dependencies on cross-linker concentrations, including morphological features such as branched meshworks and clumps. These results indicate that actin cross-linkers are crucial for node condensation during cytokinesis.

1730

Spatial and temporal control of lipids and F-actin in cytokinesis completion.

D. Dambournet[1], M. Machicoane[1], L. Chesneau[1], M. Sachse[1], M. Rocancourt[3], A. El Marjou[2], E. Formstecher[3], B. Goud[2], A. Echard[1]; [1]Institut Pasteur, Paris, France, [2]Institut Curie, [3]Hybrigenics

Cytokinesis leads to the physical separation of the daughter cells, and is characterized in animal cells by a complex series of cell shape changes and membrane remodelling. Following furrow ingression, daughter cells are connected for most of cytokinesis by an intercellular bridge, which is cut in a final step termed abscission. Cytoskeleton and lipid composition are profoundly remodelled during late cytokinesis steps, but how this occurs and whether it is important for successful cytokinesis remains to be established.
Growing evidence indicate that membrane traffic has a key contribution in the post-furrowing steps of cytokinesis. In order to identify more precisely the transport routes involved and how they function in cytokinesis, we recently conducted a systematic RNAi screen focused on Rab genes, which encode key conserved GTPases that regulate membrane trafficking in eukaryotic cells. We found that Rab35 regulates an endocytic pathway and is involved in the initial stability of the intercellular bridge, after furrow contraction, by controlling the proper localization of SEPTIN2 in human cells. In addition, we noticed that Rab35 depletion led to additional cytokinesis defects characterized by either delayed or inhibited abscission.
We will present the molecular mechanism by which the Rab35 GTPase regulates lipid and cytoskeleton remodelling in terminal cytokinesis steps. We found that Rab35 controls the localization of a phosphatase that regulates the turnover of PI(4,5)P2 in late intercellular bridges. Our results indicate that PI(4,5)P2 hydrolysis is a key requirement for local removal of cortical F-actin and therefore normal cytokinesis abscission. We will also discuss how these findings shed new light on the pleiotropic phenotypes associated with a disease in which this phosphatase is mutated.

1731

The roles of C. elegans MRCK-1 & Rho-Kinase in myosin organization and contractile ring dynamics.

C. A. P-Descovich[1], J. F. Dorn[1], P. S. Maddox[1], A. S. Maddox[1]; [1]Pathologie and cell biology, Inst Research Immunol/Cancer, Montreal, QC, Canada

During cytokinesis, the duplicated and segregated genome is physically compartmentalized into two daughter cells. The contractile ring, a highly dynamic structure, is made of actin, myosin, other actin binding proteins and additional accessory factors. Actomyosin contractility provides

the force to deform the cell equator into a cytokinetic furrow. The myosin holoenzyme of two heavy chains and four light chains can adopt three conformations: closed, open and oligomeric bipolar mini-filaments. Mini-filament assembly has major implications for myosin's processivity, and crosslinking and bundling activities. Conversion among these conformations is thought to be regulated by two phosphorylation events on the regulatory light chain protein, by conserved kinases. We are working to understand how myosin is activated, organized and regulated during cytokinesis. We **hypothesize** that the conserved kinases Rho-kinase and MRCK-1 contribute distinctly to myosin regulation in cytogenesis. We image *C. elegans* zygotes expressing GFP-tagged myosin heavy chain (NMY-2) by real-time confocal microscopy and perform quantitative image analysis with custom bio-informatics tools. We first confirmed published observations that Rho-kinase depletion leads to decreased myosin recruitment, a delay in furrow initiation, slower closure and a significant increase in ring asymmetry. Also, we measured defects in contractile ring cortical organization into patches. *C. elegans* MRCK-1 is thought to indirectly regulate myosin activation, but its mammalian homologue can directly phosphorylate myosin. We show that MRCK-1 depletion does not affect furrow initiation or closure kinetics, nor significantly affects ring closure concentricity. Paradoxically, MRCK-1 depletion increases cortical myosin recruitment, but simultaneous depletion with Rho-kinase decreases equatorial myosin compared to Rho-kinase depletion alone. Furthermore, the double kinase depletion leads to a unique ring asymmetry phenotype with very asymmetric initiation, following a recentering of the ring. Together, our results support the idea that these two kinases have different contributions to myosin organization, thus are non redundant.

1732

Roles of Gef2 in division-site positioning and contractile-ring function in fission yeast cytokinesis.

Y. Ye[1], K. Runge[2], J-Q. Wu[1]; [1]The Ohio State Univ, Columbus, OH, [2]Cleveland Clinic Lerner College of Medicine at CWRU

Cytokinesis is crucial for integrating genome inheritance and cell functions. In higher eukaryotes, Rho-GEFs and Rho GTPases are key regulators for division-plane specification and contractile-ring formation during cytokinesis. However, how they regulate early steps of cytokinesis remains unknown in fission yeast. Here we show that *S. pombe* Rho-GEF like protein Gef2 and Polo kinase Plo1 coordinate to control the medial cortical localization and function of anillin-related protein Mid1, which specifies the medial division plane by recruiting contractile-ring components. The division-site positioning defects of *gef2 plo1* double mutant can be partially rescued by increased dosages of Mid1. We find that Gef2 modulates Mid1 cortical binding and is required for the cortical localization of Mid1 NH2 terminus by physical interactions. Gef2 cortical localization depends on its last 145 residues. In addition, Gef2 also functions in late cytokinesis involved in contractile-ring stability/anchoring. We propose that the mechanism regulating cytokinesis by Rho-GEF related proteins is conserved in fission yeast: Plo1 dependent phosphorylation triggers Mid1 nuclear exit, and Gef2 facilitates the binding of Mid1 to the medial cortex, subsequently Mid1 induces division-plane specification and contractile-ring assembly.

1733

Supervillin-mediated Myosin II Activation Is Required for Normal Cytokinesis.

T. C. Smith[1], S. Basil[1], S. Arjun[1], R. M. Friesen[1], E. J. Luna[1]; [1]Department of Cell Biology, Cell Dynamics Program, University of Massachusetts Medical School, Worcester, MA

Supervillin (SV), a large member of the villin/gelsolin/flightless family, coordinates motor proteins at membranes during motile processes. Supervillin binds tightly to lipid raft membranes

and is a regulatory hub for cytoskeletal, membrane, and signaling proteins. Many supervillin interactors are involved in cell cycle control, and supervillin knockdown inhibits early cytokinesis. In the absence of supervillin, myosin II heavy chain and phosphorylated myosin light chain are recruited normally to the furrow, but activated myosin II subsequently becomes mis-localized to non-equatorial sites. GFP-tagged full-length supervillin partially rescues the RNAi-mediated defect in cytokinesis, and overexpressed full-length supervillin improves the fidelity of cell division in HeLa cells. By contrast, expression of supervillin lacking the N-terminal 170 amino acids (SV171-1792) increases the numbers of bi- and multi-nucleated cells. We have shown previously that the N-terminal 174 amino acids in supervillin (SV1-174) enhance myosin II contractility, and we have proposed that they do so by cross-bridging the S2 regulatory region in non-muscle myosin II heavy chain with the long (L) isoform of myosin light chain kinase (L-MLCK). Expression of GFP-SV1-174 has no effect on the inherent cell division defect in HeLa cells, even though it is present at the furrow. However, GFP-SV1-174 promotes hyper-activation of myosin II during interphase, leading to the disruption of stress fibers into myosin II "punctae" containing supervillin and L-MLCK. We have used smaller deletions and point mutagenesis to identify sequences within SV1-174 that participate in myosin II activation. Supervillin residues 1-11 and 127-174 are necessary for the formation of myosin II punctae. Pulldowns with GST-tagged constructs indicate that SV1-11 enhances and that SV127-174 is absolutely required for binding to the S2 regulatory region of myosin IIA. In addition, we find that SV23-101 is required for binding to the GST-tagged L-MLCK N-terminus. These results suggest a U-shaped model for the supervillin N-terminus, in which L-MLCK binds to sequences interior to the myosin II-binding sites at each end of SV1-174. In ongoing experiments, we are selectively disrupting individual binding sites in full-length supervillin to examine the molecular basis for the important role of the supervillin N-terminus for myosin II anchorage to the cytokinetic cell furrow. Supported in part by NIH grant GM33048.

1734

Roles of the Drosophila RZZ complex in membrane traffic and cytokinesis.

A. Wainman[1], M. Giansanti[1], M. L. Goldberg[2], M. Gatti[1]; [1]IBPM c/o Biology and Biotechnology, Sapienza, University of Rome, Roma, Italy, [2]Molecular Biology and Genetics, Cornell University, Ithaca, NY

The conserved Rod-Zwilch-Zw10 (RZZ) complex is a well-known kinetochore component required for proper activity of the spindle assembly checkpoint in both Drosophila and mammals. In yeast and mammals, Zw10 participates in a second complex involved in membrane traffic. However the role of the Drosophila RZZ complex in membrane trafficking has never been addressed. We found that Zw10 is enriched at both the Golgi and the ER of Drosophila spermatocytes; Rod concentrates at the Golgi but not at the ER, while Zwilch does not accumulate in any membrane compartment. Mutations in zw10 and rod severely affect Golgi structure, while zwilch is not required for Golgi maintenance. In addition, loss of Zw10 results in frequent failures of spermatocyte cytokinesis, whereas Rod and Zwilch are not required for this process. zw10 mutant spermatocytes assemble regular central spindles and acto-myosin rings, but furrow ingression halts prematurely due to defective plasma membrane addition. Collectively, our results suggest roles for Zw10 in the ER-Golgi traffic and membrane addition during cytokinesis, while Rod appears to mediate proper Golgi function but is dispensable for cytokinesis. Given their different functions and subcellular localizations, Zw10 and Rod might be part of different subcomplexes involved in membrane traffic during Drosophila spermatogenesis.

1735

Activated H-Ras in recycling endosomes regulates endosomal trafficking to the cleavage furrow and is required for efficient cytokinesis.

P. Kumar[1], J. G. Wurtzel[1], J. D. Cohen[1], L. E. Goldfinger[1]; [1]Anatomy & Cell Biology, Temple University School of Medicine, Philadelphia, PA

We describe here a new set of functions for the Ras small G protein: regulation of endosomal traffic into the cleavage furrow in dividing cells, and a requirement for this process in efficient cytokinesis. Ras small G proteins are molecular switches which drive signaling pathways stimulating transcription and cell proliferation, apoptosis, differentiation and migration. Transcriptional activation leading to cell proliferation is the best studied Ras function, and this cellular function has been considered the principal explanation for the very high incidence of somatic activating mutations in hyperproliferative diseases, most notably cancers. However, Ras genes are clearly pleiotropic, as indicated in part by distinct signaling patterns and cellular and physiological functions of Ras isotypes which share common effector pathways. Much current research is focused on the role of spatial segregation of Ras signaling in specifying these distinct functions. Owing to the requirement of membrane anchorage of Ras for its functions, Ras signaling was originally believed to be restricted to the plasma membrane. However, several Ras isotypes also attach to the membranes of internal organelles such as the Golgi and ER. Recently H-Ras and N-Ras, but not K-Ras, were localized in cells to recycling endosomes (REs), dynamic endosomal compartments engaged in receptor recycling and secretory trafficking pathways. A functional role for Ras at these sites remains to be elucidated. Also recently, REs were shown to traffic centripetally into the cleavage furrow which develops between daughter cells during telophase, and this trafficking is essential for cytokinesis, the physical separation of the daughter cells. Using real-time live cell confocal fluorescence microscopy, we have found that activated H-Ras (expressed as a red fluorescent protein fusion), highly concentrated on recycling endosome membranes, engages in centripetal trafficking patterns as endosomal cargo into the cleavage furrow in cells, beginning in late anaphase and continuing through telophase. Activated H-Ras was also concentrated in the midbody as the daughter cells pulled apart, whereas dominant negative H-Ras was excluded from the midbody. Furthermore, dominant negative H-Ras, although localized to REs, did not traffic efficiently into the cleavage furrow. We found two important Ras effectors, RalGDS and the p110α subunit of PI3 Kinase, but neither c-Raf nor B-Raf, co-localized with activated H-Ras on recycling endosomes in the cleavage furrow, suggesting that activated H-Ras engages in signaling at these sites. Interestingly, dominant negative H-Ras severely delayed abscission, the final separation step in cytokinesis, in synchronized cells compared to control. Conversely, constitutively active H-Ras slightly accelerated the time to abscission. Thus, blockade of H-Ras activity and signaling stalls recycling endosome traffic to the cleavage furrow with a subsequent inhibition of cytokinesis. These data represent two related functions of Ras previously undescribed: regulation of endosome traffic and its downstream requirement for efficient cytokinesis. Thus, H-Ras regulates cell proliferation at multiple stages – transcriptional activation and regulation of cell division. Whereas the former function is driven by signaling relays, the latter is due to H-Ras effects on the trafficking of sub-cellular organelles and their contributions to cell morphology. These results therefore widen the picture of the pleiotropic cellular functions of Ras genes to include multiple processes throughout the cell cycle.

1736

Super-resolution Analysis of Cytokinetic Ring Formation.

E. R. Griffis[1], M. Arocena[1]; [1]Wellcome Trust Centre for Gene Regulation and Expression, University of Dundee, Dundee, United Kingdom

The formation of the cytokinetic ring has been visualized by many imaging modalities. We previously used TIRF microscopy to visualize the accumulation of Myosin II, Kinesin-6, Diaphanous, and Aurora B with high temporal and spatial resolution. We observed that there is a substantial pool of Kinesin-6 that accumulates on the cortex at the site of cytokinetic ring formation and is not associated with microtubule tips. We hypothesized that this motor protein may be associated with the nascent ring through an interaction between centralspindlin and the scaffold protein anillin in order to concentrate this Rho activator and stimulate faster and more robust cytokinetic ring assembly. In order to test this model, we've been performing more detailed spatial analysis of the distribution of Kinesin-6, microtubules, and the proteins of the cytokinetic ring with super-resolution imaging combined with RNAi of various components of the cytokinetic ring. Additionally, we are trying to dissect the signaling pathways and interactions that allow for the recruitment of centralspindlin to the cytokinetic ring, independent of microtubule binding, by generating some novel mutants that may uncouple these interactions and then observing the effects that these mutants have on the spatial and temporal dynamics of Kinesin-6 and myosin recruitment. We hope that these results will better illuminate the feedback loops and pathways that drive cytokinetic ring formation and allow for assembly to occur even in areas of low microtubule density.

1737

Role of the Contractile Ring in Cytokinesis.

M. Stachowiak[1], C. Laplante[2], B. Guirao[3], T. Pollard[2], B. O'Shaughnessy[1]; [1]Department of Chemical Engineering, Columbia University, New York, NY, [2]Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, [3]Institut Curie, France

In animals and fungi cytokinesis involves constriction of an actomyosin contractile ring, but the constriction mechanisms and the role of the ring are not established. The constriction rate could be determined only by the properties and internal dynamics of the ring itself, as recently suggested by experiments on *C. elegans* embryos [Carvalho et al, Cell (2009)]. Alternatively, the constriction rate could be set by other processes coupled to constriction. In fission yeast constriction is tightly coupled to septation, the growth of new cell wall in the wake of the constricting ring. To isolate ring mechanisms, we combined mathematical modeling of the ring with experiments on fission yeast protoplasts which lack cell wall and adopt a rounded shape. Protoplasts contained ring precursor nodes as in normal cells and assembled functional contractile rings that constrict without septation by sliding along the plasma membrane without cleaving the cell. By manipulating the shape of the protoplasts, we showed that the ring's shape evolution and constriction rate depend on the shape of the protoplast surface, in remarkably close quantitative agreement with model predictions. Therefore, ring constriction dynamics depend on external factors: in protoplasts, the ring tension couples to ring anchors whose sliding response determines the constriction rate. This suggests that in normal yeast cells the function of the ring is to exert tension upon the septum and the septation rate then determines the closure rate. We used the model to examine how ring tension depends on the dynamics of actin and the relatively disordered non-sarcomeric arrangement of ring components suggested by prior experiments. Simulations predicted that the ring generates ~40-80 pN of tension, and comparison with our observations of protoplast ring constriction revealed that the net drag of ring-membrane anchors during constriction is ~20-fold greater than the combined drag of the precursor nodes. Anchoring of actin filament barbed ends maximizes tension, and actin turnover

plays a vital role by remodeling the ring throughout constriction while maintaining organizational correlations that set the tension. In agreement with experiment, the model showed that suppression of actin polymerization slows ring constriction because actin filaments are then shorter and couple to fewer myosins, with consequently reduced tension. Thus, the model articulates a mechanistic relationship between organization, turnover kinetics, ring tension and closure rate.

1738

Interdependence of ring constriction and septation in fission yeast cytokinesis.

S. Thiyagarajan[1], B. O'Shaughnessy[2]; [1]Physics, Columbia University, New York, NY, [2]Chemical Engineering, Columbia University, New York, NY

Cytokinesis is the final stage of the cell cycle where the cell physically divides into two daughters. In animals and fungi, cytokinesis involves constriction of an actomyosin contractile ring coupled to other simultaneous processes. While the ring is thought to generate tension, its role has not been established, and whether the ring or coupled processes drives constriction is unknown. In fission yeast, constriction is tightly coupled to septation: the growth of new cell wall in the wake of the constricting ring. How these processes coordinate to complete cytokinesis is not established: septation could be driven by ring tension, or ring closure could instead be driven by septation. Here we developed a model of cytokinesis in fission yeast that describes the coupling of the tensile contractile ring to the growth of primary septum by Bgs1p and other proteins that synthesize septum material. The model hypothesizes that ring tension influences the local rate of septum growth through the effect of radial ring-generated forces on Bgs1p or other motors. We used our model to calculate the rate of inward growth of the septum and the evolution of the shape of the inner septum boundary during ring closure. Our model results are consistent with experimental observations in wild type and mutant yeast cells, and suggest that while the ring-septum closure rate is independently set by the septation process, the ring tension serves a vital role by regulating septum growth, and thereby suppressing roughness of the septum boundary, and maintaining its circular shape. From the model, we calculated the minimum ring tension required for a given degree of smoothness in the growing septum, consistent with calculations of wild type fission yeast ring tension. Thus, our model suggests that the primary role of the contractile ring in fission yeast cytokinesis is as a tension-producing machine that regulates septum circularity to ensure ordered closure and separation of the daughter cells.

1739

Forces in fission yeast cytokinesis.

S. Proctor[1], N. Minc[2], A. Boudaoud[3], F. Chang[1]; [1]Microbiology, Columbia University, New York, NY, [2]Inst. Curie, [3]Université de Lyon

A paradigm of cytokinesis in animal cells is that the actomyosin contractile ring provides the primary contractile force to divide the cell. In the fission yeast Schizosaccharomyces pombe, cytokinesis also involves a conserved actin-myosin ring, which has been generally assumed to provide the force for cleavage. However, in contrast to animal cells, yeast cells assemble a cell wall septum concomitant with ring contraction and possess large (MPa) internal turgor pressure. Here, we show that the inward force generated by the division apparatus must oppose turgor pressure. Reducing effective turgor pressure leads to an increase in cleavage rate. We estimate that the contractile ring can only provide a tiny fraction (less than 1/1000) of the mechanical stress required to overcome turgor. Indeed, we find that once septation has started, cleavage can continue in the absence of the contractile ring. Instead, we propose that cell wall synthesis provides the primary force for cleavage furrow ingression. We develop a quantitative model in

which the assembly of cell wall fibrils in the growing septum pushes in the plasma membrane for ingression using a rachet-based mechanism. We show that this mechanism may be sufficient to provide the large MPa pressures to work against turgor pressure. This work begins to provide some initial estimates of force production in division of a walled cell.

1740

In vivo measurements of cell shape reveal the dynamics of early cytokinesis.

R. Cautain[1], D. Paul[1], P. S. Maddox[1], A. S. Maddox[1], J. F. Dorn[1]; [1]IRIC, Montreal, QC, Canada

Cytokinesis is the final step of cell division. Failure of cytokinesis can lead either to cell death, or to cancerous transformation. Cytokinesis is achieved by the contractile ring, located at the cell equator, which constricts to split the cell into two daughter cells, dramatically deforming the cell membrane in the process. Most work has been done on the signalling that elicits contractile ring assembly. Investigating membrane curvature and the early mechanics that drive cytokinesis remain experimental challenges because of the difficulty of extracting 3D shape information from microscopy data.

We investigate the early events of cytokinesis by determining the 3D cell shape of living cells by combining high resolution microscopy with automated image analysis. We use the *C. elegans* zygote expressing fluorescently labelled membrane-associated proteins, a powerful system due to the highly stereotypical nature of cell division events in this cell. To visualize and analyze cell shape dynamics, we map deformation, protein distribution, and membrane curvature into 2D via Mercator projection, the method used to visualize the surface of the Earth, for example, in 2D.

We find that furrow ingression starts locally and propagates around the circumference of the division plane at ~65 μm/min. Initially, when the furrow has gentle curvature, it radially ingresses at ~2.4μm/min, which is consistent with measurements made using traditional imaging approaches. During furrow initiation, we observe local changes in the concentration of a PH domain marker for PIP2: it is first depleted from the future furrow site and then from regions flanking the furrow. Finally, we note that the cytokinetic ring is surprisingly non-planar, suggesting that cortical mechanics outside the division plane play a more important role in shaping cytokinesis than previously appreciated.

1741

Molecular basis for the interactions of the F-BAR protein Hof1 with septin filaments and myosin-II during yeast cell cycle.

Y. Oh[1], E. Bi[1]; [1]Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

F-BAR domain belongs to a subfamily of the BAR domains that are known to dimerize, bind phospholipids, and cause membrane curvatures. Hof1, a cytokinesis protein in the budding yeast *Saccharomyces cerevisiae*, contains a F-BAR domain at its N-terminus and a SH3 domain at its C-terminus. Hof1 localizes to the mother-bud neck in a septin-dependent manner from S phase to the onset of cytokinesis and contracts with the actomyosin ring (AMR) during cytokinesis. The mechanism underlying the dynamic localization of Hof1 during the cell cycle remains largely unknown. We found that the F-BAR domain of Hof1 co-localizes with the septins throughout the cell cycle and interacts strongly with septin filaments *in vitro*. The F-BAR also interacts with a number of septin subunits *in vivo*, particularly strongly with Cdc10, by bimolecular fluorescence complementation. This result is further supported by the striking observation that GFP-tagged F-BAR fails to associate with the septins in *cdc10* but not in *shs1* deletion cells. Unlike other F-BAR domains, the F-BAR of Hof1 does not bind any phospholipid

with specificity and high affinity. These data suggest that the F-BAR of Hof1 binds to septin filaments in a Cdc10-dependent manner.

The C-terminal half of Hof1 (C-Term) localizes to the mother-bud neck right before septin hourglass splitting and contracts with the AMR during cytokinesis. The C-Term interacts with the tail of Myo1, the sole myosin-II in budding yeast. In the absence of Myo1, the level of C-Term phosphorylation is reduced and the C-Term co-localizes with split septin rings during cytokinesis. These data suggest that Myo1 may provide a scaffold for protein kinases to phosphorylate Hof1 during cytokinesis. Together, our study provides biochemical evidence for the discrete localizations of Hof1 during the cell cycle, which are presumably associated with its role in cytokinesis and beyond.

1742

Reactive oxygen species increase binucleated cells through perturbation of cytokinesis progression via unresolved DNA bridges in HeLa cells.

M-G. Cho[1,2], I-J. Lee[1], Y-Y. Park[1], J-H. Lee[1]; [1]Department of Molecular Science and Technology, Ajou University, Suwon, Korea, [2]Department of Biochemistry and Molecular Biology, Ajou university, Suwon, Korea

Aneuploidy, an abnormal number of chromosomes which is one of the major characteristics of cancer cells, can arise from tetraploid cells resulting from a failure of the cytokinesis. Reactive oxygen species (ROS) have been implicated in processes as diverse as cancer, inflammation, cardiovascular disease and ageing. However, the role of ROS in cytokinesis progression has not been studied well. In time-lapse analysis, 100 μM H2O2 treatment during mitosis induced early- and late-cytokinesis failure in HeLa cells. In addition, the number of binucleated cells was significantly increased by H2O2 treatment. Treatment with 10 mM N-acetyl-L-cystein (NAC), an anti-oxidant reagent, abrogated cytokinesis failure and binucleated cell formation induced by H2O2, suggesting that ROS is involved in cytokinesis perturbation. Next we examined whether major molecules working in cytokinesis progression such as Anillin and Rho A were affected by treatment with ROS. However, our observation revealed that these proteins did not participate in H2O2 induced cytokinesis failure. One of the possible ways inducing cytokinesis failure is increase of DNA bridges. Immunocytochemistry and confocal microscopy data revealed a significant increase in DNA bridges as well as γ-H2AX expression (80.9%), a maker for DDSBs. Moreover the binucleated cells resulted from the cytokinesis failure by ROS also contained DNA bridges (probably nucleoplasmic bridges; NPBs) between two nuclei. Interestingly, while the DNA bridges induced by etoposide were rapidly resolved during telophase, those induced by H2O2 were mostly maintained during the same period, indicating the perturbation in DNA bridge resolution by H2O2 treatment. Taken together, we propose that ROS increases polyploid cells resulting from cytokinesis failure *via* DNA bridge formation that are not effectively resolved.

1743

Chlamydia trachomatis Inclusions Induce Asymmetric Cleavage Furrow Formation and Ingression Failure in Host Cells.

H. Sun[1], A. Wilde[2], M. Terebiznik[1], R. Harrison[1]; [1]Cell and Systems Biology, University of Toronto, Scarborough, ON, Canada, [2]Molecular Genetics, University of Toronto, Toronto, ON, Canada

Chlamydia trachomatis, an obligate intracellular bacterium, is the most common cause of bacterial sexually transmitted diseases worldwide. Epidemiological studies have linked *C. trachomatis* infections to increased risks of cervical cancer. Here we show that *C. trachomatis* disrupts host cell division and induces host genome duplication, a phenomenon well linked to

tumorigenesis. Through long-term live cell imaging of *C. trachomatis*-infected cells, we observed the consistent formation of a single unilateral cleavage furrow instead of the normal bilateral furrows that occur during host cell division. The absent furrow and the *C. trachomatis* inclusion always resided on the same side of the cell, when unilateral cleavage furrow was observed. In these instances, host cells would often prematurely exit mitosis, resulting in binucleated cells. We demonstrated with both fluorescent live cell imaging and immunofluorescence that *Chlamydia* inclusions located in the polar region of the host cells did not disrupt the normal bilateral cleavage furrow formation. We recapitulated the unilateral cleavage furrow defect in CHO cells that engulfed 15-micron latex beads, indicating that the *Chlamydia* inclusion acted as a physical barrier to prevent normal cleavage furrow initiation. We also performed an exhaustive study of various signaling proteins involved in furrow formation in *Chlamydia*-infected cells using immunofluorescence. The accumulation of F-actin, myosin II, RhoA, anillin, Ect2, centralspindlin complex, Aurora B, PRC1 and Plk1 were sharply reduced or completely absent at the side of the cell containing *Chlamydia* inclusions. We confirmed that the localization of these signaling proteins was normal in cells containing *Chlamydia* inclusions in the polar region. Since *Chlamydia* is genetically intractable at this time, we prevented bacterial protein synthesis with antibiotics. A significant increase in the number of inclusions located in the polar region of the host cells after antibiotics treatment was observed. Moreover, *Chlamydia* inclusions localized to the cell center more efficiently than similarly-sized latex beads, indicating *Chlamydia* was actively localizing to the host cell equator. We took advantage of the robustness of the equatorial localization and protein displacing capability of the *Chlamydia* inclusions to address a prevalent controversy regarding the role of MTs in cleavage furrow formation. It has been proposed that astral MTs have an inhibitory effect on the contractile activity of the plasma membrane and the absence of astral MTs leads to ectopic furrowing. In our experiments, *Chlamydia* inclusions consistently generated regions on the host plasma membrane receiving minimal astral MT and in such regions, no ectopic furrowing was ever observed, indicating that the lack of astral MTs do not promote furrow formation. This study not only delineates the mechanism by which *Chlamydia* causes cleavage furrow defects and host genome duplication but also illustrates how we can take advantage of this bacterium to address the basic cell biology question of how the cleavage plane is defined.

Mitosis and Meiosis: Focus on Centrosomes, Kinetochores, and Microtubules

1744

Accurate chromosome segregation requires a tunable binding affinity between core kinetochore components and microtubules.

L. J. Sundin[1], A. Zaytsev[2], B. Nikashin[2], G. J. Guimaraes[1], K. F. DeLuca[1], J. Mick[1], E. Grishchuk[2], J. G. DeLuca[1]; [1]Department of Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, [2]Physiology Department, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

The ability to stably bind microtubules (MTs) is an obvious requirement for the proteins that make up the kinetochore-MT attachment site. However, the binding strength must be finely tuned to allow for the maintenance of force-generating attachments and for the fluid gain and loss of tubulin subunits at MT plus-ends. The kinetochore-associated NDC80 complex can bind directly to MTs and is proposed to couple chromosome movements to growing and shortening MT plus-ends. The Hec1 protein of the NDC80 complex contains two putative MT-binding motifs: a well-structured calponin homology domain and a poorly-structured amino terminal “tail” domain. Recent studies have indicated that both domains are required to achieve high affinity

MT binding in vitro and for stable kinetochore-MT attachment in vivo. Additionally, the tail domain plays a role in regulation of the attachment strength between kinetochores and MTs through phosphorylation by Aurora kinases. How tail domain phosphorylation contributes to the regulation of kinetochore-MT attachments remains a highly debated topic. To investigate this issue, we generated a series of Hec1 constructs encoding for either truncated tail domains or tail domains containing various phospho-mimetic mutations. The mitotic phenotypes of PtK1 and HeLa cells expressing these mutants were then analyzed. We find that only a very short tail domain (6 amino acids) is required for the formation of stable kinetochore-MT attachments in cells, but a much longer tail is required for proper regulation of kinetochore-MT binding. In addition, we find that kinetochore-MT attachment strength in cells is tunable, as increasing the number of phospho-mimetic mutations within the tail domain decreases kinetochore-MT attachment strength and increases the rate of kinetochore oscillatory movements. To gain molecular insight into these cellular phenotypes, we turned to in vitro single molecule approaches using TIRF microscopy. The diffusion coefficient and residency time of purified GFP-NDC80Bonsai complexes containing Hec1 phospho-mimetic substitutions were measured on the surface of coverslip-attached taxol-stabilized MTs under physiologically-relevant conditions. To determine the dissociation constants for these proteins we developed a TIRF-based assay, in which the intensity of the GFP-NDC80 complex-MT decoration was measured for a wide range of soluble protein concentrations. At saturation, we observe that both the unphosphorylated complex and the mutant forms achieve a high density of binding, which corresponds to about 2 NDC80 complexes per tubulin dimer. Our in vitro data show that even a single phospho-mimetic substitution in the Hec1 tail has a measurable impact on the interaction of NDC80 complexes with MTs: with increasing phospho-mimetic mutations, the dissociation constant and diffusion coefficient increase, while the residency time shortens. These results are consistent with the view that the differential phosphorylation of Hec1, rather than an abrupt switch from the fully phosphorylated to fully unphosphorylated form, regulates the ability of the NDC80 complex to couple kinetochores to MTs, and to produce cohesive chromosomal oscillations.

1745

Cdk activity couples epigenetic centromere inheritance to cell cycle progression.

M. C. Silva[1], D. L. Bodor[1], M. E. Stellfox[2], N. M. Martins[1], H. Hochegger[3], D. R. Foltz[2], L. E. Jansen[1]; [1]Instituto Gulbenkian de Ciência, Oeiras, Portugal, Oeiars, Portugal, [2]Department of Biochemistry and Molecular Genetics, University of Virginia, [3]Genome Damage and Stability Centre, University of Sussex, UK, United Kingdom

Centromeres are chromosomal loci that drive their segregation during mitosis. Structure and identity of centromeres are maintained epigenetically by nucleosomes containing the histone H3 variant CENP-A. Propagation of CENP-A chromatin is uncoupled from DNA replication and initiates following mitotic exit implicating mitotic events in controlling the propagation of centromeric chromatin. However, the nature of the signal that triggers assembly of CENP-A is unknown.

We now show that mitotic passage itself is dispensable for CENP-A loading and that this process is directly triggered by the loss of cyclin dependent kinase 1 (Cdk1) activity in early G1. Treatment of cells in G2 phase with Cdk inhibitors induces rapid assembly of newly synthesized CENP-A at centromeres. Using pharmacogenetics in chicken DT40 cells we show that direct inhibition of Cdk1 and Cdk2 activities is sufficient for rapid CENP-A assembly at centromeres throughout the cell cycle. Consistent with canonical loading in G1, premature CDK inhibition induces recruitment of the CENP-A assembly factors hMis18 and Mis18BP1/HsKNL2 to centromeres that precedes arrival of CENP-A. G2 phase loading is dependent on these factors as well as on the CENP-A chaperone HJURP. Critically, drug induced centromere targeting of

CENP-A does not require proteolysis, uncoupling CENP-A assembly not only from mitotic events but also from the specific involvement of any APC targets that are degraded upon mitotic exit. We further show that the key CENP-A assembly factor Mis18BP1/HsKNL2 is phosphorylated in a cell cycle dependent manner controlling its centromere localization during mitotic exit.
Our results strongly support a model in which the CENP-A assembly machinery is poised for activation throughout the cell cycle, but kept in an inactive non-centromeric state by Cdk1 and Cdk2 activities during S, G2 and M phases, thus ensuring tight coupling between DNA replication, cell division and subsequent centromere maturation.

1746

Nucleophosmin/B23 acts as an interphase activator of Aurora-A at the centrosome.

D. Reboutier[1], M. Troadec[1], J. Cremet[1], K. Fukasawa[2], C. Prigent[1]; [1]Institut of Genetics and Development, CNRS, Rennes, France, [2]Molecular Oncology Program, H. Lee Moffitt Cancer Center & Research Institute, Tampa, FL

Aurora-A is a serine/threonine kinase required for centrosome maturation and spindle assembly. In a proteomic screen designed to unravel new Aurora-A substrates, we identified Nucleophosmin/B23 (NPM). NPM is a histone chaperone that is involved in regulation of transcription and translation, in DNA replication, in centrosome duplication and in cytoplasm/nucleus trafficking. We showed that NPM is not only a substrate, but also an activator of Aurora-A. In vitro NPM activates Aurora-A in a way that is different from the activation of Aurora-A by TPX2. Indeed, NPM doesn't trigger autophosphorylation of Aurora-A on T288 and doesn't protect T288 from dephosphorylation by PP1. In vivo, Aurora-A and NPM co-localize at centrosomes during interphase and mitosis. We validated physiological activation of Aurora-A by NPM, since NPM depletion by RNAi leads to the decrease in CDC25B phosphorylation at centrosomes in early prophase. In summary, our work suggests that NPM is a new Aurora-A activator that may act through an original activation mechanism.

1747

Temporal regulation of Haspin, the histone H3 Threonine 3 kinase, by Polo-like Kinase 1 and Cdk1.

C. Ghenoiu[1,2], H. Funabiki[1]; [1]Chromosome and Cell Biology, The Rockefeller University, New York, NY, [2]Cell and Molecular Biology, Weill Cornell Graduate School of Biomedical Sciences, New York, NY

Haspin is a critical activator of Aurora B, one of the major mitotic kinases that orchestrate cell cycle progression. Phosphorylation of histone H3 at threonine 3 by Haspin (H3T3ph) creates a chromosomal docking site that recruits and ultimately activates Aurora B, leading to reaction cascades on chromosomes that coordinate mitosis. The temporal regulation of Haspin is key for proper cell cycle progression; in its absence, metaphase spindles are shorter, while persistence of its activity after exit from M phase results in a delay in chromosome decondensation and nuclear re-formation. We employed the Xenopus egg extract system to show that Haspin activity is restricted to M phase through the combined action of Cdk1 and Polo-like kinase (Plx1). Upon entry into M phase, Cdk1 phosphorylates the N terminus of Haspin to recruit Plx1. The N terminus of Haspin contains an evolutionally conserved polo-box binding domain, an STP motif, and we show that the prephosphorylation of this motif by Cdk1 promotes binding of purified Plx1-PBD to Haspin. Consistently, a point mutation of the Plx1-docking site abolishes Haspin-dependent phosphorylation of H3T3 in egg extracts. In Plx1-depleted egg extracts, histone H3T3 phosphorylation is greatly impaired and the phospho-dependent mobility shift of Haspin is greatly reduced. Therefore, Plx1 seems to phosphorylate Haspin on multiple sites to

maintain the kinase active up to anaphase. The molecular details of this phospho-dependent activation are still under study. We identified a C-terminal domain within Haspin that possesses inhibitory activity and removal of which renders the kinase constitutively active in a Plx1-independent manner. Plx1 and Cdk1 may control Haspin kinase activity either by inducing a direct conformational change through phosphorylation to relieve this inhibition, or by regulating the binding of an inhibitor in that region. We are currently investigating a number of potential Haspin binding partners as well as further dissecting the structure of Haspin to gain insight into its cell cycle dependent activation.

1748

Elucidation of the Aurora A activation module that drives centrosome maturation.

V. Joukov[1], A. De Nicolo[1], J. C. Walter[2]; [1]Cancer Biology, Dana-Farber Cancer Institute, Boston, MA, [2]Biological Chemistry and Molecular Pharmacology, Harvard Medical School, Boston, MA

The function of centrosomes as the major sites of spindle microtubule (MT) assembly relies on recruitment of pericentriolar material (PCM), a proteinaceous matrix containing the gamma tubulin ring complexes (γ-TuRC) and other spindle assembly factors. This process, known as centrosome maturation, occurs at the onset of mitosis via incompletely understood mechanisms.

Our recent study revealed that Cep192/Spd-2, a key regulator of centrosome biogenesis and PCM recruitment, is a cofactor of the mitotic serine/threonine kinase, Aurora A (AurA), at centrosomes. Specifically, Cep192 targets AurA to these organelles, where it promotes oligomerization-dependent activation of the kinase characterized by extensive phosphorylation at a critical threonine residue within the activation loop (T-loop) (Joukov et al., 2010, PNAS 107:21022). This process is essential for the recruitment of the PCM components, such as γ-TuRC and pericentrin, and for the function of centrosomes as MT-organizing centers (MTOCs).

Although at least two other cofactors, Bora and TPX2, have previously been implicated in AurA regulation during mitosis, the Cep192-mediated mechanism appears to account for most of the T-loop phosphorylated AurA. We found that Bora, Cep192, and TPX2 form distinct endogenous complexes with AurA and compete with one another for binding to the kinase, thus suggesting that the binding occurs at an overlapping segment on AurA. Cep192 appears to regulate AurA downstream of Bora since Cep192-dependent AurA activation occurs at mitotic entry and coincides with the degradation of Bora.

While elucidating the mechanisms underlying Cep192-dependent AurA activation, we identified CCDC21 (Coiled-Coil Domain Containing 21), a centrosomal protein of unknown function, as an abundant component of the AurA-Cep192 complex. CCDC21 localizes to mitotic centrosomes independently of AurA and it is not required for the targeting of Cep192 and AurA to these organelles. Yet, CCDC21 is essential for AurA activation by centrosomes, as well as for PCM recruitment and centrosome-mediated spindle MT assembly. Based on our data, CCDC21 seems to function by facilitating the formation and/or stability of AurA-Cep192 oligomers.

These observations reveal that PCM recruitment, a prerequisite for centrosomes to act as major spindle MTOCs, relies on a specialized mechanism of potent AurA activation, which involves at least two proteins, Cep192 and CCDC21 (“AurA activation module”).

1749

Rsf-1, a protein involved in chromatin remodeling, is functionally related to the activation of aurora B kinase.

S. Chae[1], H-S. Lee[2], H. Cho[2]; [1]Biochemistry, Ajou University School of Medicine, Suwon, Korea, [2]Biochemistry and Molecular Biology, Ajou University School of Medicine, Suwon, Korea

Rsf-1/HBxAP interacts with hSNF2H, a ATPase to form a chromatin remodeling complex, RSF (remodeling and spacing factor). Recently, Rsf-1 is suggested to be involved in centromere formation. Here, we show that Rsf-1/HBxAP protein accumulates in mitosis and localizes at the centromeres. Depletion of Rsf-1/HBxAP caused severe defects in chromosomal congression, resulting in accumulation of prometaphase cells. Despite the defects in congression, the analysis of time-laps images showed the acceleration of mitotic progression, which indicates that the mitotic checkpoint is compromised in Rsf-1 deficient cells. In Rsf-1 depleted cells, Aurora B and hBubR1 properly localize to kinetochores. However, the activity of Aurora B kinase was significantly decreased in the absence of Rsfp1/HBxAP or hSNF2h. Depleted cells defect localization of Plk1 at the kinetochore. Our results suggest that Rsf-1/HBxAP depletion decreases Aurora kinase activity by impairing the localization of Plk1 at the kinetochore. This study provides the evidence that Rsf1/HBxAP play an important role in mitosis.

1750

IPL1/Aurora B kinase inhibits bipolar spindle assembly during meiotic prophase.

S. Kim[1], R. Meyer[1], D. Dawson[1]; [1]Cell cycle and cancer biology, Oklahoma Medical Research Foundation, Oklahoma City, OK

The coordination of spindle assembly with chromosome dynamics is a prerequisite for correct chromosome segregation during mitosis and meiosis. Spindle assembly occurs following the separation of side-by-side microtubule organizing centers (MTOC). In budding yeast, the spindle pole body (SPB) functions as the MTOC. In mitotic growth, the single SPB duplicates in G1/S and the duplicated SPBs soon separate to form a bipolar spindle. However, in meiosis, the duplicated SPBs stay side-by-side and their separation is delayed during a protracted prophase in which pairing and recombination between homologous chromosomes prepares them to be segregated at metaphase I. Only as the cell exits prophase do the duplicated SPBs separate to form a spindle. Thus, it appears there is a mechanism that coordinates these two seemingly independent events (chromosome interactions/spindle assembly) so that SPB separation does not precede the completion of homologous chromosomal interactions. Here, we combine genetic and microscopic approaches to demonstrate that Ipl1/Aurora B kinase is essential for inhibiting bipolar spindle assembly during prophase. When this inhibition is removed spindles form prematurely in prophase cells. We examined whether premature spindle formation in prophase leads to chromosome mis-segregation. Our results show chromosomes do not interact with the precocious spindles in prophase but that when cells exit prophase in the presence of pre-formed spindles they exhibit increased rates of chromosomes mis-segregation. Our results suggest that Ipl1/Aurora B kinase plays a critical role in coordinating the timing of bipolar spindle formation with chromosomal events to prevent chromosome mis-segregation in meiosis.

1751

Mechanisms of acentrosomal spindle assembly during C. elegans oocyte meiosis.

S. M. Wignall[1], A. Villeneuve[2]; [1]Molecular Biosciences, Northwestern University, Evanston, IL, [2]Developmental Biology, Stanford University, Stanford, CA

Although centrosomes serve to organize microtubules in most cell types, oocyte spindles form in their absence. We are investigating acentrosomal spindle assembly using *C. elegans* as model. High resolution imaging of acentrosomal spindle formation revealed that following nuclear envelope breakdown, microtubules form a "cage-like" structure that forms adjacent to remnants of the nuclear envelope. At later stages, arrays form where minus ends are associated at multiple sites before achieving bipolarity. These findings suggest a model where acentrosomal spindle assembly proceeds by: 1) microtubule nucleation within the disassembling nuclear envelope, 2) organization of minus ends at sites away from the chromosomes, and 3) coalescence of these sites into two poles. We are currently testing this model and identifying proteins required for these events.

Through the course of an RNAi screen, we identified proteins required for multiple aspects of acentrosomal spindle assembly. Depletion of either KLP-18 (kinesin-12 family) or MESP-1 (meiotic spindle 1) results in the formation of monopolar oocyte spindles, implicating these proteins in establishing and/or maintaining spindle bipolarity. KLP-18 was previously shown to localize to the poles of oocyte spindles, and we found that MESP-1 colocalizes with KLP-18 throughout the cell cycle. In *klp-18* mutants MESP-1 fails to localize to the poles of the monopolar spindles, and KLP-18 fails to localize to microtubules following *mesp-1 (RNAi)*, suggesting that these proteins are interdependent for their localization and likely collaborate to promote acentrosomal spindle bipolarity. In contrast, depletion of ASPM-1 (homolog of *Drosophila* Abnornal spindle protein) in oocytes results in disorganized structures that either lack or have unfocused poles. ASPM-1 localizes to spindle poles and to regions where minus ends begin to associate during the early stages of acentrosomal spindle formation, and KLP-18 and MESP-1 are not required for this localization. Double depletion of ASPM-1 and either KLP-18 or MESP-1 prevents monopolar spindle formation, and a disorganized structure without a focused pole forms. Therefore, ASPM-1 is required for acentrosomal pole formation, and we propose a model in which ASPM-1 contributes to coalescing minus ends during spindle assembly.

1752

The *fragile centrioles (fract)* gene is required for the maintenance of centriole integrity during *Drosophila* male meiosis.

R. Lattao[1], M. Gatti[1], S. Bonaccorsi[1]; [1]Dept. Biology and Biotechnology, "La Sapienza" University of Rome, Rome, Italy

We have isolated and characterized a mutation in a *Drosophila melanogaster* gene we name *fragile centrioles (fract)*; this mutation disrupt male meiosis and causes male sterility. Immunostaining with antibodies against centriolar components such as DSpd2 and Asl showed that premeiotic spermatocytes of *fract* mutants display 2 centrioles at each cell pole. However, meiotic ana-telophase I figures of *fract* mutants often exhibit two regular centrioles at one cell pole but only one at the opposite pole. As a result, a number of secondary spermatocytes assemble bipolar monastral spindles that are unable to mediate proper chromosome segregation. *fract* encodes a 322 aa protein that contains WD repeats; this protein is expressed only in testes, suggesting that *fract* is specifically required for meiotic centriole stability. The EMS-induced *fract*[1] mutant allele we characterized carries a stop codon that truncates the Fract protein into a 298 aa polypeptide. A polyclonal antibody raised against Fract decorates the distal end of male meiotic centrioles. This specific staining pattern is lost in *fract* mutants, where the

antibody decorates the entire centriole, suggesting that the C-terminal region of Fract is crucial for its correct localization. Asl, DspD2, Sas4 and Dplp localize normally to the intact centrioles of *fract* mutants, indicating *fract* is not is not required for recruitment of these major centriole components. Collectively our results strongly suggest that *fract* does not play an essential role in centriole assembly but it is instead required for the maintenance of centriole integrity during male meiosis. We are currently characterizing centriole behavior in living spermatocytes of *fract* mutants and looking for proteins that physically interact with Fract.

1753

Regulation of kinetochore-microtubule attachment during meiosis I by Mps1 and Ipl1/Aurora-B.

R. Meyer[1], P. Straight[2], S. Kim[1], D. Obeso[1], M. Winey[3], D. Dawson[1]; [1]Cell Cycle & Cancer Biology, Oklahoma Medical Research Foundation, Oklahoma City, OK, [2]Dept. of Biochemistry and Biophysics, Texas A&M University - College of Agriculture & Life Sciences, Tamu, TX, [3]Molecular, Cellular, and Developmental Biology, University of Colorado, Boulder, CO

Kinetochores are large protein complexes which define the site of microtubule attachment to the chromosome. Regulation of kinetochore attachment and orientation on the spindle is essential to insure proper segregation of chromosomes during mitosis and meiosis. The 1st meiotic division, which separates homologous chromosomes, requires attachment of the sister chromatids to the same pole. This monopolar attachment is promoted in budding yeast by the monopolin complex and Ipl1 (=Aurora-B). Recent observations in budding yeast suggest that in meiosis I, there are two periods in which kinetochore-microtubule (kMT) associations are regulated: an early release of attachments in prophase and a period of attachment and orientation in metaphase.
Mps1 is an evolutionarily conserved Serine/Threonine kinase. Mps1 is implicated in different functions linked to chromosome segregation including spindle pole body duplication (Mono-Polar Spindle 1), the spindle checkpoint and promotion of bi-orientation in mitosis. The pleiotropic phenotypes of MPS1 mutations have complicated the studies of the different individual functions/targets of Mps1, and for this reason the precise roles of this kinase remain mysterious. We have circumvented this problem with a separation of function point mutation of MPS1 that is located in domain recently described as specifically implicated in promoting bi-orientation during mitosis. Mutants bearing this allele are perfectly viable during vegetative growth. Surprisingly, the same mutants exhibit extremely high levels of mis-segregation during meiosis I. During the 1st meiotic division, this allele mutant suppresses the monopolar attachment defect of monopolin mutants, much like IPL1 mutants do. Comparative analyses with ipl1 mutants suggest that Ipl1 and Mps1 play similar roles in promoting kMT attachment in meiosis but at different times in the meiotic program.

1754

Pac-man motility of kinetochores unleashed by laser microsurgery.

J. R. LaFountain[1], C. S. Cohan[2], R. Oldenbourg[3]; [1]Biological Sciences, University at Buffalo, Buffalo, NY, [2]Anatomy and Pathology, University at Buffalo, Buffalo, NY, [3]Marine Biological Laboratory, Woods Hole, MA

Typically anaphase segregation entails a kinetochore moving poleward as its kinetochore (K-) fiber shortens. In crane-fly spermatocytes, the sex chromosomes – X and Y – are found as univalents during meiosis I, and they exhibit a very atypical segregation mechanism in which each has K-fibers to both poles. X-Y segregation is based on their being led to opposite poles, each connected with a leading fiber (which shortens) to one pole, and a trailing fiber (which elongates) to the other. We used a combination of fluorescent speckle microscopy, liquid crystal

polarized light microscopy and laser microsurgery to show that segregation is based on a traction fiber model in which leading kinetochores function in a polymerization (reverse pac-man) state, whereas trailing kinetochores are in a neutral state that cannot foster poleward movement. To investigate the motile states that the kinetochores are able to support, we used the laser to knock out one of a univalent's two kinetochores, so as to release the remaining intact kinetochore from the resistive influence of its sister's K-fiber. This resulted in impressively more-rapid-than-normal poleward movement of the released kinetochore and attached arms. Fluorescent speckle microscopy of such released kinetochores revealed their motile state. Through analysis of poleward movement of released kinetochores relative to fluorescent speckles within microtubules, we found that our experiment had caused the released kinetochore to convert from reverse pac-man to pac-man motility. This novel result demonstrates that it is indeed possible for a spindle that normally employs traction fiber mechanics to exhibit pac-man motility. This unleashing of kinetochore motility through loss of resistive force is further evidence for the emerging model that kinetochores are subject to tension-sensitive regulation.

1755

Architecture and kinetochore binding of the yeast monopolin complex.

K. D. Corbett[1,2], L-S. Ee[3], A. Amon[4], S. Harrison[5]; [1]University of California, San Diego, La Jolla, CA, [2]Ludwig Institute for Cancer Research, La Jolla, CA, [3]University of Massachusetts Medical School, [4]Biology, Massachusetts Institute of Technology, [5]BCMP, Harvard Medical School

In fungi, the monopolin complex prevents certain types of improper kinetochore-microtubule (MT) attachments, both in mitosis and meiosis. In *Saccharomyces cerevisiae*, monopolin binds kinetochores in meiosis I and enforces co-orientation of sister chromatids; while in *Schizosaccharomyces pombe*, the complex inhibits merotelic attachment of individual kinetochores in mitosis and meiosis II. How monopolin accomplishes these tasks, in addition to a seemingly unrelated function in rDNA silencing and recombination control, is not well understood. We have examined the architecture of the conserved core of monopolin from both *S. cerevisiae* (the Csm1/Lrs4 complex) and *S. pombe* (Pcs1/Mde4). The *S. cerevisiae* Csm1/Lrs4 complex adopts a distinctive V-shaped structure, with two globular 'heads' spaced ~10 nm apart. We identified direct physical interactions between the globular head domains of Csm1 and both the MIND/Mis12 complex, a conserved inner-kinetochore subcomplex, and the inner-kinetochore subunit Mif2/CENP-C. Point-mutations in Csm1 that disrupt these interactions in vitro result in a loss of sister chromatid co-orientation in meiosis I, indicating their functional importance. Together, our data support a model in which Csm1/Lrs4 and Pcs1/Mde4 act as bivalent clamps, which can cross-link kinetochores' microtubule-binding sites in order to co-orient sister chromatids in meiosis I (*S. cerevisiae*) or prevent merotelic attachment (*S. pombe*). More recently, we have dissected the protein-protein interactions of the two other *S. cerevisiae* monopolin complex subunits, Mam1 and the casein kinase Hrr25. We have determined the structure of the Mam1/Csm1 complex, and are also working to image the intact *S. cerevisiae* monopolin complex, which we recently expressed and purified.

1757

Replacement of Histone H3 with CENP-A Directs Global Nucleosome Array Condensation and Loosening of Nucleosome Superhelical Termini.

T. Panchenko[1], T. C. Sorensen[2], C. L. Woodcock[3], Z-Y. Kan[1], W. Englander[1], J. C. Hansen[2], B. E. Black[1]; [1]Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA, [2]Biochemistry and Molecular Biology, Colorado State University, [3]Department of Biology, University of Massachusetts

Centromere protein A (CENP-A) is a histone H3 variant that marks centromere location on the chromosome. The goal of this work was to study the subunit structure and folding dynamics of human CENP-A-containing chromatin. We generated a set of nucleosomal arrays with canonical core histones and another set with CENP-A substituted for H3. Then we coupled folding measurements using analytical ultracentrifugation (AUC) with mass spectrometry-based hydrogen/deuterium exchange (H/DX-MS). The AUC studies measure the bulk behavior of the arrays, while H/DX-MS is used to measure the dynamic behavior of the polypeptide backbone of each histone in the nucleosome core. At the level of quaternary structure and assembly, we find that CENP-A arrays are composed of octameric nucleosomes that assemble in a stepwise mechanism, recapitulating conventional array assembly with canonical histones. At intermediate structural resolution, we find that CENP-A-containing arrays are globally condensed relative to arrays with the canonical histones. At high structural resolution, using H/DX-MS, we find that the DNA superhelical termini within each nucleosome are loosely connected to CENP-A, and we identify the key amino acid substitution that is largely responsible for this behavior. Also the C-terminus of H2A undergoes rapid hydrogen exchange relative to canonical arrays, and does so in a manner that is independent of nucleosomal array folding. These findings have implications for understanding CENP-A-containing nucleosome structure and higher order chromatin folding at the centromere.

1758

Quantification of CENH3/CENP-A and NDC80 Complexes in Individual *Arabidopsis* Kinetochores During Mitosis and Meiosis.

J. S. Ramahi[1], P. N. Kwong[2], R. Maruthachalam[1], S. W. Chan[1]; [1]Department of Plant Biology, University of California, Davis, Davis, CA, [2]Department of Chemisty and Biochemistry, University of California, Los Angeles, Los Angeles, CA

The kinetochore protein complex attaches chromosomes to spindle microtubules to facilitate chromosome segregation. Kinetochore size varies greatly between organisms, but the effect of this structural plasticity on protein stoichiometry is not well understood. We replaced the *Arabidopsis thaliana* kinetochore proteins CENH3 and NUF2 (a member of the microtubule binding NDC80 complex) with GFP-tagged variants. This allowed us to measure their amounts in individual mitotic and meiotic kinetochores using quantitative fluorescence microscopy with *Saccharomyces cerevisiae* GFP-tagged proteins as standards. *A. thaliana* kinetochores contained an average of 375 ± 111 CENH3 molecules, and had a much higher CENH3:NDC80 ratio than budding yeast kinetochores. The number of CENH3 molecules in plant mitotic kinetochores varied more than the number of NDC80 complexes. Interphase kinetochores contained fewer CENH3 molecules, further indicating that the level of CENH3 is plastic. Meiotic kinetochores differ from mitotic kinetochores in three respects. First, the NDC80 complex is transiently removed from meiosis I kinetochores during chromosome pairing. Second, fused kinetochores in meiosis I are larger than mitotic kinetochores and have an elongated morphology. Third, the lowest levels of CENH3 and NDC80 complexes are observed in the tetrad stage of meiosis, indicating that kinetochores are significantly smaller before meiocytes return to the mitotic cell cycle.

1759

KNL-2 acts as a licensing factor for CENP-A loading in G1 through its Myb domain binding to centromeric DNA.

V. De Rop[1], M. J. Osborne[1], C. Moevus[1], A. Padeganeh[1], K. L. Borden[1], P. S. Maddox[1];
[1]Pathologie et biologie cellulaire, IRIC-Université de Montréal, Montréal, Québec, Canada

Centromeres are chromosomal loci that direct kinetochore assembly in mitosis. Unlike genetic features, centromere DNA sequence is not conserved through phylogeny nor is it sufficient for centromere function. Therefore, it is commonly accepted that centromeres are epigenetically defined; a process mediated by the histone H3 variant CENtromere Protein-A (CENP-A). CENP-A loading at centromeres is a replication independent mechanism, occurring from late telophase until early G1. However, the mechanism of centromere recognition by the loading machinery is not well understood. Kinetochore NulL-2 (KNL-2) was identified in *Caenorhabditis elegans* (*C. elegans*) by functional genomics as required for CENP-A loading at centromeres. Sequence analysis reveals a conserved MYB like DNA binding domain within KNL-2. In other well studied MYB proteins, this domain is known to bind DNA with high specificity via the 3rd of three helices. Here we show that the *C. elegans* KNL-2 (CeKNL-2) MYB domain is able to bind genomic DNA in vitro. Furthermore, CeKNL2 localizes to centromeres when ectopically expressed in human cells and in rat kangaroo kidney epithelium (PtK2). Together, these results indicate that the KNL2 Myb domain does not utilize a sequence specific DNA binding mechanism and possibly recognizes a specific structure generated by the presence of CENP-A nucleosomes at centromeres. To test this model, we solved the 3 dimensional structure using Nuclear Magnetic Resonance (NMR). This revealed an expected helix-loop-helix-loop-helix structure. Also, a 1H-15N Heteronuclear Single Quantum Coherence (HSQC) NMR spectra of the MYB domain in presence of centromeric DNA sequence (α-satellite sequence) revealed the amino acids that are potentially interacting with the DNA, and surprisingly they all reside within the first helix. The NMR results were further confirmed by an Electrophoretic Mobility Shift Assay (EMSA), deletion of the first helix of the Myb domain is not able to bind DNA compared to full length (or control deletions). To test whether KNL2 recognizes a specific structure given by CENP-A at centromeres, we are currently testing Myb domain binding to chromatin using Total Internal Reflection Fluorescence (TIRF) microscopy. Preliminary data shows that the CeKNL-2 Myb domain can localize to CENP-A-YFP foci. Moreover, Chromatin ImmunoPrecipitation followed by deep Sequencing (ChIP-Seq) shows an enrichment at centromere loci. Together, those results indicate that KNL-2 recognizes a specific structure given by CENP-A chromatin. Although not conserved at the sequence level, CeKNL-2 MYB domain displays conserved activity in human cells. Thus, the mechanism controlling centromere specification may be ubiquitous in metazoans.

A test of structural rigidity of CENP-A-containing chromatin as the epigenetic mark of centromere identity.

D. Fachinetti[1], L. Jansen[2,3], D. Cleveland[1];[1] Ludwig Institute Cancer Research, La Jolla, CA,
[2]Laboratory for Epigenetic Mechanisms, Oeiras, Portugal, [3]Instituto Gulbenkian de Ciência

The centromere is a specialized chromosomal domain necessary for the correct segregation of eukaryotic chromosomes during cell division. This region is a complex chromosomal structure containing extensive tandem repeated arrays of a DNA sequence element called α-satellite. The centromeres have a distinct type of chromatin in which histone H3 is replaced by a structurally different homologue identified in humans as CENP-A. These conformational differences can be transmitted into histone H3 when the 22 amino acid differences between helix α1 and α2 of CENP-A and histone H3 are substituted into histone H3. Since this short domain is sufficient to

drive histone H3.1 to the centromere when substituted into histone H3, this domain is called the CENP-A targeting domain (CATD). Furthermore the chimeric histone $H3^{CATD}$ can maintain centromere function when CENP-A levels are lowered. For these reasons, CENP-A chromatin is thought to be the major determinant of centromere identity since specific DNA sequences are neither required nor sufficient for centromere identity.
I aim to define the importance of the conformational difference of chromatin assembled with CENP-A compared with chromatin with canonical histone H3 to test the hypothesis that the structural rigidity conferred by CENP-A to centromeric chromatin is the epigenetic mark of centromere identity that templates its own replication.
For this purpose I used gene replacement in diploid human cells to construct a CENP-A Flox/- cell line that have null allele missing exon 3 and 4 (where the CATD domain is) and a conditional allele with two LoxP sites flanking exons 3 and 4. Inactivation of the floxed CENP-A allele is achieved after transient expression of Cre recombinase. I then determine if the chimeric histone H3 with the centromeric targeting domain of CENP-A ($H3^{CATD}$) can maintain centromere functionality and identity when endogenous CENP-A is completely absent.

1761

CENP-A Exceeds Microtubule Attachment Sites in Centromere Clusters of Both Budding and Fission Yeast.

V. C. Coffman[1], P. Wu[1,2], M. R. Parthun[4], J-Q. Wu[1,3]; [1]Molecular Genetics, The Ohio State University, Columbus, OH, [2]National Institute of Biological Sciences, Beijing, China, [3]Molecular and Cellular Biochemistry, The Ohio State University

The kinetochore stoichiometries in yeast and vertebrate cells were determined using the histone H3 variant CENP-A, Cse4 of budding yeast, as a counting standard. One Cse4-containing nucleosome exists in the centromere of each chromosome, so it is assumed that each anaphase centromere/kinetochore cluster contains 32 Cse4 molecules. We report that anaphase centromere clusters contained ~4× as much Cse4 in *S. cerevisiae* and ~40× as much CENP-A (Cnp1) in *S. pombe* as reported. These results suggest that CENP-A molecules exceed the numbers of kinetochore-microtubule attachment sites on each centromere and that CENP-A is not the sole determinant for specifying kinetochore assembly sites in either yeast. In addition, fission yeast has enough Dam1/DASH complex for ring formation around attached microtubules. This study prompts the need for significant revision of the centromere/kinetochore architectural models.

1762

HP1-Borealin interaction specifies CPC localization to the centromere.

X. Liu[1], Y. Huo[2], Z. Dou[3], J. Wang[2], X. Ding[4], X. Yao[5]; [1]Cancer Biology Program, Morehouse School of Medicine, Atlanta, GA, [2]Cell Biology, University of Science & Technology of China, [3]University of Science & Technology of China, [4]Beijing University of Chinese medicine, [5]Morehouse School of Medicine

During cell division, chromosome segregation is orchestrated by the interaction of spindle microtubules with the centromere. Accurate attachment of spindle microtubules to kinetochore requires the chromosomal passenger of Aurora B kinase complex with borealin, INCENP and survivin. However, the chromatin factors that recruit the CPC to centromeres have remained elusive. Here we show that the C-terminal borealin contains readers for the chromatin shadow domain of heterochromatin protein 1 (HP1£\). This borealin-HP1£\ binding is very specific and it mediates recruitment of the CPC to the centromere and the resulting activation of its kinase subunit Aurora B. Consistently, perturbation of such an borealin- HP1£\ interaction leads to defects in CPC targeting and aberrant Aurora B activity in centromere. Importantly, the

kinetochore microtubule attachment and tension across the kinetochores are attenuated due to the perturbation of borealin targeting. These findings establish a direct link between HP1£\ and CPC plasticity in centromere and its cellular role for Borealin-HP1£\ƒn interaction in orchestrating an accurate cell division. Using an optical sensor reporting kinase in centromere, we are illustrating the temporal dynamics of aurora B/haspin activity during kinetochore maturation and tension development during mitotic chromosome segregation.

1763

Crosstalk Between the Ndc80 Complex and the Dynein Motor Module at the Kinetochore.

D. K. Cheerambathur[1], K. Oegema[1], A. Desai[1]; [1]Ludwig Institute for Cancer Research, University of California, San Diego, La Jolla, CA

The Ndc80 complex forms the primary attachment site for microtubules at kinetochores. Microtubules capture kinetochores via transient lateral attachment, which mature to end-on stable load-bearing attachment. A poorly conserved basic 60-100 amino acid tail and a highly conserved globular calponin homology (CH) domain in the N-terminus of the Ndc80 subunit directly contact the microtubule lattice in vitro. Divergent results have been obtained on the importance of the basic tail in vivo; in yeast the tail is dispensable whereas in mammalian cells it is reported to be essential. Phosphorylation of the tail by Aurora B kinase is proposed to regulate the stability of kinetochore microtubule attachment by the Ndc80 complex. Analysis in the C. elegans embryo has also revealed that the formation of load-bearing microtubule attachments by the Ndc80 complex is regulated by the dynein motor module, presumably to facilitate the transition from an initial dynein motor-mediated lateral to end-on attachment. To investigate formation of end-on microtubule attachments by the Ndc80 complex in vivo, we developed a single copy transgene insertion system that enables precise phenotypic characterization of engineered mutants in the early C. elegans embryo. In parallel, we analyzed reconstituted complexes in vitro. Deletion of the tail, which severely reduced microtubule-binding affinity in vitro, or mutation of Aurora B sites on the Ndc80 complex, did not perturb load-bearing attachment formation or cause detectable chromosome missegregation. By contrast, mutations in the CH domain severely inhibited attachment formation and chromosome segregation, indicating that the primary load-bearing attachment activity of the Ndc80 complex resides in the Ndc80 CH domain. Unexpectedly, deletion of the Ndc80 basic tail disrupted the ability of the dynein motor module to regulate the formation of load-bearing attachments. Prior work indicates that the dynein-tethering RZZ (Rod/Zwilch/Zw10) complex (Gassmann et al. Genes Dev. 2008 22:2385-99) transiently inhibited the formation of load-bearing attachments by the Ndc80 complex. Deleting the Ndc80 tail prevented this crosstalk between the dynein motor module and the Ndc80 complex, accelerating the formation of end-on attachments. Taken together, our results reveal that the basic tail of Ndc80 is dispensable for load-bearing attachment formation but serves as the primary target for regulation by the dynein tethering RZZ complex at the kinetochore. We propose that crosstalk between the two major microtubule-binding activities at the kinetochore in metazoans coordinates conversion of initial dynein-dependent lateral microtubule capture into the load-bearing end-on Ndc80 complex-mediated attachments that align and segregate chromosomes.

1764

Fast removal of TACC3/ch-TOG/clathrin inter-microtubule bridges from kinetochore fibers during mitosis.

L. Cheeseman[1], I. Prior[1], S. Royle[1]; [1]Physiology, University of Liverpool, Liverpool, United Kingdom

The equal distribution of chromosomes between daughter cells during mitosis by the spindle apparatus is essential to avoid aneuploidy, one of the main hallmarks of cancer. The regulation of spindle microtubule dynamics and kinetochore fiber (K-fiber) stability is key to achieve correct mitosis. A TACC3/ch-TOG/clathrin complex was previously shown to stabilize K-fiber microtubules by acting as an inter-microtubule bridge, thus contributing to the alignment of chromosomes on the metaphase plate.

The use of RNAi to study spindle protein function has disadvantages due to slow depletion over several days, during which the cell can compensate for the missing proteins. Furthermore, distinguishing between the roles of proteins in either spindle assembly or spindle maintenance is difficult. Here, we removed specific spindle proteins from K-fibers by rapamycin-induced rerouting to the mitochondria: a technique known as knock-sideways (KS).

KS of TACC3 resulted in complete removal of the protein within 10 minutes of rapamycin application. Its mitotic partners, ch-TOG and clathrin were also removed from K-fibers; whereas the unrelated spindle proteins, NuMA and HURP were unaffected. Interestingly, KS of clathrin light chain induced the removal of clathrin heavy chain but only partial removal of TACC3 and ch-TOG from spindle fibers. This argues that TACC3, and not clathrin, serves as the microtubule-binding element of the TACC3/ch-TOG/clathrin complex.

Removal of the TACC3/ch-TOG/clathrin complex by KS of TACC3 during metaphase resulted in delayed progression to anaphase. By immunofluorescence, KS of TACC3 resulted in a ~20% decrease in the half-spindle length suggesting that K-fibers had become destabilized. Tension was reduced, as evidenced by a reduction in the inter-kinetochore distance. Moreover, a subset of kinetochores in metaphase-like cells where TACC3 had been rapidly removed still recruited the mitotic checkpoint protein MAD2. Correlative light-electron microscopy was used to study the loss of inter-MT bridges and the MT packing in K-fibers at either 10 or 30 minutes after removal of the complex.

Our results show that the TACC3/ch-TOG/clathrin complex contributes to maintaining the integrity of the mitotic spindle by stabilizing K-fiber microtubules. Using the KS method it was possible to distinguish these functions from roles in early mitosis, such as spindle assembly. As such, rapid methods for removal of spindle proteins show clear advantages over more chronic methods, such as RNAi.

1765

The Role of Slk19 in Centromere Cohesion.

D. Richmond[1], Y. Wang[1]; [1]Biomedical Sciences, Florida State University, Tallahassee, FL

To ensure faithful chromosome segregation, sister kinetochores must attach to microtubules emanating from opposite spindle poles to establish chromosome bipolar attachment. Once attached, the microtubules apply a pulling force against the sister kinetochores. This force is counter-acted by the cohesin complex, which holds sister chromatids together until anaphase onset to prevent premature chromosome separation. This conserved complex, thought to be in the form of a ring structure which entraps sister chromatids, is located throughout the

chromosomes and plays an essential role in chromosome segregation. Slk19 is a budding yeast kinetochore protein that has been previously shown to interact with a cohesin subunit Mcd1/Scc1, but its role in chromosome segregation has not been well defined (Zhang et al. 2006. J Cell Sci 119:519-31). Our data indicate that Slk19 could function as a centromeric-specific cohesin. We have observed separated sister centromeres in *slk19*$_{\Delta}$ mutant cells even when the pulling force is absent. Although *slk19*$_{\Delta}$ mutants undergo a relatively normal mitosis, they exhibit an anaphase entry delay after the kinetochore-microtubule interaction is disrupted by nocodazole. This delay is dependent upon Sgo1, a tension checkpoint component, which suggests that Slk19 is required for the reestablishment of bipolar attachment after the disruption of the kinetochore-microtubule interaction. We found evidence of a Slk19-Slk19 physical interaction and interestingly, we observed that overexpression of Slk19 also leads to centromeric cohesion defects. Furthermore, our evidence indicates the presence of a cohesin-cohesin interaction, but this interaction is reduced in *slk19*$_{\Delta}$ mutants. All of these results support the possibility that a single sister chromatid is entrapped within the cohesin ring at the centromeric region and dimerized Slk19 brings the cohesin rings from sister centromeres together.

1766

Enrichment of the Aurora B Kinase on the Centromeres of Incorrectly Attached Chromosomes.

K. Salimian[1], E. Ballister[1], E. Smoak[1], S. Wood[1], T. Panchenko[1], M. Lampson[2], B. Black[1];
[1]Department of Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA,
[2]Department of Biology, University of Pennsylvania

Maintenance of genome stability during cell division depends on establishing correct attachments between chromosomes and spindle microtubules. Correct, bi-oriented attachments are stabilized, while incorrect attachments are selectively destabilized. This process relies largely on increased phosphorylation of kinetochore substrates of Aurora B kinase at misaligned versus aligned kinetochores. Current models explain this differential phosphorylation by spatial changes in the position of substrates relative to a constant pool of kinase at the inner centromere. However, these models are based on studies in aneuploid cells. We show that normal diploid cells have a more robust error correction machinery. Aurora B is enriched ~3-fold at misaligned centromeres in these cells. Live-cell imaging studies demonstrate that the Aurora B enrichment at misaligned centromeres is due to a switch-like mechanism based on chromosome attachment status. Indeed, re-enrichment of Aurora B occurs within 1-4 minutes on the centromeres of individual chromosomes that lose initial bipolar attachment in otherwise unperturbed cells or on all the centromeres of cells treated with the microtubule poison, nocodazole. We show that this enrichment substantially increases the dynamic range of Aurora B substrate (Dsn1) phosphorylation at misaligned versus aligned kinetochores. We also show that, in addition to Aurora B, phospho-H2A-T120 levels, but not phospho-H3T3 levels, are enriched at the centromeres of misaligned chromosomes. Further, using cell fusions, we show that the deficiency of Aurora B enrichment in aneuploid cells can be rescued by the cytoplasm of healthy diploid cells. Our findings indicate that in addition to Aurora B regulating kinetochore-microtubule binding, the kinetochore also controls Aurora B recruitment to the inner centromere. We show that this recruitment depends on both activity of Plk1, a kinetochore-localized kinase, and activity of Aurora B itself. Our results suggest a feedback mechanism in which Aurora B both regulates and is regulated by chromosome attachment to the spindle, which amplifies the differential phosphorylation of kinetochore substrates and increases the efficiency of error correction.

1767

Characterization of centrosome positioning at nuclear envelope breakdown and its potential role in cancer cell chromosome mis-segregation.

W. Silkworth[1], I. Nardi[1,2], R. Paul[3], A. Mogilner[4], D. Cimini[1]; [1]Biological Sciences, Virginia Tech, Blacksburg, VA, [2]Department of Molecular Cell and Developmental Biology, University of Virginia, School of Medicine, Charlottesville, VA, [3]Indian Association for the Cultivation of Science, Jadavpur, India, [4]Department of Neurobiology, Physiology and Behavior and Department of Mathematics, UC Davis, Davis, CA

The microtubule-based bipolar mitotic spindle ensures accurate partitioning of chromosomes to two identical daughter cells. Although the mitotic spindle can assemble in the absence of centrosomes, when centrosomes are present, they act as major sites of MT nucleation. In preparation for mitotic spindle assembly, the replicated centrosomes can move to opposing sides of the nucleus before nuclear envelope breakdown (NEB) through a mechanism typically referred to as the prophase pathway of centrosome separation. However, in some cases centrosomes do not completely separate to opposite sides of the nuclear space until after NEB, which occurs through a mechanism known as the prometaphase pathway. Using PtK1 cells with fluorescently labeled centrosomes we found a continuous distribution of inter-centrosome distances at NEB, arguing against the presence of two distinct pathways of centrosome separation. Moreover, we found elevated numbers of anaphase lagging chromosomes in cells that have an inter-centrosome distance at NEB that is less than 75% of the inter-centrosome distance at the end of prometaphase. Additionally, we observed three types of arrangements in cells that fail to complete centrosome separation before NEB. These include a top-bottom, top-side, and a side-side orientation of centrosomes around the nucleus. Interestingly, when centrosomes are positioned in top-bottom configuration (which would entail completion of centrosome separation before NEB), they move to the same focal plane in the center of the nuclear space upon NEB, thus turning into a situation of incomplete centrosome separation. Finally, we tested whether failure of centrosomes to completely separate prior to NEB is a common phenomenon in cancer cells. We found that in a panel of human cancer cell lines 30-70% of early prometaphase cells exhibited incomplete centrosome separation. Such high frequencies suggest that incomplete centrosome separation at NEB may represent an additional mechanism by which cancer cells mis-segregate chromosomes at high rates.

1768

BubR1 Autophosphorylation is a Signaling Switch at the Kinetochore in Response to Microtubule Capture.

Y. Guo[1], S. Ahmad[1], Y. Mao[1]; [1]Department of Pathology and Cell Biology, Columbia University College of Physicians and Surgeons, New York, NY

Whether and how spindle microtubule capture can be translated into signaling at the kinetochore remain unresolved. Here we demonstrate that the kinetochore-associated mitotic kinase BubR1 is able to autophosphorylate itself in vitro and in cultured cells in the presence of its binding partner, a kinetochore motor CENP-E. This autophosphorylation is sensitive to microtubule attachment in cells. Replacing endogenous BubR1 with a nonphosphorylatable BubR1 mutant, but not a phosphomimetic mutant, results in not only metaphase chromosome misalignment, but also a decrease of Aurora B kinase activity. Depletion of CENP-E, the BubR1 kinase activator, also causes decreases of BubR1 autophosphorylation and Aurora B kinase activity. Furthermore, expression of a phosphomimetic BubR1 mutant in CENP-E-depleted cells substantially reduces incidents of polar chromosomes. Thus, CENP-E-dependent BubR1 autophosphorylation serves as a signaling switch at the kinetochore to directly regulate Aurora B kinase activity in response to spindle microtubule capture by CENP-E.

1769

Three-dimensional high-resolution colocalization of centromere and kinetochore proteins.

C. J. Fuller[1], A. F. Straight[1]; [1]Biochemistry, Stanford University, Stanford, CA

The kinetochore is the primary microtubule-binding site on the chromosome and governs accurate chromosome segregation during cell division. Kinetochores form during mitosis on a specialized chromatin domain called the centromere. The centromere and kinetochore are large multiprotein complexes. Understanding centromere and kinetochore function requires knowing how individual protein subunits of the centromere and kinetochore are spatially arranged and how this organization changes in response to microtubule binding and spindle forces. High-resolution localization of many centromere and kinetochore proteins has provided a map of the linear distribution of proteins along the sister kinetochore axis (Wan et al. 2009) but it has not been possible to measure the three-dimensional organization of centromere and kinetochore subunits or how this organization responds to microtubule based tension.

We present an extension of the high-resolution colocalization technique that allows us to measure three-dimensional distances between diffraction-limited objects to better than 10 nm absolute accuracy using standard widefield fluorescence microscopy. We apply this method to measure the three-dimensional distances between proteins of the centromere and kinetochore in human cells and examine asymmetry about the interkinetochore axis between two paired metaphase chromatids. We compare these distances between individual kinetochores from paired chromatids in untreated cells and cells treated with taxol to examine the differential response of paired kinetochores to microtubule-based tension.

1770

Tension dependent nucleosome remodeling at the pericentromere in yeast.

J. Verdaasdonk[1], R. Gardner[1], M. Anderson[1], E. Yeh[1], K. Bloom[1]; [1]Biology, UNC Chapel Hill, Chapel Hill, NC

Nucleosome positioning is important for the structural integrity of chromosomes. During metaphase the mitotic spindle exerts physical force on pericentromeric chromatin, and the cell must adjust the pericentromeric chromatin to accommodate the changing tension resulting from microtubule dynamics. Here we examine the effects of spindle-based tension on nucleosome dynamics by measuring the histone turnover of the chromosome arm and the pericentromere during metaphase in the budding yeast *Saccharomyces cerevisiae*. We find that both histones H2B and H4 exhibit greater turnover in the pericentromere during metaphase. Loss of spindle-based tension by treatment with the microtubule depolymerizing drug nocodazole results in reduced histone turnover in the pericentromere. The observed dynamics in the pericentromere under tension are influenced by the chromatin remodeling activities of STH1/NPS1 and ISW2. Sth1p is the ATPase component of the remodel the structure of chromatin (RSC) complex and is known to displace histones from chromatin, whereas Isw2p is known to insert nucleosomes via sliding activity. The balanced displacement and insertion of histones in the pericentromere allows the cell to accommodate spindle-based tension while maintaining proper chromatin packaging during mitosis.

1771

Defining how HJURP Differentiates CENP-A/H4 from Canonical H3/H4 in the Centromere Chromatin Assembly Pathway.

E. Bassett[1], M. Barnhart[2], D. Foltz[2], B. Black[1]; [1]Department of Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA, [2]Department of Biochemistry and Molecular Genetics, University of Virginia

Centromeres are the genomic locus required for proper chromosome segregation. Centromere Protein A (CENP-A) is a histone H3 variant present at all active centromeres and is the best candidate to provide the epigenetic mark that specifies centromere location on the chromosome. The CENP-A Targeting Domain (CATD), containing the L1 and α2 helix from the histone fold domain, confers unique dynamic and structural features to CENP-A-containing complexes and is sufficient for centromere maintenance when substituted into H3. HJURP (Scm3 in yeast) is the CENP-A specific chaperone that is required for recruitment of newly expressed CENP-A to centromeres, and its ectopic targeting onto a chromosome arm site directs local CENP-A loading and acquisition of a functional centromere (Barnhart et al., 2011, J. Cell Biol. 194: 229-43). How HJURP recognizes and binds specifically to CENP-A remains unclear despite a recent crystal structure of the ternary HJURP/CENP-A/H4 complex (Hu et al., 2011, Genes Dev. 25:901-6). By reconstituting complex formation with purified components and using the cell-based HJURP chromosome-tethering approach, we have now performed extensive mutagenesis of both CENP-A and H3 and defined the 7 residues within the CATD that are necessary and sufficient for HJURP binding. Our findings are a direct challenge to the proposal that a single CENP-A residue outside of the CATD is the major HJURP recognition element (Hu *et al*., 2011, Genes Dev. 25:901-6), and, indeed, direct tests in our functional biochemical and cell-based assays failed to support the earlier GST pulldowns experiments that originally led to this view. Surprisingly, we found that HJURP binding is insufficient for centromere targeting of CENP-A, suggesting that the dynamic and structural features of the CATD have other essential functions in conferring centromere targeting to CENP-A. In addition, we also found that a mutant version of CENP-A that cannot form a $(CENP\text{-}A/H4)_2$ subnucleosomal heterotetramer robustly assembles into a complex with HJURP but fails to assemble at centromeres, strongly suggesting that two copies of CENP-A are required in a stable centromeric nucleosome. In sum, our findings suggest that the CATD provides HJURP specificity and fulfills structural and dynamic requirements for effective centromeric nucleosome assembly and stability.

1772

The organization of the pericentromere chromatin spring by cohesin and condensin determined using model convolution.

A. D. Stephens[1], C. W. Quammen[2], W. D. Lewis[1], B. Chang[1], R. Haggerty[1], R. Taylor II[2], K. Bloom[1]; [1]Department of Biology, Univ North Carolina-Chapel Hill, Chapel Hill, NC, [2]Department of Computer Science, Univ North Carolina-Chapel Hill

The mitotic chromatin spring is composed of cohesin, condensin, and an intramolecular loop of pericentric chromatin. We utilized model convolution methods to compare quantitative computer simulations of pericentric cohesin and condensin to experimentally acquired microscopy images. Condensin lies proximal to the spindle microtubules in line with and spanning the distance between the inner kinetochores whereas cohesin is radially displaced from condensin by ~75 nm and does not span the full interkinetochore distance. Experimental condensin fluorescence is accurately modeled by clustering condensin complexes between the kinetochores whereas cohesin is modeled as a random distribution of single or paired complexes. Condensins aggregate to accomplish the compaction of the primary chromatin axis

forming loops. Cohesin slides along the pericentric chromatin to a spindle distal position where it interconnects and confines inter-chromatid loops generated by condensin. In conjunction, we are developing a mathematical model of the mitotic spindle to deduce the structure of the chromatin spring. Utilizing model convolution we report the sub-structures of cohesin and condensin that organize the pericentromere chromatin.

1773

Point centromeres contain greater than a single centromere-specific Cse4 (CENP-A) nucleosome.

J. Lawrimore[1], K. S. Bloom[1], E. D. Salmon[1]; [1]Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Cse4 is the budding yeast homolog of CENP-A, a modified histone H3 that specifies the base of kinetochores in all eukaryotes. Budding yeast is unique in having only one kinetochore microtubule attachment site per centromere. The centromere is specified by CEN DNA, a sequence specific binding complex (CBF3) and a Cse4-containing nucleosome. Here we compare the ratio of kinetochore proximal Cse4-GFP fluorescence at anaphase to several standards including purified EGFP molecules in vitro to generate a calibration curve for the copy number of GFP-fusion proteins. Our results yield on average ~5 Cse4s, ~2.5 inner kinetochore CBF3 complexes and ~20 outer kinetochore Ndc80 complexes per kinetchore. Our calibrated measurements increase ~2.5 fold protein copy numbers at eukaryotic kinetochores based on previous ratio measurements assuming 2 Cse4s per budding yeast kinetochore. All ~5 Cse4s may be associated with the CEN nucleosome, but we show that it is possible that ~3 Cse4s on average could be located within flanking nucleosomes at random sites that differ between chromosomes. Supported by NIGMS 24364(EDS) and 32238(KB).

Spindle Checkpoints

1774

Resolving the Spindle Assembly Checkpoint.

M. S. Manak[1,2], H. K. Buch[3], A. LaBonte[1,2], Y. Guan[1,2], J. V. Shah[1,2]; [1]Systems Biology, Harvard Medical School, Boston, MA, [2]Renal Division, Brigham and Women's Hospital, Boston, MA, [3]Eidgenössische Technische Hochschule, Institute of Cell Biology, Switzerland

Accurate chromosomal segregation is governed by the spindle assembly checkpoint (SAC) which functions to ensure that anaphase onset is delayed until all chromosomes are under tension on the mitotic spindle. The SAC signal is generated by a mitotic checkpoint complex (MCC) formed by interactions amongst Mad2, Mad3/BubR1, Bub3, and CDC20 which together inhibit the E3 ubiquitin-ligase anaphase promoting complex/cyclosome (APC/C). The high affinity between the MCC and APC/C protects cyclin B1 and securin from ubiquitination while the MCC is bound to the APC/C. The pathway of MCC formation and inhibition of the APC/C is understood at the level of a generally excepted working model. However, the pathway of APC/C activation via disruption of the bound MCC is not well established. Using mitotic HeLa extracts, we have examined how the checkpoint protein p31comet contributes to APC/C activation. In HeLa extracts, synergy between UbcH10, a critical E2 of the APC/C, and p31comet is observed and depends on p31comet binding Mad2. To understand this synergy we measured the in vitro activities of p31comet and UbcH10 against anaphase inhibitors. P31comet acts primarily to dissociate the free MCC complex, whereas UbcH10 acts primarily on the MCC-APC/C to disrupt this complex by ubiquitination of Cdc20. Thus the observed synergy is due to two parallel

pathways one where p31 disrupts the free MCC and the other being UbcH10 dissociating the MCC-APC/C complex. Coordinating p31comet binding to Mad2 and UbcH10 binding to the APC/C is a key regulatory step in releasing MCC from the APC/C and subsequently resolving the spindle assembly checkpoint. Indeed, computational simulations show that a kinetochore-regulated dissociation pathway is necessary for tight APC/C inhibition followed by rapid re-activation. These calculated predictions agree well with the observations regarding the long time cells can maintain mitotic arrest and the short time cells take to transition from metaphase to anaphase.

1775

Quantitative analysis of the spindle assembly checkpoint.

The spindle assembly checkpoint (SAC) is a surveillance mechanism, which ensures that cells only enter anaphase once all chromosomes have become properly attached to the mitotic spindle. The proteins constituting the SAC network are known and are conserved in eukaryotes. SAC proteins enrich at unattached kinetochores and ultimately lead to the inhibition of the anaphase-promoting complex. However, the complex *in vivo* signaling pathway is still only fragmentarily understood. Mathematical modeling can be a valuable means to explore possibilities for the signaling mechanism, but requires accurate quantitative data. We have determined the relative and absolute abundance of GFP-labeled SAC proteins *in vivo* in fission yeast by quantitative fluorescence microscopy and fluorescence correlation spectroscopy. The SAC proteins differ in their abundance, but all are present in the fission yeast cell at low nanomolar concentration. To further explore the robustness of the signaling mechanism and our mathematical representation of it, we modified SAC protein abundances and compared the outcome on SAC activity. We found strong differences in the ability of the SAC to tolerate changes in the abundance of single SAC proteins, and these results shed light on the signaling mechanism. To further unravel the organization of the SAC network, we determined the hierarchy of SAC protein localization to kinetochores upon mitotic entry and SAC activation. When comparing our results to data obtained in other eukaryotes, evolutionary differences become apparent. Exploring how the conserved SAC signaling mechanism has been shaped in different organisms in adaptation to their specific needs will be an interesting area for future investigation.

1776

Artificial Checkpoint Activation by Overpression of Checkpoint Complexes in the budding yeast Saccharomyces cerevisiae.

D. T. Lau[1], A. W. Murray[1]; [1]Molecular and Cellular Biology, Harvard University, Cambridge, MA

The spindle checkpoint is an elaborate system that is essential for accurate chromosome segregation. It involves proteins such as Mad1p, Mad2p, Mad3p, Mps1p, Bub1p, and Bub3p, most of which are highly conserved among eukaryotes. The absence of microtubule attachment or the lack of tension at the kinetochore (because of a failure to establish bi-orientation) activates the checkpoint, which arrests cells at the metaphase-to-anaphase transition by targeting the anaphase promoting complex (APC) and its co-activator Cdc20 for inhibition until errors are corrected. Despite numerous studies, we still do not understand how the checkpoint proteins coordinate with each other to inhibit APC-Cdc20 activities in the presence of errors at kinetochores.

To investigate how the checkpoint proteins induce metaphase arrest, we generated and express different checkpoint fusion proteins in the budding yeast Saccharomyces cerevisiae to mimic complexes that might form during checkpoint activation. Unexpectedly, we found that overexpression of Mad2-Mad3 fusion proteins arrest the cells in metaphase in the absence of obvious chromosome and spindle defects. The arrest doesn't require the presence of functional kinetochores or other checkpoint proteins. The effect of the Mad2-Mad3 construct could be due to its ability to bind and inhibit APC-Cdc20, as artificially tethering Mad2 to Cdc20 in cells can also lead to metaphase arrest. The Mad2-Mad3 construct may represent a complex formed during normal checkpoint activation and additional studies on this system will be helpful for understanding the complicated interactions among the checkpoint proteins.

1777

Par1b regulates mitotic spindle orientation and promotes asymmetric division in epithelial cells.

F. Lazaro-Dieguez[1], D. Cohen[1], D. Fernandez[1], A. Muesch[1]; [1]Department of Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY

Symmetrically dividing columnar epithelial cells align their mitotic spindle parallel to the basal domain in metaphase. However, the molecular mechanisms implicated in mitotic spindle orientation remain poorly understood. Here we show that the serine/threonine kinase Par1b controls mitotic spindle orientation along the x-z axis in columnar and hepatic epithelial cells. Par1b overexpression causes a hepatic-like phenotype in kidney-derived MDCK cells where their mitotic spindles are oriented at a 20°-45° angle rather than parallel to the substratum, and divide asymmetrically relative to the luminal domain. Tilted spindles were also found in β1-integrin disrupted MDCK cells. Interestingly, the expression of dominant-negative Par1b promotes parallel spindles and symmetric divisions in hepatic-derived WIF-B9 cells. We observed that Par1b overexpression causes a defect in the localization of endogenous collagen IV and disrupts the localization of spindle orientation-related proteins dynein, NuMA, and $p150^{glued}$ in the cell cortex during mitosis. Strikingly, extracellular collagen IV rescues the localization of these proteins at the cell cortex and promotes parallel spindles in Par1b-overexpressing and β1-integrin disrupted cells. Taken all together, we suggest that Par1b regulates both mitotic spindle orientation and type of cell division through the β1-intengrin/collagen IV signalling.

1778

Changes in molecular composition and kinetochore structure in response to different types of attachments.

M. Shen[1], D. Cimini[1]; [1]Biological Sciences, Virginia Tech, Blacksburg, VA

Each mitotic chromosome is constituted by two sister chromatids whose correct segregation to the daughter cells is ensured by amphitelic attachment, in which the two sister kinetochores (KTs) are attached to microtubules (MTs) from opposite mitotic spindle poles. Other types of KT attachment can occur in early mitosis and can cause chromosome mis-segregation and aneuploidy if not converted into amphitelic attachments before anaphase onset. These attachments include monotelic (one attached and one unattached sister KT), syntelic (both sister KTs attached to the same spindle pole), and merotelic (a single KT attached to MTs from opposite spindle poles) attachment. A biochemical pathway named the Spindle Assembly Checkpoint (SAC) is responsible for delaying anaphase onset to allow correction of KT mis-attachments. SAC activation is believed to occur due to KT localization of certain SAC proteins and/or lack of tension, but only monotelic attachment has been proven to activate the SAC. To determine if and how other types of KT attachment may activate the SAC, we investigated the

localization of certain SAC proteins, as well as members of the chromosome passenger complex at the KT/centromere of chromosomes with different types of attachment. Furthermore, we measured intra- and inter-KT stretching for chromosomes with different types of attachment, as both intra- and inter-KT stretching have been proposed to play some role in SAC signaling, correction of KT mis-attachments, or both (reviewed in Maresca and Salmon, J. Cell Sci., 2010; Nezi and Musacchio, Curr. Opin. Cell Biol., 2009). Our data suggest that monotelic attachment is the only type of attachment that can induce a SAC response thanks to the accumulation of the SAC protein Mad2 at the KT. Our data also suggest that structural changes of the KT, measured as intra- or inter-KT stretching, do not directly induce a SAC response, although they may contribute to correction of mis-attachment as previously proposed.

1779

Mps1/Mph1 kinase recruits SAC components to kinetohores through phosphorylation of KNL1/Spc7.

Y. Yamagishi[1], Y. Watanabe[1]; [1]Institute of Molecular and Cellular Biosciences, University of Tokyo, Tokyo, Japan

The spindle assembly checkpoint (SAC) delays anaphase onset in the presence of unattached kinetochores. Bub1 is a well conserved SAC protein and temporarily recruited to kinetochores in mitosis. In addition to SAC function, kinetochore associated Bub1 has a role in proper chromosome segregation in part through recruiting shugoshin proteins to centromeres.The kinetochore localization of Bub1 requires its binding partner Bub3 as well as another SAC protein kinase Mps1/Mph1. But how Mps1/Mph1 regulates the kinetohore localization of Bub1 is unknown. Here, we show that Mph1 promotes the interaction of the Bub1-Bub3 complex with the kinetochore protein KNL1/Spc7 through phosphorylation of Spc7 in fission yeast. Mph1 phosphorylates Spc7 at multiple sites containing conserved MELT repeats in vitro. In cells expressing the non-phosphorylatable spc7-12A mutant, the kinetochore localization of Bub1 and Bub3 are abolished, resulting in impaired chromosome segregation and SAC. Moreover, artificial targeting of Mph1 to kinetochores or expression of the phospho-mimetic mutant spc7-12E causes ectopic localization of Bub1 and Bub3 at kinetohores in interphase. Our results suggest that Spc7 is a hitherto unknown critical target of Mph1 in both chromosome segregation and SAC.

1780

Loss of function of the Cik1/ Kar3 motor complex results in chromosomes with syntelic attachment that are sensed by the tension checkpoint.

F. Jin[1], H. Liu[2], Y. Wang[1]; [1]Department of Biomedical Sciences, Florida State University, Tallahassee, FL, [2]Biology Science, Florida State University, Tallahassee, FL

The attachment of sister kinetochores by microtubules emanating from opposite spindle poles establishes chromosome bipolar attachment, an essential step for sister-chromatid separation. The bipolar attachment generates tension on chromosomes, and lack of tension or defects in kinetochore attachment activate the spindle checkpoint to prevent anaphase onset. Tension checkpoint proteins, Aurora/Ipl1 kinase and centromere-localized Sgo1, are required to prevent anaphase entry when tension is missing, but they are dispensable for the checkpoint response to detached kinetochores. Syntelic attachment occurs when both sister kinetochores are attached by microtubules from the same spindle pole and this attachment is unable to generate tension on chromosomes, but a reliable method to induce syntelic attachments is not available. In budding yeast Saccharomyces cerevisiae, we found that the loss of function of a motor protein complex Cik1/Kar3 leads to syntelic attachments. First, we showed that the expression of the coiled-coil domain in Cik1 from a galactose-inducible promoter disrupts Cik1-Kar3

interaction, therefore the function of Cik1/Kar3 can be inactivated conditionally. With this approach, we demonstrated that inactivation of either the spindle or tension checkpoint enables premature anaphase entry in cells with dysfunctional Cik1/Kar3. In these cells, both sister chromatids move along with one spindle pole, resulting in co-segregation. Moreover, the abolished Kar3-kinetochore interaction in cik1 mutants suggests that the Cik1/Kar3 complex mediates chromosome movement along microtubules, which could facilitate bipolar attachment. Consistent with the role in chromosome bipolar attachment, the association of Cik1/Kar3 with kinetochores occurs when cells are treated with a DNA synthesis inhibitor or microtubule poison, but the association disappears when cells arrest at preanaphase or telophase. In summary, we can induce syntelic attachments by inactivating the Cik1/Kar3 complex and this approach will be very useful to study the checkpoint response to syntelic attachments.

1781

Both Plk1 and AurB Are Required for Assembly of a Dynein-binding Platform on Kinetochores.

K. T. Vaughan[1], E. H. Hinchcliffe[2]; [1]Department of Biological Sciences, University of Notre Dame, Notre Dame, IN, [2]Hormel Institute, University of Minnesota, Austin, MN

Cytoplasmic dynein is a prominent component of kinetochores from nuclear envelope breakdown to anaphase onset. During prometaphase, dynein is responsible initiating and regulating linkages to microtubules. At metaphase, dynein is responsible for silencing the spindle assembly checkpoint by removing checkpoint proteins from kinetochores through poleward streaming. Polo-like kinase 1 (Plk1) and Aurora B (AurB) are important for both of these processes, so we investigated if they regulated dynein. Inhibition of Plk1 with BTO-1 or analogue-sensitive Plk1 constructs ablated dynein phosphorylation, reduced recruitment of dynein to kinetochores and induced errors in chromosome alignment during prometaphase. Dynein-binding proteins implicated in recruiting kinetochore dynein were not affected. Based on the antagonistic roles of PP1 phosphatases and AurB homologues in yeast, we assessed the requirement for AurB in dynein recruitment. Inhibition of AurB blocked recruitment of dynein to kinetochores. However, the effects on dynein recruitment were indirect. Dynactin, spindly and ZW10 were each reduced after AurB inhibition, whereas zwint-1, Hec1 and Knl1 were not affected. Because the interaction between zwint-1 and ZW10 has been implicated in recruiting the rod-zw10-zwilch (RZZ) complex to kinetochores, we compared phosphorylation of zwint-1 and ZW10 using in vitro kinase assays. Zwint-1 but not ZW10 was phosphorylated by AurB, and a set of three novel AurB phosphorylation sites was mapped in zwint-1 by MS/MS analysis. A 3A zwint-1 mutant blocked recruitment of the RZZ complex and all RZZ-dependent proteins to kinetochores and induced prometaphase arrest. A 3E zwint-1 mutant overcame the effects of AurB inhibition on kinetochore assembly. However, the 3E mutant interfered with dynein-driven removal of checkpoint proteins at metaphase, inducing metaphase arrest. These results suggest that phosphorylation of zwint-1 by AurB is required for assembly of a dynein-binding platform at kinetochores during prometaphase. However, dephosphorylation of zwint-1 at metaphase defines the boundary between stable and streaming proteins implicated in checkpoint silencing. These studies indicate that Plk1 and AurB play critical roles in regulating kinetochore dynein.

1782

Dynamic regulation of kinetochore microtubules by changes in Plk1 activity.

D. Liu[1], O. Davydenko[1], M. Lampson[1]; [1]Biology Department, University of Pennsylvania, Philadelphia, PA

Plk1 (Polo-like kinase 1) is a highly conserved mitotic kinase that regulates multiple processes in cell division. Plk1 localizes to kinetochores and spindle poles but disappears from kinetochores at metaphase. The loss of kinetochore localization as chromosomes align is similar to many mitotic checkpoint signaling proteins, but Plk1 is not required for the checkpoint. Plk1 function at kinetochores and the importance of the localization change are unclear. Here we show that changes in Plk1 activity at kinetochores are critical for regulation of microtubule dynamics. Constitutive targeting of Plk1 to kinetochores suppresses microtubule dynamics and leads to reduction of both intrakinetochore and interkinetochore tension and mitotic arrest. Conversely, prematurely displacing Plk1 from kinetochores slows the initial formation of stable microtubule attachments. Using a FRET-based biosensor, we find that a Plk1 substrate at kinetochores is highly phosphorylated in the absence of microtubules and subsequently dephosphorylated as kinetochore align at metaphase. Our results reveal that kinetochore microtubules are regulated by a dynamic balance between the destabilizing activity of Aurora B and the stabilizing activity of Plk1. Initially, Plk1 activity allows attachments to form even when Aurora B activity at kinetochores is high, and later Plk1 is removed so that microtubules remain dynamic to apply tension and satisfy the spindle checkpoint.

1783

COMA/CENP-H/I/K kinetochore proteins and Aurora B kinase are required to generate the spindle checkpoint.

D. R. Matson[1], P. Demeril[1], D. J. Burke[1], P. T. Stukenberg[1]; [1]Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA

It is currently unclear how kinetochores generate a spindle checkpoint signal and how this is regulated by kinetochore microtubule attachment. Budding yeast cannot generate a spindle checkpoint signal in the presence of unreplicated chromosomes if the Aurora phosphorylation site on Mad3 (Mad3-S337) is mutated, but they can arrest in nocodazole. We have screened for benomyl sensitive mutants in a Mad3(S337A) background to identify proteins required to arrest cells by the putative occupancy branch of the checkpoint. Budding yeast lacking the kinetochore proteins Chl4, Ctf3 and Ctf19 arrest in nocodazole but not if they also contain the Mad3(S337A) mutation. These proteins are members of the COMA complex, which is a large set of conserved kinetochore proteins with unknown functions. The human homologs of the COMA proteins are a recently identified complex containing CENP-N, CENP-H, CENP-I, and CENP-K. We have found that after siRNA knockdown of CENP-N, CENP-H, CENP-I or CENP-K, cells arrest in nocodazole but this arrest is sensitive to low doses of the Aurora B inhibitors ZM447439 or Hesperadin. These cells can arrest in response to taxol. Mad2 binding to kinetochores is lost in cells knocked down of CENP H/I/K. We argue that the COMA/CENP H/I/K proteins have a highly conserved role to generate a spindle checkpoint signal before microtubule attachment and they function in a pathway that is redundant with Aurora B. CENP H/I/K is the first set of proteins implicated in the spindle checkpoint that are not required after microtubule attachment. In addition, it is currently controversial if the Aurora B kinase is required to generate a spindle checkpoint or only to release microtubules from kinetochores. Aurora kinase activity is activated by CENP H/I/K knockdown and cells with completely depolymerized microtubules require Aurora activity to maintain a functioning spindle assembly checkpoint when the CENP H/I/K complex is absent.

1784

Aurora B kinase activation requires PLK1-mediated survivin phosphorylation.

Y. Chu[1], D. Wang[2], W. Wanf[3], Z. Wang[2], L. Zhang[4], X. Yao[5]; [1]Cellular Dynamics, Anhui Laboratory for Cellular Dynamics and Chemical Biology, Hefei, China, [2]USTC, [3]Cell Biology, USTC, [4]Morehouse School of Medicine, [5]University of Science & Technology of China

During cell division, chromosome segregation is orchestrated by the interaction of spindle microtubules with the centromere. Accurate attachment of spindle microtubules to kinetochore requires the chromosomal passenger of Aurora B kinase complex with borealin, INCENP and survivin. The current working model argues that survivin is responsible for docking Aurora B to the centromere whereas its precise role in Aurora B activation has been unclear. Recently, we showed that Aurora B kinase activation requires survivin priming phosphorylation at Ser20 which is catalyzed by PLK1 (Chu et al., 2011. J. Mol Cell Biol.). Inhibition of PLK1 kinase activity or expression of non-phosphorylatable survivin mutant prevents Aurora B activation and correct spindle microtubule attachment. The PLK1-mediated regulation of Aurora B kinase activity was examined in real-time mitosis using fluorescence resonance energy transfer-based reporter and quantitative analysis of native Aurora B substrate phosphorylation. We reason that the PLK1-mediated priming phosphorylation is critical for orchestrating Aurora B activity in centromere which is essential for accurate chromosome segregation and faithful completion of cytokinesis. Currently, we are delineating the spatiotemporal dynamics of Aurora B activity during kinetochore maturation and spindle microtubule attachment error correction.

1785

CDK-dependent potentiation of MPS1 kinase activity is essential to the mitotic checkpoint.

V. Morin[1], S. Prieto[1], S. Melines[1], T. Lorca[1], J. Espeut[1], N. Morin[1], A. Abrieu[1]; [1]CRBM - CNRS, Montpellier, France

Accurate chromosome segregation relies upon a mitotic checkpoint that monitors kinetochore attachment towards opposite spindle poles before enabling chromosome disjunction. MPS1/TTK is a protein kinase essential to this process, but the mechanisms underlying its regulation during mitosis remain elusive. By mass spectrometry, we mapped several phosphorylation sites onto MPS1 and we show that phosphorylation of one site in the non-catalytic region of MPS1 is required for full kinase activity. Strikingly, this phosphorylation potentiates MPS1 catalytic efficiency without impairing its affinity for the substrates. Using Xenopus egg extracts depleted of endogenous MPS1 and reconstituted with single point mutants, we show that phosphorylation of that site is essential to activate the mitotic checkpoint. This phosphorylation does not regulate the localization of MPS1 to the kinetochore, but is required for the recruitment of MAD2, demonstrating its role at the kinetochore. This phosphorylation is not sufficient to prevent the metaphase-to-anaphase transition in the absence of kinetochore-dependent signaling. Nevertheless, this essential phosphorylation of MPS1 is mediated by CDK1 in the cytoplasm independently of the kinetochore. Altogether, this study uncovers a new step of amplification of the checkpoint signal via a CDK-dependent phosphorylation of MPS1.

1786

MPS1 kinase activity is essential for C-MAD2 production and assembly of the mitotic checkpoint complex (MCC).

A. R. Tipton[1], M. E. Bekier II[1], W. Taylor[1], S-T. Liu[1]; [1]Dept. of Biological Sciences, University of Toledo, Toledo, OH

The spindle assembly checkpoint (SAC) is an evolutionarily conserved mechanism that preserves genomic integrity through regulating proper timing of the metaphase-to-anaphase transition during cell division. Closed MAD2 (C-MAD2), one of the two native conformations adopted by the checkpoint protein MAD2, is a well-recognized component of the "wait anaphase" signal generated in response to SAC activation. However, it has been controversial whether MAD2 is an integral component of the mitotic checkpoint complex (MCC), the suggested SAC effector that potently inhibits the anaphase promoting complex/cyclosome (APC/C). We have recently provided strong evidence demonstrating that C-MAD2 (but not the inactive O-MAD2) is indeed incorporated into the MCC. Intriguingly, selective incorporation of C-MAD2 into the MCC arises not only from the previously characterized CDC20:C-MAD2 interaction, but also from a novel direct interaction between C-MAD2 and BUBR1. The C-MAD2:BUBR1 interaction has been observed both *in vitro* and *in vivo*, and is fundamental for both assembly and inhibitory activity of the MCC (Tipton AR et al., JBC, 286:21173). Here we report that MPS1, a classical SAC kinase, functions through regulating MCC assembly, yet appears to have no role in maintaining the stability of pre-assembled MCC. Inhibition of MPS1 kinase prevents MAD2 incorporation into the MCC, simultaneously impairing both CDC20:MAD2 and BUBR1:MAD2 interactions but having no apparent effect on the BUBR1:CDC20 interaction. Strikingly, the impairment caused by MPS1 inhibition can be rescued by expressing a C-conformation locked MAD2 mutant in mitotic cells. C-MAD2 incorporation into the MCC correlates with MCC:APC/C binding, APC/C inhibition and SAC function. We propose a model whereby MPS1 kinase contributes to the SAC through promoting C-MAD2 production and subsequent MCC assembly.

1787

Tpr promotes the formation of the Mad1-cMad2 template required to amplify and sustain spindle assembly checkpoint response.

C. Ferrás[1], N. Schweizer[1], M. Barisic[1], H. Maiato[1,2]; [1]Chromosome Instability & Dynamics, Institute for Molecular and Cell Biology, Porto, Portugal, [2]Faculty of Medicine Unversity of Porto, Porto, Portugal

Translocated promoter region (Tpr) is a highly conserved nuclear pore complex protein involved in nuclear transport. Recently, we and others have uncovered a novel role of human Tpr, and respective orthologs in Drosophila and fungi, in the spindle assembly checkpoint (SAC). This is likely to rely on a functional interaction between Tpr, Mad1, Mad2 and Mps1, however, the precise mechanism remains unknown. By using conformation-specific antibodies here we show that human Tpr promotes the dimerization between Mad1 and the closed conformer of Mad2 (c-Mad2), being rate-limiting in the formation of the Mad1:c-Mad2 template before it reaches the kinetochore. Consistent with this function, Tpr depletion prevented normal Mad1 and c-Mad2 recruitment to nuclear pores, but Mad1 targeting to kinetochores was independent of Tpr. Due to a limited amount (50%) of the Mad1:c-Mad2 template at kinetochores, the conversion of the open-Mad2 (o-Mad2) conformer into new c-Mad2 at the basis of the signal amplification cascade was also compromised. In agreement, Tpr depleted cells exited mitosis faster than normal and were not able to sustain a prolonged SAC response. Importantly, this was independent of the role of Tpr in mRNA transcription/export and rather reflected a role in the stabilization of SAC proteins. Finally, we show that Mps1 spatially regulates Tpr localization

during mitosis, independent of its kinase activity and Mad1:c-Mad2. Overall, our data implicate Tpr in the formation of the Mad1:c-Mad2 template required to amplify and sustain SAC response.

1788

A Role for the KNL1-PP1 Interaction at the Kinetochore in Coupling Microtubule Attachment to SAC Silencing.

J. S. Rosenberg[1], F. R. Cross[1], H. Funabiki[1]; [1]Rockefeller University, New York, NY

Accurate chromosome segregation in mitosis is necessary to ensure that each daughter cell gets a full complement of the genome. This is accomplished by a pair of sister kinetochores on each chromosome attaching to microtubules emanating from opposite poles of the spindle (biorientation). The spindle assembly checkpoint (SAC) inhibits anaphase onset until all kinetochores establish bipolar attachment. A network of protein kinases, localized to centromeres and kinetochore, are required for SAC activation, while phosphatase protein phosphatase 1 (PP1) is required to silence the SAC. We have recently shown that the evolutionarily conserved PP1-binding motif at the N-terminal region of the kinetochore protein KNL1 (Spc105 in budding yeast) is essential for silencing the SAC. However, constitutive PP1-Spc105 interaction alone is insufficient to silence the SAC in the absence of microtubules. While constitutive PP1-Spc105 interaction itself has no impact on cell cycle progression or chromosome segregation, targeting one extra copy of PP1 to Spc105 is detrimental. These results indicate that PP1 activity at the kinetochore must be both finely tuned and coupled to kinetochore-microtubule attachment so that the SAC is silenced only when kinetochores accomplish bipolar attachment. To understand the molecular basis for the coupling, we are currently systematically investigating how the phosphorylation level of different kinetochore proteins is affected by kinetochore-microtubule attachment and the PP1-Spc105 interaction. Furthermore, our preliminary data indicate that the N-terminal region of Spc105 plays an important role for cell proliferation other than its function for PP1 recruitment and SAC silencing. Together, our studies will help understand how phosphorylation and dephosphorylation reactions at the kinetochore are spatiotemporally coordinated with microtubule attachment status for proper SAC signaling.

1789

Structure Function Analysis of the mitotic checkpoint kinetochore protein, Spindly.

D. Kaur[1], G. Chan[1]; [1]Oncology, University of Alberta, Edmonton, AB, Canada

Spindly was shown to recruit dynein to the kinetochore in Drosophila S2 cells and the dynein/dynactin complex in human cells. The dynein/dynactin complex is required for alignment of chromosome during prometaphase and silencing the mitotic checkpoint following the proper attachment of chromosomes by mediating the transport of the checkpoint proteins off the kinetochore. Recruitment of Spindly to the kinetochore is dependent on the RZZ (Roughdeal, Zeste-White10 and Zwilch) complex in Drosophila, C. elegans and human cells. Spindly is localized to kinetochores at prometaphase and once the chromosomes are aligned properly on the metaphase plate, it is translocated to the poles. Little is known about the interactions of Spindly or its mechanism of function. It has been shown that Spindly mediates the mitotic checkpoint signaling by acting as an adaptor between RZZ and the dynein complex but its interacting partners are not yet known. The aim of the study is to characterize the structural and functional domains of Spindly. Spindly consists of two coiled coil domains, which are separated by a conserved spindly box. We have made 18 insertion, 16 truncation, 15 site-directed and 6 phospho Spindly mutants. These mutants were transfected into HeLa cells followed by fluorescence microscopy analysis. The kinetochore localization of Spindly is found to be

dependent on both N and far C-terminal regions, which correspond to the data, published by Barisic et al. Also, we are looking into the potential interacting partners of Spindly using yeast 2-hybrid and pull down assays. We are also interested in how Spindly is recruited to kinetochore by RZZ complex and dynein/dynactin recruitment by Spindly.

1790

Novel Role for a Mitotic Checkpoint Protein in the Termination of Vacuole Inheritance.

R. Yau[1], Y. Peng[2], R. Valiathan[3], T. Wilson[1], L. Weisman[1]; [1]University of Michigan Ann Arbor, Ann Arbor, MI, [2]University of California Berkeley, [3]Wayne State University

The initiation and termination of organelle inheritance is coordinated with the cell cycle. In *Saccharomyces cerevisiae*, organelle specific adaptor proteins in conjunction with the myosin V motor, Myo2, play a key role in this coordination. To date, the best characterized example is vacuole inheritance, where the vacuole specific adaptor, Vac17, attaches the vacuole to Myo2. Regulation of the interaction between Vac17 and Myo2 both initiates and terminates vacuole movement.

Early in the cell cycle, Vac17 is phosphorylated by the cyclin dependent kinase, Cdk1, which promotes its interaction with Myo2 and initiates vacuole movement. Once the vacuole arrives in the bud, Vac17 dissociates from Myo2 and vacuole movement is terminated even though Myo2 continues to move other organelles to different places. We sought to determine the mechanisms that signal the vacuole to detach from Myo2. We found that further post-translational modifications of Vac17 regulate its dissociation from Myo2 and terminate vacuole inheritance.

In a random mutagenesis screen of Vac17 we identified two new phosphorylation sites, Ser222 and Thr240, which are required for the regulated dissociation of Vac17 from Myo2. Moreover, in an EMS mutagenesis screen we identified Dma1, an E3 ubiquitin ligase and spindle positioning checkpoint protein, as a novel regulator of the detachment of the vacuole from Myo2. We found that Dma1 binds specifically to phosphorylated Vac17-T240 but not mutant vac17-T240A. Furthermore, we show that Dma1 localizes to the vacuole and colocalizes with the Myo2/Vac17 vacuole transport complex. Expression of the enzymatically inactive mutant, dma1-I329R, results in the constitutive attachment of Vac17 and the vacuole to Myo2. Together, these results suggest that phosphorylation of Vac17 at Thr240 recruits Dma1 to the vacuole transport complex where Dma1 ubiquitinates an as yet unknown substrate and thus signals the dissociation of Vac17 from Myo2. Dma1 is a mitotic checkpoint protein, therefore it is tempting to speculate that Dma1 coordinates the termination of vacuole movement with mitotic exit.

Signaling Receptors (RTKs and GPCRs)

1791

Thrombin promotes cyclin D1 upregulation and RPE cell proliferation through the activation of Akt.

A. Parrales[1], E. López[1], A. López-Colomé[1]; [1]Neuropatología Molecular, Instituto De Fisiologia Celular, UNAM, Mexico City, Mexico

The retinal pigment epithelium (RPE) forms the outer blood-retina barrier (BRB) and plays an essential role in the survival of retinal neurons and the maintenance of visual function. Proliferative ocular pathologies are characterized by the epithelial-mesenchymal transition, proliferation and migration of RPE cells, eventually, leading to blindness. Existing evidence

suggests that exposure of RPE cells to serum-contained thrombin upon BRB breakdown may be responsible for the development of these diseases.
The serine protease thrombin stimulates growth factor secretion and mitogenic activity in several cell types, acting on a family of protease-activated receptors (PARs 1-4), coupled to G-proteins Gq, Gi/s and G12/13. We have previously shown that thrombin promotes cyclin D1 expression, the progression of cell cycle, and the proliferation of RPE cells. The present study was aimed to identify the molecular mechanism leading to thrombin-induced cyclin D1 expression in RPE.
Results demonstrate that: 1) thrombin stimulates Ser 473 Akt phosphorylation without affecting Thr 308 basal phosphorylation; 2) thrombin-induced Akt activation indirectly promotes cyclin D1 accumulation through the phosphorylation/inhibition of GSK-3β, which prevents cyclin D1 phosphorylation, nuclear export and degradation; 3) Akt signaling requires the upstream activation of PLC and PI3K. Since pharmacological inhibition of these pathways or the silencing of cyclin D1 expression prevent proliferation, these results contribute potential information for preventing the development of proliferative eye diseases. This work was partially supported by Grants IN228203 (PAPIIT, U.N.A.M) and CB-80398 (CONACyT) to A.M.L.C.

1792

ARRDC2: a Human Arrestin-Related Protein with a Potential Role in Cargo Protein Trafficking within the Endo-Lysosomal System.

D. Lake[1], N. Holliday[1], S. Dawson[1]; [1]School of Biomedical Sciences, University of Nottingham, Nottingham, United Kingdom, Nottingham, United Kingdom

β-Arrestins are essential adaptors for G-protein coupled receptor (GPCR) trafficking. Recently, arrestin-related proteins have been identified in yeast/fungi that, similar to β-arrestins, recognise cargo proteins and mediate their intracellular trafficking. In mammals, five largely uncharacterized arrestin domain-containing (ARRDC) proteins display a predicted arrestin fold; here we focus on human ARRDC2. Confocal microscopy was used to determine the subcellular localization of ARRDC2. In cultured cells (osteosarcoma; U2OS) transiently transfected fluorescent protein-tagged ARRDC2 localized to punctate vesicular structures throughout the cytoplasm and the plasma membrane (PM). ARRDC2 puncta colocalized with late endosomal/lysosomal markers (Rab7, Lamp1, LysoTracker) but not early/recycling endosomal markers (Rab5, EEA1, transferrin, Rab11). However, overexpression of constitutively active Rab5 or Rab7 mutants (commonly used to block transport through early or late endosomes, respectively) resulted in ARRDC2 accumulation within Rab mutant-positive endosomes. These data suggested that ARRDC2 predominantly localizes to late endosomes/lysosomes, but may also be dynamically distributed throughout the endocytic system. Biochemical studies were next used to investigate ARRDC2 interactions with potential trafficking related partners. ARRDC2 coimmunoprecipitated with several members of the homologous to E6-AP C-terminus (HECT) E3 ligase family. These included WW domain-containing ubiquitin protein ligase-1 (WWP1) which, when coexpressed with ARRDC2 and imaged by confocal microscopy, changed from a diffuse cytoplasmic distribution to a more punctate pattern that colocalized with ARRDC2. ARRDC2 contains two proline-proline-x-tyrosine (PY) motifs that we hypothesized might bind WW domains in the HECT ligases. Accordingly, mutation of both ARRDC2 PY motifs (ARRDC2ΔΔ) abolished the interaction detected with one of the ligases, NEDD4-like ubiquitin protein ligase-1 (NEDL1), and ARRDC2ΔΔ was no longer able to induce WWP1 redistribution. Coimmunoprecipitation was also used to detect basal ubiquitination of ARRDC2; this was unaltered in ARRDC2ΔΔ implying that ARRDC2 ubiquitination is not dependent upon ARRDC2-HECT ligase interaction. Interestingly, ARRDC2 also coimmunoprecipitated with itself and β-arrestin2, suggesting that the purported ability of β-arrestins to oligomerize may also extend to the ARRDC proteins. In conclusion, we have identified ARRDC2 as a human arrestin-related

protein localized to the endo-lysosomal system. The distant homology of ARRDC2 to β-arrestins, ARRDC2 interaction with multiple E3 ubiquitin ligases, and the potential for ARRDC2 to homo-/hetero-oligomerize with itself and β-arrestins, collectively point towards a potential role for ARRDC2 in cargo protein trafficking that merits further investigation.

Melanin-concentrating hormone receptor signaling is sensititve to both β-Arrestin levels and Caveolae.

J. I. Moden[1], L. D. Field[1], K. M. Haude[1], R. T. Carroll[1], L. B. Cook[1]; [1]Biology, The College at Brockport, SUNY, Brockport, NY

The melanin-concentrating hormone signaling pathway is a candidate in the pharmacological treatment of eating and appetite disorders. G protein-coupled receptors for MCH are expressed in the central nervous system and peripheral tissues such as the pancreas and adipose tissue. Unfortunately, little is known about how these receptors signal and desensitize. Investigations by other groups point to clathrin-mediated endocytosis as a desensitization mechanism for MCHR1, however our initial observations of little to no visible internalization of MCHR1 in BHK570 cells led us to question this conclusion. We began with measurements of VSVg-tagged MCHR1 surface levels following timed MCH treatments by cell-based ELISA. This resulted in barely 15% of MCHR1 internalizing following 30 min agonist exposure; which was undetectable by fluorescence microscopy. We next co-transfected GFP β-arrestin 1 or β-arrestin 2 to see if the potential for MCHR1 internalization existed and indeed we observed up to 40% loss of surface receptor via both methods. Overexpression of GRK2 resulted in a partial recovery while dominant-negative GRK2 had no effect. Therefore MCH signaling is influenced by the levels of both arrestins and GRK2. We have previously identified caveolae as a potential mediator of MCH signaling and our working hypothesis is that these membranes act to enhance MCH signaling in some cell types. We previously reported pharmacological depletion of cholesterol decreases, but does not eliminate ERK1/2 phosphorylation by MCH in CHO cells. In this study we also reaffirm co-localization of MCHR1 in caveolar membranes biochemically by several different extraction methods and begin to explore the effects of its depletion on MCH-signaling. For example, MCH-mediated activation of a leptin promoter is enhanced in cells expressing a RNAi-plasmid targeting Cav-1, which specifically depletes caveolae. While this seems contradictory, it may signify differences in the regulation of MCHR1 by membrane microdomains for short- and long-term signaling events. Future experiments will extend these studies into an adipocyte cell culture model with variable caveolae membrane content depending upon differentiation state.

G Protein-Coupled Receptor Kinases 2 and 3 Regulate CCR7 Internalization.

C. T. Winebrenner[1], K. H. Overbey[1], C. A. Bill[1], L. J. Kilgore[1], H. D. Cunningham[2], C. M. Vines[1]; [1]Microbiology, Molecular Genetics & Immunology, Univ Kansas Med Ctr, Kansas City, KS, [2]Internal Medicine, Univ Kansas Med Ctr, Kansas City, KS

C-C chemokine receptor 7 (CCR7) targets migration of T cells to the lymph nodes. While the two known agonists for CCR7, CCL19 and CCL21, internalize to differing extents, the underlying molecular mechanisms regulating CCR7 internalization and downstream signaling in T cells to control migration, remain largely undefined. G protein coupled receptor kinases (GRKs) can regulate receptor internalization, and their functions are largely dependent upon the relative levels that are expressed in different cells. To characterize the roles of GRKs in the internalization of CCR7 in T cells, we used wild type (WT), GRK2+/- and GRK3-/- primary murine cells. Unlike WT murine T cells that internalized only ~38% of CCR7/CCL19 and failed

to internalize CCR7/CCL21, we found that GKR2+/- T cells internalized ~57% of CCR7 in the presence of either ligand. In contrast, GRK3-/- cells failed to internalize CCR7 independent of ligand. To determine if the levels of GRKs expressed control CCR7 internalization we used HEK293T cells to titrate GRK2-GFP or GRK3-GFP levels and assayed for CCR7 internalization. We found that low levels of GRK2 promoted CCR7 internalization, while higher levels stabilized CCR7 surface expression. Expression of GRK3 promoted CCR7 internalization. We characterized the effect of GRK2 on T cell migration and found that while WT murine T cells migrated to both CCR7 ligands, GRK2+/- cells migrated only in the presence of CCL19 and GRK3-/- cells failed to migrate independent of ligand. Taken together, these results indicate that the agonist-induced internalization and downstream signaling which controls T cell migration via CCR7 is regulated by GRK2 and GRK3.

1795

Dependence of the mating pathway on components of the Gpr1p-mediated glucose sensing pathway in *Saccharomyces cerevisiae.*

J. Brigati[1], D. G. Willhite[2], J. R. Carter[1], J. Hoover[1], S. O'Brien[1], K. Selcer[1], S. Wright[3]; [1]Maryville College, Maryville, TN, [2]Tennessee Weslyan College, [3]Carson-Newman College

Haploid strains of *Saccharomyces cerevisiae* express two unique GPCRs, a pheromone receptor (Ste2p or Ste3p) and a glucose sensor (Gpr1p). GPCR-mediated pathways in other organisms have been found to interact with one another either through direct contact between the GPCRs or through interactions between downstream elements. This research focused on identifying the components of the Gpr1p-mediated glucose sensing pathway required for full activation of the pheromone sensing pathways in Mata and Matα *S. cerevisiae*. To achieve this, the ability of strains lacking various components of the Gpr1p-mediated glucose-sensing pathway to undergo growth arrest and shmooing in response to α-factor, mate with wild-type cells, and activate fus1 transcription was determined. Mating efficiency is significantly reduced in Mata cells lacking Gpr1, Gpa2, Plc1, Asc1, Gpb1, and Gpb2, all of which encode components of the Gpr1p-mediated glucose sensing pathway. Preliminary data indicates that Mata strains lacking components of the Ras signaling pathway also had reduced mating efficiency. Preliminary data also indicates that Matα strains lacking Gpa2 and Gpr1 have reduced mating efficiencies compared to wild-type cells. In many of the Mata strains examined, including strains lacking Gpr1 and Gpa2, shmoo formation and growth arrest in response to α-factor were not depressed to the same degree as mating efficiency, narrowing down the possible mechanisms by which glucose-sensing impacts mating efficiency. In addition, a Fus1-lacZ assay was used to demonstrate that deletion of Gpr1 in Mata cells reduces expression of Fus1, and addition of Gpr1 on a plasmid can restore fus1 expression to wild-type or higher levels. Overexpression of Gpr1 in wild-type cells leads to increased expression of Fus1. Together, these data indicate that components of the Gpr1p pathway are required for proper function of the Ste2p and Ste3p pathways

1796

Heat Shock Analysis of the Interdependency of Pheromone and Glucose Sensing G-Protein Coupled Receptor Pathways in *Saccharomyces cerevisiae.*

Z. A. Duck[1]; [1]Biochemistry, Carson-Newman College, Jefferson City, TN

In *Saccharomyces cerevisiae*, the G-protein coupled receptors (GPCR) Gpr1p and Ste2p/Ste3p are known to initiate signaling through two separate pathways, the glucose sensing pathway and pheromone sensing pathway, respectively. One known role of the glucose-sensing pathway is to cause the cell to exhibit an increased sensitivity to heat shock when introduced to high concentrations of glucose after a period of starvation. The pheromone-sensing pathway does

not share this characteristic. However, research in our lab has indicated that disruption of the Gpr1 pathway negatively affects mating in Mat**a** cells. In an attempt to determine if the reciprocal effect might be present, mutants of Matα and Mat**a** cells lacking components of the pheromone pathway were assayed for their sensitivity to heat. The results show that Matα cells exhibit no increased resistance to heat shock when the components of the pheromone-sensing pathway are removed, because the relative survival of cells after heat shock is approximately equal to the relative survival of wild type cells. On the other hand, Mat**a** cells can exhibit between a 5 to 25-fold increase in relative survival or resistance to heat shock when components such as STE2, STE4, STE5, STE7, STE11, STE18, and FUS3 are removed from the pheromone-sensing pathway. These results support the hypothesis that in Mat**a** cells (but not Matα cells) there is a connection between the components of the pheromone and glucose sensing pathways that directly affects the cell's response to heat shock in the presence of glucose. The interaction point between the two pathways is certainly crucial in regard to the heat shock stress response and, thus, is likely to play an important role controlling the many additional functions that each GPCR pathway executes.

1797

CNP-1 (ARRD-17), a novel substrate of calcineurin, is critical for modulation of egg laying and locomotion in response to food, and lysine sensation in Caenorhabditis elegans.

C. Jee[1], T-W. Choi[2], K. Kalichamy[2], H-O. Song[3], J. Z. Yee[2], Y. J. Ji[1], J. Lee[5], J. Lee[1], N. L¡ÇEtoile[4], J. Ahnn[2], S-K. Lee[5]; [1]Life Science, GIST, Korea, [2]Life Science, Hanyang University, [3]Medicine, Wonkwang University, [4]Center for Neuroscience, University of California, Davis, [5]Hanyang University, Seoul, Korea

CNP-1 (ARRD-17), a novel substrate of calcineurin, is critical for modulation of egg laying and locomotion in response to food, and lysine sensation in *Caenorhabditis elegans.*
Calcineurin is a Ca^{2+}/calmodulin-dependent protein phosphatase involved in calcium signaling pathways. In *Caenorhabditis elegans*, the loss of calcineurin activity, causes pleiotropic defects including hyperadaptation of sensory neurons, hypersensation to thermal difference and hyper-egg-laying when worms are re-fed after starvation. In this study, we report on *arrd-17* as *calcineurin interacting protein-1* (*cnp-1*), which is a novel molecular target of calcineurin. CNP-1 interacts with the catalytic domain of the *C. elegans* calcineurin A subunit, TAX-6, in a yeast two-hybrid assay, and is dephosphorylated by TAX-6 *in vitro*. *cnp-1* is expressed in ASK, ADL, ASH and ASJ sensory neurons as TAX-6. It acts downstream of *tax-6* in regulation of locomotion and egg-laying after starvation, and lysine chemotaxis, which is known to be mediated by ASK neurons. Altogether, our biochemical and genetic evidence indicates that CNP-1 is a direct target of calcineurin and required in stimulated egg-laying and locomotion after starvation, and attracts to lysine, which is modulated by calcineurin. We suggest the phosphorylation status of CNP-1 plays an important role in regulation of re-fed stimulating behaviors after starvation and attraction to amino acid, which provides valuable nutritious information.

Key Words: calcineurin, CNP-1, ARRD-17, ASK

Constitutive Activity of Orphan G Protein Coupled Receptors.

A. L. Martin[1], K. Z. Williams[1], H. L. Chambers[1], R. A. Reichard[1], E. K. Shannon[1], H-J. Wang[1], A. G. Martin[1], R. S. Aronstam[1]; [1]Biological Sciences, Missouri University of Science & Technology, Rolla, MO

Constitutive signaling in the absence of an activating ligand has been reported in over 60 members of the G-protein coupled receptor family (GPCRs). The signaling pathways of orphan GPCRs are difficult to characterize because their native activators are unknown, a limitation that can be partially overcome when the receptors exhibit constitutive activity. Thirty-six Class-A orphan GPCRs were screened for constitutive activity using luciferase coupled reporter vectors. Orphan GPCRs and reporter plasmid pairs were transiently co-transfected into CHO-K1 cells (40,000 cells in 96-well plates) and grown for 24 hours before measuring luciferase expression. Experiments were performed three times in quadruplicate. Receptor constitutive activity was reflected by induction of luciferase expression under the control of either the cAMP response element (CRE) or the Nuclear Factor of Activated T-Cell response element (N-FAT). Gαs pathway activity increased expression under control of the CRE promoter; Gαi pathway activity inhibited forskolin-induced expression under control of the CRE promoter; Gαq/11 pathway activity increased expression under control of the calcium-sensitive NFAT promoter. Most of the orphan receptors (86%; 31 of 36) exhibited some form of constitutive activity: 31% of the receptors more than tripled CRE mediated expression through the Gαs pathway; 64% of the receptors inhibited (by more than 50%) forskolin-induced CRE mediated expression through the Gαi pathway; and two receptors more than doubled N-FAT mediated expression through the Gαq pathway. Seven of the receptors increased signaling through both the Gαs and Gαi pathways (i.e., both increased CRE mediated expression over baseline and decreased forskolin-stimulated CRE mediated expression). Interestingly, 8 receptors increased Gαi signaling while decreasing basal CRE and N-FAT mediated expression. These findings suggest that constitutive activity plays a prominent role in the physiological activities of the majority of orphan GPCRs.

1799

A Novel Mechanism of Signal Transduction: Oxytocin Receptors Activated by the Ligand Translocate in the Nucleus to Enhance Osteoblast Transcription.

A. Di Benedetto[1], G. Colaianni[1], R. Tamma[1], C. Cuscito[1], S. Dell'Endice[1], B. Nico[1], B. Chini[2], D. Calvano[3], C. Zambonin[3], L. Sun[4], M. Zaidi[4], A. Zallone[1]; [1]Human Anatomy and Histology, University of Bari, Bari, Italy, [2]Neuroscience, CNR Milano, [3]Chemistry, University of Bari, [4]Mount Sinai School of Medicine

Oxytocin (OT), acts through a seven-transmembrane G-protein coupled receptor OTR, and exert a direct anabolic effect on bone (Tamma et al., 2009) upregulating the expression of osteoblast markers and transcription factors as Osterix, Schnurri 2 and 3, Atf-4, Osteocalcin and Osteopontin. OT or OTR null mice develop by the time a reduced bone mass ascribable to a low turnover osteoporosis. OTRs are activated by OT signal through Gq/11, but we unexpectedly found after OT stimuli (15-30') OTRs largely relocated in osteoblast nuclei as identified by western blot analysis of cytoplasmic and nuclear extracts. These results were confirmed by immunogold identification of OTR in osteoblasts nucleus with TEM and by confocal immunofluorescence studies. Thus we asked two questions 1) how a GPCR receptor is transported to nuclei and 2) to do what.

Results 1) Within 2-3 min from OT treatment in primary osteoblasts OTRs were colocalized with â-arrestin1/2, thereafter, after â-arrestins detachment, were found colocalized with rab5 in the early endosomal compartment. Eventually the vesicles were taken in charge by transportin-1

and sorted to the nuclei. All these data were obtained by confocal microscopy of OTR-GFP in fixed and in living cells. MALDI-TOF analysis, was performed on nuclear proteins immunoprecipitated with anti-OTR 30' after OT treatment and revealed the presence of four peptides corresponding to OTR intracellular loops, further giving strong evidence of OTR nuclear localization.
Results 2) â-arrestin1/2 and Transportin-1 silencing in osteoblasts not only affected OTR nuclear localization but prevented OT induced up-regulation of several genes as ATF-4,Osterix and osteocalcin. Immunoprecipitation of OTR or the osteoblast transcription factor Runx2, and the transcription co-activator Schnurri-2 from nuclear lysates after OT treatment, demonstrated that the three proteins immunoprecipitated together. Furthermore an OTR/Smad-4 interaction was also found when osteoblasts were simultaneously stimulated with OT and BMP2. A molecular analysis of the receptor protein sequence led us to identify three putative nuclear localization sequence (NLS) in the first and second loop of OTR, and in the C-terminal tail. Surprisingly, however, the deletion of any NLS did not block its nuclear localization, suggesting that OTR translocation could be mediated by OTR-another associated protein as Schnurri-2, or Smad-4.
Conclusion. Some OT anabolic effects on osteoblast activities are mediated by a novel mechanism involving OTR nuclear interaction with the BMP-2/ Runx2 pathway with a positive regulatory effect.

Single molecule studies reveal insights on the nature of constitutively activated HER2 on living cells.

I. Chung[1], R. Akita[1], L. Shao[1], G. Schaefer[1], M. Sliwkowski[1], I. Mellman[1]; [1]Research Oncology, Genentech, Inc, S San Francisco, CA

HER2 is a highly active kinase that is distinguished from the other HER family members in that no ligand has been identified to directly bind the receptor. Although HER2 can be trans-activated by forming complexes with other receptors, it exhibits constitutive activation when it is over-expressed. This ligand-independent activation plays an important role in driving the growth of HER2 amplified tumors. To gain further mechanistic understanding of the constitutive HER2 activation, we performed single molecule tracking studies of HER2 and its mutants, also further developing new analyses tools. From these studies, we found that activation of HER2 is less regulated by the structural features of its ectodomain than for EGFR as we previously demonstrated. Rather, HER2 activation may be largely related to its density, which in turn is affected by its interaction with membrane compartments. Indeed, we found that the variation in local HER2 densities is associated with HER2 phosphorylation. It appears that some of the membrane compartments modulating HER2 density and activation of the receptor are cholesterol rich regions. Alteration of the cholesterol content of the membrane changed the diffusion behavior and distribution pattern of HER2 and its phosphorylation status. We are now examining how these HER2 density changes might affect tumor cell responsiveness to trastuzumab.

1801

ErbB1 Dimerization is Promoted by Domain Co-confinement and Stabilized by Ligand-binding.

D. S. Lidke[1], S. T. Low-Nam[2], K. A. Lidke[3], P. Cutler[2], R. Roovers[4], P. van Bergen en Henegouwen[4], B. S. Wilson[2]; [1]Pathology, University of New Mexico, Albuquerque, NM, [2]Pathology, University of New Mexico, [3]Physics, University of New Mexico, Albuquerque, NM, [4]Biology, Utrecht University

Ligand-induced signaling by the epidermal growth factor receptor (EGFR/HER1/erbB1) drives cell growth and survival, with roles in normal development and disease pathogenesis. A wealth of structural knowledge supports a model of signal initiation through the formation of back-to-back erbB1 dimers. However, the size and ligand-occupancy of the erbB1 signaling complex remains controversial.

Imaging technologies and biological tools have developed to a point where many fundamental biological questions can now be addressed at the molecular level. In particular, single particle tracking (SPT) using bright and photostable quantum dots (QDs) provides information about protein dynamics with high spatial (~10 nm) and temporal (>30 Hz) resolution. We used two-color QD tracking to directly visualize erbB1 homodimerization and determine the dimer off rate on living cells. Kinetic parameters were extracted using a 3-state Hidden Markov Model to identify transition rates between free, co-confined, and dimerized. We report that erbB1 homodimers composed of two ligand-bound receptors are long-lived and their off rate is independent of kinase activity. By comparison, unliganded erbB1 homodimers have >4-fold faster off rates. These results unequivocally link ligand occupancy to dimer stability. Transient co-confinement of receptors by the actin cytoskeleton is shown to promote repeated encounters, enhancing dimer formation. Mobility decreases when ligand-bound receptors form dimers. Inhibition of erbB1 kinase activity or disruption of the actin cytoskeleton results in faster diffusion of receptor dimers. These results implicate both signal propagation and the cortical cytoskeleton in reduced mobility of signaling-competent erbB1 dimers.

1802

Regulation of EGFR Degradation by Ankyrin105.

Z. Li[1], D. Anderson[2]; [1]University of Saskatchewan, Saskatoon, SK, Canada, [2]Saskatchewan Cancer Agency, Saskatoon, SK, Canada

Growth factors can regulate a variety of cellular processes, including cell growth, proliferation, differentiation, survival and migration, by activating receptors on the cell surface. Many of the receptors belong to the receptor tyrosine kinase (RTK) family, such as platelet-derived growth factor receptor (PDGFR), epidermal growth factor receptor (EGFR) and its related family members (e.g. ErbB2). Activated RTKs are rapidly endocytosed. Most of them are recycled back to the cell surface and only a small fraction may be diverted to late endosome and lysosome for degradation. Continuously activated RTKs and downstream signaling pathways (PI3K/Akt and Ras/MAPK pathways) are frequently observed in cancer cells. Therefore, understanding the degradation mechanism of receptors is important and may facilitate the development of new prognostic or treatment strategies. Ankyrin105 (Ank105) is the smaller isoform of Ankyrin3, and is localized to late endosomes and lysosomes. Our lab has previously shown that Ank105 can stimulate degradation of PDGFR and thus reduce its signaling. To determine whether Ank105 can induce degradation of multiple RTKs similarly, we have now extended these studies to EGFR and its signaling. We introduced HA-tagged Ank105 into several cell lines that endogenously express EGFR, and carried out EGF stimulation time courses. Cell lysates were immunoblotted with antibodies specific for phosphotyrosine, EGFR

and downstream signaling proteins to test if Ank105 expression affects the degradation kinetics of EGFR. Interestingly, some cell types were susceptible to Ank105 facilitated EGFR degradation whereas others were not. These studies will improve our understanding of how Ank105 affects EGFR degradation.

1803

Mechanisms of EGF receptor internalization.

A. Fortian[1], L. K. Go[2], A. Sorkin[1]; [1]Department of Cell Biology and Physiology, School of Medicine, University of Pittsburgh, Pittsburgh, PA, [2]Department of Pharmacology, School of Medicine, University of Colorado Denver, Aurora

Endocytosis is the major regulator of epidermal growth factor receptor (EGFR) signaling. However, the molecular mechanisms of EGFR endocytosis through clathrin coated pits remain to be poorly understood. We have recently demonstrated that clathrin-dependent internalization of activated EGFR is regulated by multiple redundant and partially interdependent mechanisms. Mutations of 21 lysines, that are modified by ubiquitination and acetylation, together with mutations of AP-2 binding motifs yielded the first internalization-defective EGFR mutant, 21KRΔAP2, with functional kinase and normal tyrosine phosphorylation. To define the mechanism of residual internalization of 21KRΔAP2, siRNA analysis was performed in human adenocarcinoma HuTu-80 cells lacking endogenous EGFR. Knock-down of clathrin heavy chain and dynamin strongly inhibited internalization of 21KRΔAP2 indicating that this mutant is internalized via clathrin coated pit pathway. This conclusion is also supported by partial inhibition of the 21KRΔAP2 mutant endocytosis by depletion of FCHo1, FCHo2 or CALM, proteins involved in the general clathrin-dependent endocytic process. As in the case of wild-type EGFR, internalization of the 21KRΔAP2 was strongly inhibited by siRNA knock-down of the Grb2 adaptor protein. Because Grb2 is known to mediate receptor ubiquitination, we first tested whether Grb2 role in 21KRΔAP2 endocytosis is ubiquitination-independent by depleting Grb2-binding protein Tom1L, that has been previously implicated in EGFR internalization by others. However, Tom1L depletion did not affect internalization of wild-type and 21KRΔAP2 mutant EGFRs. Surprisingly, depletion of the E2 ubiquitin-conjugating enzyme UbcH5b/c strongly inhibited internalization of the 21KRΔAP2 mutant, suggesting that the ubiquitination reaction is involved, despite that the mutant is not ubiquitinated. Moreover, knockdown of the E3 ubiquitin ligase c-Cbl also decreased EGF internalization rates in HuTu80 cells. Based on these results we hypothesize that in the absence of lysine residues and AP-2 binding motifs in the EGFR, the receptor is still internalized by means of Cbl/UbcH5 dependent ubiquitination of a protein associated with the receptor.

1804

Determining if spatio-mechanosensitivity of EphA2 signaling stems from physical impedance of endocytosis.

A. C. Greene[1,2], S. J. Lord[2], I. J. Lee[1,2], J. T. Groves[2,3]; [1]Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, [2]Howard Hughes Medical Institute, Department of Chemistry, UC Berkeley, Berkeley, CA, [3]Physical Biosciences and Materials Sciences Divisions, Lawrence Berkeley National Laboratory, Berkeley, CA

We recently found that the spatial organization of the receptor tyrosine kinase EphA2 plays a key role in signal transduction in breast epithelial cancer cells. Upon stimulation from its native ligand ephrinA1 bound to a supported lipid membrane, EphA2 is spatially reorganized into large clusters at the junction between the cancer cell and supported membrane. Using the spatial mutation technique, in which nanopatterned structures on the supported membrane substrate impose physical restrictions to movement of EphA2-ephrinA1 clusters, alterations in

downstream signaling events as a function of EphA2 organization were discovered. In particular, recruitment of the disintegrin and metalloprotease 10 (ADAM10) to the clusters is inhibited. ADAM10 has been implicated in the cleavage and subsequent endocytosis of other ephrin ligands, and may play a role in the endocytosis of EphA2-ephrinA1. Here we report that dynamin2, a large GTPase involved in the scission of endocytic vesicles, is recruited to the EphA2-ephrinA1 clusters. Preliminary evidence suggests that clathrin-mediated endocytosis (CME) is involved in the initial endocytosis of EphA2-ephrinA1. Finally, we have also found that the function of ADAM10 is necessary for ephrinA1 endocytosis. The implications of these observations for spatial regulation of EphA2 signaling will be discussed.

1805

Internalization and traffic of the macrophage colony stimulating factor receptor.

J. Lou[1], J. Lin[1], A. D. Hoppe[1]; [1]Chemistry & Biochemistry, South Dakota State University, Brookings, SD

Macrophage colony stimulating factor receptor (MCSFR aka CSF-1R) is essential for normal development and function of macrophages. Additionally, hyper activaiton of the MCSFR is involved in various leukemias. Here, we define the endocytic trafficking and down-modulation pathways of the MCSFR in a bone marrow derived macrophage model. To visualize the MCSFR endocytosis and traffic, we developed Texas Red labeled rhMCSF (TXR-rhMCSF). Additionally, live cell fluorescent microscopy and immunostaining were used to define the transport and degradation of the receptor. Through the use of inhibitors, we show that activated MCSFR complexes are internalized exclusively by clathrin mediated endocytosis. The vesicles containing the MCSFR undergo sequential maturation from nascent clathrin coated vesicles, to Rab5-positive early endosomes, to Rab7-positive late endosomes whereupon the receptor is packaged into multivescular bodies and finally to fuses with lysosomes for degradation.

1806

Honokiol blocks store operated calcium entry in CHO cells expressing the M3 muscarinic receptor.

A. G. Martin[1], H-J. Wang[1], R. A. Reichard[1], P-K. Chao[2], E. K. Shannon[1], A. L. Martin[1], Y-W. Huang[1], M-H. Chang[3], R. S. Aronstam[1]; [1]Biological Sciences, Missouri University of Science & Technology, Rolla, MO, [2]Life Science, National Taiwan Normal University, Taipei, Taiwan, [3]Pharmacology, Tzu Chi University, Hualien, Taiwan

Honokiol, a cell-permeable phenolic compound derived from the bark of magnolia trees and present in Asian herbal teas, has a unique array of physiological actions, including the inhibition of multiple autonomic responses. In excitable tissues, honokiol displays antioxidative actions and a depression of glutamate-receptor and calcium mediated signaling. In this study, we determined the effects of honokiol on calcium signaling underlying transmission mediated by human M3 muscarinic receptors expressed in Chinese hamster ovary (CHO) cells. Receptor binding was determined in radiolabelled ligand binding assays using [3H]N-methylscopolamine ([3H]MS); changes in intracellular calcium concentrations were determined using a fura-2 ratiometric imaging protocol; cytotoxicity was determined using a dye reduction assay. Activation of M3 muscarinic receptors with carbamylcholine induced a biphasic increase in [Ca2+]i: an initial, IP3-mediated release of Ca2+ from endoplasmic reticulum stores followed by a sustained phase of steady Ca2+ entry (i.e., store operated calcium entry, SOCE). Honokiol had a potent (EC50 ≈ 5 μM) inhibitory effect on store operated calcium entry (SOCE) that was induced by the activation of the M3 receptors. SOCE was further examined by acute exposure to thapsigarin (2 μM) in a calcium-free medium, followed by reintroduction of external calcium. Again, SOCE was severely depressed by honokiol. This effect of honokiol on SOCE was

specific, rapid and partially reversible, and was seen at concentrations not associated with cytotoxicity, inhibition of IP3 receptor-mediated calcium release, or depletion of ER calcium stores. Moreover, honokiol did not disrupt the ligand binding properties of M3 receptors as reflected in [3H]MS binding affinity, agonist binding affinity, or allosteric receptor interactions. It is likely that an inhibition of SOCE contributes to honokiol disruption of parasympathetic motor functions, as well as many of its beneficial pharmacological properties.

1807

Critical role of farnesoid X receptor (FXR) for hepatocellular carcinoma cell proliferation.

T. Fujino[1], A. Takeuchi[1], H. Ito[1], R. Sakamaki[1], J. Sato[1], Y. Furusato[1], K. Kikugawa[1], M. Hayakawa[1]; [1]School of Pharm, Tokyo Univ. of Pharm. & Life Sci., Hachioji, Japan

Farnesoid X receptor (FXR) is a bile acid-activated nuclear receptor mainly expressed in liver. FXR was originally identified as a pivotal factor maintaining bile acid homeostasis, and has been recently shown to be a critical factor required for liver regeneration. The elucidation of the mechanism how FXR controls the proliferation of hepatocellular carcinoma cells is useful to establish the novel types of therapy applicable for liver cancer. Here we show that FXR plays a crucial role in the proliferation of human hepatocellular carcinoma cell line, HepG2. The treatment of HepG2 cells with FXR siRNA elevates the level of p16/INK4a expression resulting in the inhibition of cell proliferation. By contrast, FXR activation in HepG2 cells treated with the synthetic FXR ligand GW4064 reduces p16/INK4a expression and stimulates the cell proliferation. Hepatocyte nuclear factor 4 alpha (HNF4alpha), a nuclear receptor which plays a key role in regulating the expression of metabolic genes in various tissues, is known to be involved in p16/INK4a expression. Since it has been known that knockdown of HNF4alpha stimulates p16/INK4a expression, we have examined whether or not knockdown of FXR or FXR activation alters the HNF4alpha expression. In fact, knockdown of FXR downregulates p16/INK4a expression while FXR activation stimulates it, suggesting that p16/INK4a expression is regulated by FXR in HNF4a-dependent manner. The ectopic expression of the active form of Ras that causes strong activation of extracellular signal-regulated kinase (ERK) leads to the decrease in FXR expression, suggesting that FXR expression is negatively regulated via Ras/ERK pathway. In addition, FXR level is drastically lowered in HepG2 cells treated with hepatocyte growth factor (HGF), whereas it is restored in HGF-stimulated cells pretreated with the MEK inhibitor U0126. These results indicate that HGF downregulates FXR through the activation of ERK. In this study, we have suggested a novel mechanism by which hepatocellular carcinoma cell proliferation is regulated: FXR stimulates cell proliferation by suppressing the p16/INK4a expression whereas Ras/ERK pathway downregulates the FXR expression, leading to the suppressed proliferation of HepG2 cells.

Differential regulation of CIDEA and CIDEC expression by insulin via Akt1/2- and JNK2-dependent pathways in human adipocytes.

M. Ito[1], M. Nagasawa[1], N. Omae[1], T. Ide[1], Y. Akasaka[1], K. Murakami[1]; [1]Discovery Research Laboratories, Kyorin Pharmaceutical Co. Ltd., Nogi-machi, Japan

White adipose tissue (WAT) is a key organ for energy homeostasis. Excessive lipid accumulation of WAT in obesity contributes to severe diseases, such as type 2 diabetes, hypertension, cardiovascular and kidney diseases, and several types of cancer. WAT mass is determined by the number and size of adipocytes regulated by cell differentiation, apoptosis, and lipid droplet formation. Both insulin and the cell death-inducing DNA fragmentation factor-α-like effector (CIDE) family play important roles in apoptosis and lipid droplet formation, and are closely related to energy balance and obesity. Previously, we reported that CIDEA and CIDEC

are differentially regulated by insulin and contribute separately to insulin-induced anti-apoptosis and lipid droplet formation in human adipocytes. However, the upstream signals of CIDE proteins remain unclear. Here, we investigated the signaling molecules involved in insulin regulation of CIDEA and CIDEC expression, and analyzed apoptosis and lipid droplet formation. Gene expression analysis was performed by quantitative real-time PCR. Analyses of apoptosis and lipid droplet formation were performed by fluorescence microscopy of adipocytes stained with TUNEL, Nile Red, and/or DAPI. The phosphatidylinositol 3-kinase (PI3K) inhibitors wortmannin and PI-103 blocked both insulin-induced downregulation of CIDEA and upregulation of CIDEC. The Akt inhibitor API-2 and the c-Jun N-terminal kinase (JNK) inhibitor SP600125 selectively inhibited insulin regulation of CIDEA and CIDEC expression, respectively, whereas the MAPK/ERK kinase inhibitor U0126 and the p38 inhibitor SB203580 did not. Small interfering RNA-mediated depletion of Akt1/2 prevented insulin-induced downregulation of CIDEA and inhibition of apoptosis. Depletion of JNK2, but not JNK1, inhibited insulin-induced upregulation of CIDEC and lipid droplet enlargement. Furthermore, insulin increased both Akt and JNK phosphorylation, which was abrogated by the PI3K inhibitors. These results suggest that insulin regulates CIDEA and CIDEC expression via PI3K, and it regulates expression of each protein via Akt1/2- and JNK2-dependent pathways, respectively, in human adipocytes. The identification of novel signaling pathways mediating insulin regulation of CIDEA and CIDEC will provide additional targets for the development of effective therapeutic strategies to combat obesity and its associated disorders.

Cell Death

The N-end rule pathway counteracts cell death by destroying proapoptotic protein fragments.

K. I. Piatkov[1], C. S. Brower[1], A. Varshavsky[1]; [1]Department of Biology, California Institute of Technology, Pasadena, CA, Pasadena, CA

The N-end rule relates the regulation of the in vivo half-life of a protein to the identity of its N-terminal residue. Apoptosis (a specific type of cell death) in a multicellular organism makes possible the selective elimination of supernumerary, damaged or otherwise abnormal cells. Apoptotic death of a cell is mediated by nonprocessive proteases such as caspases that make specific cleavages in a number of cellular proteins. These proteases are normally dormant, but can be activated by inducers of apoptosis. Some caspase/calpain-generated protein fragments are known to be proapoptotic in that they increase the probability of apoptosis. The naturally produced proapoptotic fragments Cys-RIPK1, Cys-TRAF1, Asn-PKCδ, Asp-EPHA4, Asp-BRCA1, Asp-BCL-xL, Tyr-MET, Tyr-HEF1, Trp-ETK, Leu-LIMK1, Ile-Hpk1, Ile-MLH1, Lys-PKCθ, Arg-BID, and Arg-BIM_{EL} bear destabilizing N-terminal residues, i.e., those that can be recognized by the Arg/N-end rule pathway of protein degradation. We found that these proapoptotic fragments are, in fact, short-lived N-end rule substrates. The resulting down-regulation of proapoptotic fragments, through their degradation by the Arg/N-end rule pathway, comprises a new layer of antiapoptotic control. In agreement with this understanding, we show that even a partial ablation of the Arg/N-end rule pathway makes mice and their cells hypersensitive to apoptosis. Together, our findings indicate that the Arg/N-end rule pathway acts to counteract cell death through the degradation of proapoptotic protein fragments, thereby setting specific thresholds that prevent a transient or an otherwise weak apoptotic signal from reaching the point of commitment to apoptosis.

Stress-inducible caspase substrate TRB3 promotes nuclear translocation of procaspase-3.

K. Shimizu[1], S. Takahama[2], Y. Endo[1,3], T. Sawasaki[1,3]; [1]Cell-free Science and Technology Research Center, Ehime University, Matsuyama, Japan, [2]The Venture Business Laboratory, Ehime University, Matsuyama, Japan, [3]The Venture Business Laboratory, Ehime University

Endoplasmic reticulum (ER) stress response normally promotes cell survival by reducing the accumulation of unfolded proteins through global transcriptional control, well known as the unfolded protein response (UPR). However, apoptosis is considered selected when the apoptotic pathway gains ascendancy over the adaptive pathway by overwhelming the ER stress. The mechanism controlling cell fate is not completely understood. Pseudokinase TRB3, one of the human homologs of Drosophila Tribbles, is up-regulated in a variety of cell types under various stress conditions including ER stress. It has recently been suggested that TRB3 functions as an important component of the stress response mechanism. We recently demonstrated that TRB3 was cleaved by caspase-3 (CASP3) at Asp338. To investigate the role of TRB3 cleavage in the apoptotic process, we carried out cell-based analysis using the wild-type and a non-cleavable mutant of TRB3. In this study, we show that the cleavage of TRB3 produced a pro-apoptotic response, and present evidence for a novel anti-apoptotic mechanism involving TRB3-mediated nuclear translocation of procaspase-3 (proCASP3). Overexpression studies revealed that the cleavage of TRB3 promoted CASP3/7 activation and apoptosis. In contrast, the anti-apoptotic effects were found under TRB3 non-cleavable conditions, such as ER stress, and also when the CASP3/7 activation was enhanced by knockdown of endogenous TRB3 expression. Interestingly, nuclear translocation of proCASP3 was observed in cells either overexpressing TRB3 or under tunicamycin-induced ER stress. Although forced cytoplasmic expression of proCASP3 enhanced apoptosis significantly, its nuclear expression did not produce any pro-apoptotic effect, suggesting that nuclear distribution of proCASP3 is not critical for the execution of apoptosis. TRB3 might prevent cytoplasmic activation of CASP3 by promoting proCASP3 entry into the nucleus, and thereby inhibit apoptosis. Taken together, our results suggest that TRB3, through its own cleavage, functions as a molecular switch between the cell survival and apoptosis pathways under stressful conditions.

1811

A Complex Role for PA28γ as a Regulator of Cell Fate Decisions Following Stress.

A. Raghunath[1], R. Jamshidi[1], A. Gunter[1], K. Hanna[1], D. McKee[1], A. Wurmbrand[1], L. Barton[2]; [1]Biology Department, Austin College, Sherman, TX

PA28γ is a nuclear proteasome activator that facilitates protein degradation by the 20S proteasome in an ATP- and ubiquitin-independent manner. Some targets of PA28γ include key cell cycle regulators such as $p21^{Cip1}$, $p16^{INK4a}$, $p19^{ARF}$, and p53, however PA28γ also has important roles in controlling cell death. PA28γ-deficient cells display increased spontaneous apoptosis in culture, but activate apoptosis signaling to different degrees following various cell stressors. These data suggest that PA28γ has a complex role in regulating survival signals, apoptosis signals, or both. We have investigated the response of PA28γ-deficient Murine Embryonic Fibroblasts (MEF) to a variety of cell stressors and characterized both the viability of the cells as well as the activation of apoptosis signaling. The response to cell stress divides into several categories that are correlated with activation of the pro-survival kinase Akt-1 and the stress response MAP-Kinases p38 and JNK. We conclude that PA28γ, through its role as a substrate-selective activator of proteasomes, controls the ratio of pro-survival to pro-apoptotic

signaling following cellular stress. Since PA28γ is differentially expressed in several cancers, these data may demonstrate one mechanism by which cancer cells can circumvent apoptosis by altering PA28γ expression.

1812

Effect of Extracellular Alzheimer Disease's Hyperphosphorylated Tau on Neuronal Toxicity.

N. J. Nunez Rodriguez[1], C. Corbo[2], E. Alaniz[2], M. Rodriguez[3], S. Debnath[2], J. Fata[2], A. Alonso[2]; [1]Hostos Community Coll, Bronx, NY, [2]Biology, College of Staten Island-CUNY, Staten Island, NY, [3]Biology, Hunter College-CUNY, New York, York

An inverse relationship has been found between the number of TAU tangles and the number of surviving cells in Alzheimer Disease damaged brain regions. The addition of recombinant pathological TAU protein to cultured neuronal cells leads to neuron degeneration as well. Experimental findings have also shown the transmission of neuropathy induced by injection of pathological TAU-brain extract in the hippocampus and overlying cortex of mice. This spreading event has been postulated in Alzheimer Disease as well. At present, there is no disease described where TAU accumulates and it is not hyperphosphorylated. In this regard, phosphorylation of some specific TAU sites, such as Thr212, Thr231 and Ser262, is sufficient to induce cell death. Indeed, the presence of TAU is required for the toxicity associated to Beta Amyloid. Those neurons that are successful in keeping low levels of hyperphosphorylated TAU are able to survive longer. The objective of this work is to test if the presence of TAU stably transfected to the neurons can protect against substances such as the minimal TAU sequence inducing aggregation, Amyloid-β peptide, and TNFα. We used PC12 and CHO cell cultures stably transfected with TAU. Apoptotic events were determined by the Active Caspase-3 inmunostainning. Initial results showed a neurotoxic effect of TNFα in PC12 cells but not in PC12-TAU cells at 24 hours as the early apoptotic marker Caspase-3 indicated it. We also found a Caspase-3 activation and membrane blebbing induced by phosphorylated TAU. These effects are ameliorated by the overexpression of normal TAU. Similar evidence showed a toxic effect of the TAU heptapeptide in cell culture. This neurotoxic effect is also decreased by the overexpression of normal TAU. Beta-Amyloid toxicity in the presence of this overexpression is currently being elucidated. All together, these results shed light on how the cellular balance regarding TAU phosphorylation determines a neuronal commitment to death in pathological conditions. The avenues for successful treatment for tauopathies may involve down regulation of the phosphorylation and up regulation of the clearance of the abnormal form of TAU.

1813

HeLa cells expressing the nuclear Poly (A) binding protein with expanded alanines undergo cell death through GAPDH nuclear translocation and stabilization of p53.

R. B. Bhattacharjee[1], J. Bag[1]; [1]Molecular & Cellular Biology, University of Guelph, Guelph, ON, Canada

The nuclear Poly (A) binding protein (PABPN1) is present ubiquitously in the nuclei of eukaryotic cells, and play an important role in polyadenylation of mRNAs. The wild type protein with a stretch of 10 alanines (PABPN1-A10) is concentrated in nuclear speckles. However, in Oculopharyngeal muscular dystrophy patients, the stretch of alanines is extended to 17 (PABPN1-A17) causing aggregation of the protein within the nucleus. We have previously shown that over expression of the PABPN1-A17 in non muscle HeLa cells leads to increased cell death compared to the wild type protein. Thus, in this study we have investigated the mechanism of cell death following expression of PABPN1 containing expanded alanines (A17 and A40). We showed that over expression of PABPN1 with A17 or A40, leads to increased

nuclear translocation of a glycolytic enzyme, GAPDH, initiating a p53 mediated apoptosis. This event is associated with phosphorylation of p53 at serine 46 in A17 and A40 cells. Once stabilized, p53 is transported to the nucleus leading to up regulation of Puma. Puma then binds to the anti apoptotic protein Bcl2. As Bcl2 is unavailable to form complex with p53, the later is free to activate and oligomerize Bax. We further detected mitochondrial localization of Bax, release of Cytochrome c from the mitochondria and increased levels of activated Caspase 3 in PABPN1-A17 cells. All these findings, therefore, suggest a possible role of GAPDH triggered p53 mediated apoptosis in cells expressing expanded alanine containing PABPN1.

1814

The multidrug resistance-associated transporters offer a differential protection against oxidative stresses induced by hydrogen peroxide or 4-hydroxynonenal in normal human epidermal keratinocytes.

E. Régulus[1], M. Garrigos[1], S. Schnebert[2], E. Perrier[2], M. Dumas[2]; [1]CEA-Saclay, iBiTec-S, F-91191 Gif-sur-Yvette Cedex, France, [2]LVMH Recherche, F-45804 St Jean de Braye Cedex, France

In normal cells the expression of membrane transporters like the multidrug resistance-associated proteins (MRPs) is often correlated with an increase detoxification capacity. This is due to their transport substrate promiscuity and their ability to segregate inside or to efflux out of the cell the toxic molecules. Recent studies revealed the expression of multiple MRP isoforms in normal human epidermal keratinocytes (NHEK). Because NHEK cells are located closer to the surface of the skin they are subjected to various oxidative stresses. Our aim was to assess whether the MRP tranporters expressed in NHEK cells could offer a protection against oxidative stresses caused by exposure to hydrogen peroxide (H_2O_2) or 4-hydroxynonenal (4-HNE). Primary cultures of purified human normal keratinocytes were treated for various incubation time (2, 12, 24 h) and concentrations of H_2O_2 or 4-HNE. Then, cell viability was determined using the tetrazolium salt 3-(4,5-dimethylthiazol bromide (MTT) assay and the effective concentrations (EC50) at which 50% of the cells died were calculated. Cell death was characterized by flow cytometry and fluorescence microscopy using propidium iodide and annexin-V-FITC as fluorescent markers of necrosis and apoptosis. For each oxidant agent, the involvement of MRPs was evaluated by comparing the effects observed in the absence or presence of a non-toxic concentration of MK571, a specific MRP inhibitor. The MTT-reducing activity of NHEK cells dose-dependently decreased in the culture exposed to either H_2O_2 (0-10 mM) for 2 h or 4-HNE (0-100 µM) for 24 h with EC50 values of 0.60 mM and 10 µM respectively. In the presence of 10 µM of MK571 a significant decrease of the EC50 value to 3 µM for 4-HNE was observed suggesting a role for MRPs in the protection of NHEK cells against 4-HNE toxicity. Moreover, flow cytometry and fluorescence microscopy data indicated that NHEK cells exposed to 0.3 to 3 mM H_2O_2 for 2 h or to 0.3 to 30 µM 4-HNE for 24 h followed a necrotic cell death pattern.

1815

Nox4, a Novel Mediator for TGF-β-Induced Apoptosis in Mouse Podocyte.

R. Das[1], X. Quan[1], S. Xu[1], C-H. Chung[2], E-Y. Lee[3], S-K. Cha[1], K-S. Park[1]; [1]Physiology and Institute of Lifestyle Medicine, Yonsei University, Wonju College of Medicine, Wonju, Korea, [2]Internal Medicine, Yonsei University, Wonju College of Medicine, Wonju, Korea, [3]Internal Medicine, Soon Chun Hyang University College of Medicine, Korea

Podocytes are terminally differentiated, actin-rich epithelial cells present on the glomerular basement membrane and critical for glomerular filtration process. Podocyte injury leads to onset of chronic renal diseases characterized by proteinuria. Elevated level of TGF-β is associated with podocyte damage ultimately resulting in apoptosis and detachment. The underlying

mechanism of apoptosis, however, remains unclear in these cells. We investigated pathogenic mediators for proapoptotic effects of TGF-β in cultured mouse immortalized podocytes. Exogenous TGF-β1 selectively up-regulates the expression of only Nox4, but not those of other NADPH oxidase (NOX) family enzymes such as Nox1, Nox2 and Nox3. Consistent with Nox4 upregulation, the total activity of NOX was higher in TGF-β1-treated podocytes. TGF-β1 enhanced reactive oxygen species (ROS) level and elicited apoptosis indicated by the increased the number of apoptotic nuclei and the level of cleaved caspase-3. All these changes by TGF-β1 in podocyte were abolished by SB431542, a potent inhibitor of ALK-5 (Type I TGF-β receptor). Apocynin and DPI, selective inhibitors of NOX, blocked TGF-β1-induced ROS generation and apoptosis. N-acetylcystein as an antioxidant also attenuated the detrimental changes by TGF-β1. In addition, TGF-β1-induced apoptosis was inhibited by SB202190, a p38 MAPK inhibitor. These results suggest that ROS production via Nox4 closely participates in TGF-β-induced apoptosis that might be a crucial mechanism in the development and progression of proteinuric glomerular diseases.

1816

Oxidative Stress Markers and Apoptosis in the Prostate of Diabetic Rats is Diminished by Vitamin C.

M. G. Gobbo[1], D. L. Ribeiro[2], S. R. Taboga[1], E. A. Almeida[3], R. M. Góes[4]; [1]Department of Biology, State University of Sao Paulo - UNESP, São José Do Rio Preto, Brazil, [2]Histology Sector, Institute of Biomedical Sciences, Federal University of Uberlandia- UFU, Uberlândia, Brazil, [3]Department of Chemistry and Environmental Sciences, State University of São Paulo, São José do Rio Preto, Brazil, [4]Department of Biology, State University of São Paulo, São José do Rio Preto, Brazil

Negative consequences of diabetes on the prostate such as involution are associated with diminished testosterone, insulin deficiency and hyperglycemia. The contributions of oxidative damage, which usually increases with diabetes, are unknown for these alterations. This study evaluated the impact of streptozotocin-induced diabetes on the biomarkers of the antioxidant system of rat ventral prostate, the influence of vitamin C supplementation on these biomarkers and on the balance between cell proliferation and death. Diabetes (D) was induced in Wistar male rats by streptozotocin (5mg/100g b.w., i.p.). Control animals (C) were injected with a vehicle. Vitamin C (150mg/kg b.w./day) supplementation was introduced by gavage in diabetes (D+V) as well as control (C+V) groups. Thirty days after diabetes onset, the rats were killed and the ventral prostates were analyzed using light microscopy, immunocytochemistry and biochemical assays for biomarkers of oxidative stress. In comparison to control groups, the levels of circulating testosterone, proliferating and androgen-receptor positive cells decreased in diabetic groups regardless of vitamin C treatment whereas apoptosis was increased. The levels of superoxide dismutase and glutathione peroxidase did not change, but the levels of catalase and glutathione S-transferase (GST) were increased in diabetic prostate. Vitamin C supplementation normalized GST activity and recovered the apoptotic rates in the prostate. These results suggested that oxidative damage is, at least in part, responsible for the unbalanced cell proliferation and apoptosis observed in the rat prostate after diabetes, and GST is a good indicator of compensatory oxidant defense in the gland at earlier stages of metabolic disease.

1817

Development of apoptotic cell mimics to assess protein binding to curved membranes.

J. C. Black[1], M. S. Wang[2], K. Palma[1], T. Campbell[1], M. K. Knowles[1]; [1]Department of Chemistry and Biochemistry, University of Denver, Denver, CO, [2]Department of Chemistry, University of Colorado Denver

Cells have intricately shaped membranes that are created and maintained by the interplay between proteins, lipids, and physical forces. These curved membranes function to control protein activity, to sort proteins in space, and are the product of protein-lipid interactions. The shapes vary dramatically in size, from nanometers to microns, and the affinity of a protein for a curved lipid surface are shape dependent. In our work, novel, nanoparticle-templated membranes have been developed and used to characterize protein interactions with spherically shaped lipid surfaces. Two types of nanoparticle-templated membranes are used. 1) Gold nanoparticles (10-100 nm) are coated with a lipid bilayer for bulk assays of protein binding using gel electrophoresis and fluorimetry. 2) Surface studies are done on single areas of curvature by depositing polystyrene nanoparticles (20-100 nm) on a glass surface and forming a conformal bilayer over top. Both types of sensors allow for the curvature and lipid composition to be separately tuned. Our results reveal that C-reactive protein (CRP), a protein involved with binding to LDL and apoptotic cells as a part of the complement immune response, preferentially binds regions of high curvature. The transition of CRP from a soluble pentamer to a modified, membrane bound form has been assessed and this transition occurs on the curved membranes. These results suggest that regions of high curvature may recruit CRP and allow for the transition of CRP to a form that is capable of binding C1q, another protein in the complement immune response, to signal clearance of apoptotic cells.

1818

C-reactive protein binding to apoptotic cellular blebs.

K. M. Palma[1], J. C. Black[1], M. Wang[2], T. Campbell[1], A. Alnaas[1], M. K. Knowles[1]; [1]Department of Chemistry and Biochemistry, University of Denver, Denver, CO, [2]Department of Chemistry, University of Colorado - Denver

This project is advancing research in the study of the innate immune response by investigating C-reactive protein's (CRP) interaction with curved membrane surfaces, or blebs, a condition present in apoptotic cells. CRP has been known to bind to apoptotic cells to facilitate clearance, possibly converting between two isoforms – pentameric CRP and modified CRP. CRP binding to apoptotic mimics has been explored. Nanoparticles were deposited onto a glass substrate prior to creation of a supported lipid bilayer, which induces curvature in the bilayer as it forms. Using confocal microscopy, fluidity was observed and diffusion rates characterized for bilayers formed over the nanoparticles (20-100 nm in diameter). CRP binding to this induced curvature has been explored. Furthermore, for our *in vivo* work, we induced apoptosis in Chinese Hamster Ovary (CHO) cells and measured the binding of CRP, using Western blotting and fluorescence microscopy. Using the drug, Valinomycin, apoptosis has been confirmed after one hour of incubation and up to 7 hours of incubation. Blebs have been visualized using Annexin V, which binds phosphotidylserine present on the extracellular side of apoptotic membranes, and apoptosis is additionally confirmed using DAPI to visualize the condensed nucleus. Visualization of the blebs allows us to image the binding of CRP to the curved membrane. Preliminary work has been done to determine if CRP undergoes isoform conversion from pentamer to monomer on the surface of the apoptotic cellular membrane and if membrane bound CRP interacts with C1q in an effort to better understand how apoptotic cells are cleared.

1819

Role of lipids in apoptosis in *Xenopus laevis* eggs.

B. Fulroth[1], C. Fees[1], B. J. Stith[1]; [1]Integrative Biology, University of Colorado Denver, Denver, CO

The eggs of many species spontaneously die due to apoptosis (Pasquier et al., 2011). The fertilized egg (zygote) switches off this suicide pathway whereas aged unfertilized eggs rapidly undergo apoptosis (Pasquier et al., 2011). Perhaps to prevent the use of damaged eggs in fertilization, the egg will spontaneously undergo apoptosis unless fertilization takes place. This creates problems in storage and use of eggs for in vitro fertilization. Tilly et al. (2002) and Kolesnick et al. (2007) found that apoptosis in mouse eggs can be induced by exogenous addition of ceramide. In effort to better understand the role of ceramide and other lipids in the apoptotic switch in unfertilized eggs, we conducted our studies using the National Institute of Health recognized model organism *Xenopus laevis*.

Spontaneous Apoptosis: One major enzyme of apoptosis is caspase-3 which is activated by limited proteolysis. To define apoptosis in *X. laevis* eggs, we developed an assay for detecting cleaved caspase-3. Detection of cleaved caspase-3 began ~16 hours after incubation (RT) in 100% Modified Barth's Saline (MBS). Micrographs show cells became mottled soon after this time. In addition, preliminary data suggest that ceramide mass increases as *X. laevis* eggs die naturally in storage media. Ceramide was separated by HPLC and quantified by evaporative light scattering mass detection. A time course of these three apoptotic measures during spontaneous egg apoptosis will be compared and presented.

The Role of Ceramide in Apoptosis: To investigate the role of lipids in egg apoptosis, the addition of the sphingolipid C2 ceramide to *X. laevis* eggs was found to induce caspase-3 activation and egg mottling over four hours. Ceramide addition also increased intracellular calcium which was measured using a calcium sensitive Fluo-4 dye. The calcium sensitive dye was injected into *Xenopus* oocytes prior to ceramide addition.

1820

Activation of intracellular tissue transglutaminase 2 by hyperglycemia potentially contributes to endothelial apoptosis in diabetes.

M. P. Bhatt[1], Y-C. Lim[1], Y-M. Kim[1], K-S. Ha[1]; [1]Cellular and Molecular Biochemistry, Kangwon National University School of Medicine, Chuncheon, Korea

Elevation of intracellular reactive oxygen species (ROS) and calcium (Ca^{2+}) has been implicated in various hyperglycemia-induced endothelial dysfunctions in diabetes. However, the individual roles of ROS and Ca^{2+} as well as their unified molecular mechanism linked with endothelial dysfunctions in diabetes remains to be clarified. The aim of this study was to explore the role of intracellular ROS and Ca^{2+} in activation of tissue transglutaminase 2 (TG2), and induction of endothelial cell apoptosis in vascular system. We observed that hyperglycemia substantially increased intracellular Ca^{2+}, and increased ROS predominantly via Ca^{2+}, activation of PKC and NADPH oxidase pathway. Intracellular ROS- and Ca^{2+}-dependent increase in TG2 activity, was revealed as a previously unrecognized mediator of endothelial cell apoptosis in diabetes. In addition, elevated TG2 activity was observed in aortic segments of streptozotocin-induced diabetic mice in comparison to normal mice. Prevention of cellular apoptosis by inhibition of intracellular Ca^{2+}, ROS, and knockdown of TG2 by siRNA, indicating the crucial role of intracellular ROS, Ca^{2+} and TG2 in cell death mechanism. These findings identify intracellular ROS, Ca^{2+} and TG2 as potential new therapeutic targets for the prevention and treatment of diabetic vasculopathies.

1821

Mitochondrial dysfunction and Purkinje cell loss in the human spastic ataxia ARSACS.

M. Girard[1], R. Larivière[2], D. Parfitt[3], E. Deane[4], R. Gaudet[2], F. Blondeau[1], G. Prenosil[4], E. Vermeulen[3], M. Duchen[5], K. Gehring[6], A. McKinney[4], B. Brais[2], J. Chapple[3], P. McPherson[5]; [1]Department of Neurology and Neurosurgery, Montréal Neurological Institute, McGill University, Montreal, QC, Canada, [2]Laboratoire de Neurogénétique de la Motricité, Centre de Recherche du Centre Hospitalier de Montréal, Université de Montréal, [3]William Harvey Research Institute, Barts and the London School of Medicine, Queen Mary University, [4]Department of Pharmacology, McGill University, [5]Department of Molecular Neuroscience, University College London, Institute of Neurology, [6]Department of Biochemistry, McGill University

Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS) (OMIM: 270550) is a childhood-onset neurological disease resulting from mutations in the *SACS* gene encoding sacsin, a massive 4579 amino acid protein of unknown function. Originally identified as a founder disease in Quebec, ARSACS is now recognized worldwide. Prominent features include pyramidal spasticity, peripheral neuropathy and cerebellar ataxia but the underlying pathology and pathophysiological mechanisms are unknown. We have now generated sacsin knock out mice that display age-dependent neurodegeneration of Purkinje cells and modified mitochondrial function. Mitochondrial dysfunction is a common pathophysiological feature of major neurodegenerative diseases including Huntingtin's, Parkinson's, and Alzheimer's. We show that sacsin localizes to mitochondria in neurons and nonneuronal cells and that it interacts and co-localizes with dynamin-related protein 1, which participates in mitochondrial fission. Disruption of sacsin function leads to an overly interconnected and functionally impaired mitochondrial network. Mitochondria accumulate in the soma and proximal dendrites of neurons and there are striking alterations in the organization of dendritic fields and the morphology of dendritic spines that precede neuronal cell death. Our data reveals mitochondrial dysfunction/mislocalization as the likely cellular basis for ARSACS.

1822

Visualization of Bcl-2 family protein interactions enables screening and characterization of Bcl-2 family small molecule inhibitors in live cells.

D. Anderson[1], C. Wong[1], E. Lee[2], W. Fairlie[2], M. Ludlam[1]; [1]Genentech, S San Francisco, CA, [2]The Walter and Eliza Hall Institute

Bcl-2 super-family of proteins interact at the mitochondria to regulate apoptosis. Overexpression of pro-survival Bcl-2 family proteins is observed in some cancers and confers resistance to chemotherapeutics. Therefore, small molecule inhibitors (SMI) are being developed to block interactions of pro-survival Bcl-2 proteins with their pro-apoptotic counterparts, thereby causing apoptosis.

Current cell-based assays for screening SMIs of Bcl-2 pro-survival proteins rely on indirect, downstream read-outs of apoptosis such as cytochrome-c release, caspase cleavage or cell viability. These assays are unable to detect Bcl-2 family member specificity and may identify compounds that cause cell death by off-target mechanisms. To address these shortcomings, we set out to develop live-cell assays that would detect the direct interactions of Bcl-2 pro-survival proteins with pro-apoptotic BH3-only proteins. This was accomplished by establishing stable cell lines expressing differentially fluorescently-tagged Bcl-2 super family proteins. These fluorescent fusion proteins were engineered to facilitate quantitative assessment of pro-survival Bcl-2 protein binding-dependent localization of BH3-only proteins at the mitochondria. We showed that disruption of the Bcl-2: BH-3-only protein-protein interaction results in cytoplasmic retargeting of BH3-only proteins and that the sensitivity of these assays can be adjusted by

using BH3-only proteins engineered to have reduced binding affinity for Bcl-2 pro-survival proteins. We observed that the decreased binding affinity of these affinity mutants results in BH3-only displacement from the mitochondria in the presence of lower potency compounds.

In addition to SMI screening, we are currently characterizing the biological mechanisms that regulate interaction between pro-survival and pro-death proteins with these novel assays. Given that these protein-protein interactions are critical to determining cell survival, a better understanding of how they are regulated within the cell will allow for the development of new and more effective strategies for targeting them in a clinical setting.

1823

Silver nanoparticles induce apoptotic cell death in *Candida albicans* through the increase of hydroxyl radical.

I-S. Hwang[1], J. Lee[1], J. Hwang[1], D. Lee[1]; [1]School of Life Sciences and Biotechnology, College of Natural Sciences, Kyungpook National University, Daegu, Korea

Silver ions are well known to have inhibitory and antimicrobial effects, but the effects of silver nanoparticles on microorganisms and antimicrobial mechanism have not been revealed clearly. In this study, it was found that silver nanoparticles exerted its antifungal effect via apoptosis. *Candida albicans* exposed to silver nanoparticles showed the increased reactive oxygen species (ROS) production, measured by DHR-123 staining and then we investigated that silver nanoparticles induced the accumulation of hydroxyl radical, which is one of the more active oxygen among the reactive oxygen species (ROS) formed, on *C. albicans* as an oxidative stress response to the drug. The apoptotic effects of silver nanoparticles were detected by fluorescence microscope using Annexin V-FITC, TUNEL, DAPI and FITC-VAD-FMK staining further confirmed diagnostic markers of yeast apoptosis including phosphatidylserine externalization, DNA and nuclear fragmentation, and activation of metacaspase. In addition, the reduction of mitochondrial membrane potential through flow cytometry analysis after staining these with $DiOC_6$ or JC-1, and the release of cytochrome *c* from mitochondria were also assured. Furthermore, the effect of thiourea as hydroxyl radical scavenger in *C. albicans* was investigated. The results suggest that silver nanoparticles possess antifungal effects with another mechanism promoting such as apoptosis and we thought hydroxyl radical generated by silver nanoparticles play a significant role in mitochondrial dysfunction.

Evaluating the Neurotoxicity of Manganese Oxide Nanoparticles using Caenorhabditis elegans.

L. R. Connell[1], J. E. Blalock[2], D. R. Hodge[3], F. N. Norflus[4], J. A. Jordan[4]; [1]Clayton State University, Peachtree City, GA, [2]Natural Science, Clayton State University, Stone Mountain, GA, [3]Natural Sciences, Clayton State University, Lithonia, GA, [4]Natural Sciences, Clayton State University, Morrow, GA

Nanoparticles are defined as the smallest unit (1-100nm) that can still represent the characteristics and functionality of an entity in terms of properties and transport. They can be applied to electronics, medicine, cosmetics and clothing. Recently, various neurodegenerative diseases have been linked to metal oxide nanoparticle exposure. The exact mechanism of toxicity following exposure to these nanoparticles is unknown. Our interest in metal oxide nanoparticles is based on the fact that experimental studies have shown a positive link between manganese exposure and a Parkinson's disease-like syndrome called manganism. The symptoms of this manganism include tremors, bradykinesia, and involuntary muscle movements. In this study, to assess the neurotoxicity manganese oxide nanoparticles, *C.*

elegans were used as the model organisms. These small nematode worms have been used in several areas of research including developmental biology, neurobiology, oxidative stress, and aging. In this study, *C. elegans* were exposed to manganese oxide nanoparticles (Mn_2O_3), silicon dioxide (SiO_2), titanium dioxide (TiO_2), and manganese chloride (MnCl) as an ionic control. The nanoparticles were introduced to bacterial cultures at concentrations of up to 100µg/ml and compared to untreated controls. Following the growth of treated bacteria on petri dishes, the C. elegans were then applied to the bacterial plates and allowed to grow on feed on bacteria containing particles. After 1 and 2 weeks of feeding, the plates were then washed and worms were collected. The worms were evaluated for viability and the induction of oxidative stress. In summary, increasing nanoparticle concentration resulted in decreased viability and oxidative stress occurring in pharynx and intestine of the worm. These studies suggest *C. elegans* as a potential model system in evaluating a role of metal oxide nanoparticles in neurodegenerative disorders.

Immunoassays for the quantitation of two key autophagy biomarkers p62 and NBR1.

R. J. Olson[1], M. Webb[1], E-R. Hahm[2], J. Zielinski[1], J. Samoy[1], S. V. Singh[2], M. C. Mullenix[1];
[1]Enzo Life Sciences Inc., Ann Arbor, MI, [2]University of Pittsburgh Cancer Institute

p62 and NBR1 share similar functions within the autophagy pathway. NBR1 and p62 aid in protein trafficking and degradation. Although the proteins differ in size and sequence, both proteins contain N-terminal Phox domains and Bem1 (PB1) domains, LC3-interacting region (LIR) motifs, and C-terminal ubiquitin-associated (UBA) domains. Although NBR1 and p62 interact and form oligomers, they can also function independently.

Immunoassay kits using a colorimetric 96-well microtiter plate format ELISA have been developed for the detection and quantitation of p62 and NBR1. The sensitivities of the individual kits were determined to be 500 pg/mL and 66 pg/mL, respectively. Both assays demonstrated parallel dose response curves between the recombinant standard and cell lysates from human, mouse and rat origin. Distinct concentrations of recombinant p62 were spiked into three cell lysates, diluted in assay buffer and run in the assay. Similarly, recombinant NBR1 concentrations were spiked into lysis buffer, diluted in assay buffer and run in the assay. The recovery of the spiked p62 was 91, 90 and 95% following a 1:16 dilution. The recovery of the spiked NBR1 was 89, 88 and 106% following a 1:8 dilution. The p62 ELISA intra-assay precision ranged from 3.7 to 3.9% CV and inter-assay precision ranged from 5.2 to 7.0% CV. The NBR1 ELISA intra-assay precision ranged from 4.4 to 7.8% CV and inter-assay precision ranged from 15.6 to 21.8% CV.

The immunoassays were used to measure autophagy flux by detecting changes in p62 and NBR1 levels. This was shown in a time course study in which MDA-MB-231 human breast cancer cells were treated with an autophagy inducing drug withaferin A (WA). Both p62 and NBR1 levels were reduced in response to drug treatment at 6 hour and 12 hour time points. Interestingly, both protein levels increased at the 24 hour time point. p62 ELISA results correlated with western blot (NBR1 not tested). WA treatment of cells correlated with induction of autophagy as confirmed by LC3-II levels in western and puncta formation in immunofluorescence. The accumulation of p62 and NBR1 at the 24 hour time point contrasted with elevated LC3-II possibly indicating the beginning of autophagy resolution. In a second experiment, HeLa cells were treated with Bafilomycin A1 or Rapamycin. After Bafilomycin A1 treatment, both p62 and NBR1 protein levels showed significant increases, 18-fold and 1.8-fold, respectively. In the Rapamycin cell treatment, p62 protein level showed a modest decrease,

25%, whereas no decrease in NBR1 protein level was noted. ELISA results for both p62 and NBR1 correlated with western blotting results.

An attempt to identify biomarkers in mouse lung exposed to single wall carbon nanotubes.

V. Goornavar[1], P. Ravichandran[1], R. Gopikrishnan[1], S. Biradar[1], V. Ramesh[1], R. Jeffers[1], J. C. Hall[1], R. Govindarajan[1]; [1]Biology, Norfolk State University, Norofolk, VA

With the widespread application of carbon nanotubes (CNTs) in diverse commercial processes, scientists are now concerned about the potential health risk of occupational exposures. In this study, Single wall carbon nanotubes (SWCNTs) induced pulmonary toxicity was investigated by exposing Balb/c mice to aerosolized SWCNT (5µg/g of mice) for 7 consecutive days in nose-only exposure system. The microscopic studies showed that inhaled SWCNTs were homogeneously distributed in the mouse lung. The total number of bronchoalveolar lavage (BAL) polymorphonuclear leukocytes recovered from the SWCNT exposed mice (1.2×10^6 ±0.52) was significantly greater than control mice (5.46×10^5 ±0.78). Rapid development of pulmonary fibrosis in SWCNTs inhaled mice was also confirmed by significant increases in the collagen level. The lactate dehydrogenase (LDH) levels were increased nearly by 2 folds in SWCNT inhaled mice respectively, as compared to control mice. In addition, exposure of SWCNTs to mice showed a significant ($p<0.05$) reduction of antioxidants; glutathione, superoxide dismutase, catalase activity and induction of oxidants; myloperoxidase, oxidative stress lipid peroxidation product compared to control. Apoptotic related proteins such as caspase-3 and -8 activities were also significantly increased in SWCNTs inhaled mice than control. Together, the present study shows that inhaled SWCNTs induce an inflammation, fibrosis, alteration of oxidant and antioxidant levels and induction of apoptotic related proteins in the lung tissues to trigger the cell death.

Polarity in Development

1827

The role of RNA binding proteins in dendritic morphogenesis.

E. Olesnicky[1,2], E. Gavis[3]; [1]Biology, University of Colorado Colorado Springs, Colorado Springs, CO, [2]Molecular Biology, Princeton University, Princeton, NJ, [3]Molecular Biology, Princeton University

Neurons have highly asymmetric cellular morphologies and polarized cellular functions that are necessary for establishing neural circuitry and for proper functioning of the nervous sytem. Specialized processes called dendrites are used by neurons for reception of stimuli, while axons function in the transmission of signals. The mechanisms for establishing neuronal polarity are poorly understood, however, it is well established that mechanisms that generate asymmetric protein distributions are essential for establishing such morphological and functional polarities in many different cell types. In neurons, mRNA localization and translational repression are used to change the protein composition of various regions of the cell, allowing for distinct axonal and dendritic morphologies and environments that are equipped for their various cellular tasks. A significant portion of eukaryotic genomes encode for RNA-binding proteins and other components of post-transcriptional regulatory machinery. Moreover, a large number of dendritically localized mRNAs have been identified, suggesting that regulation of localized

mRNAs contributes broadly to neuronal development and function. **Objective:** We performed a candidate RNAi screen to identify genes involved in the development of the highly complex dendritic trees of Class IV dendritic arborization (da) neurons of the *Drosophila* larval peripheral nervous system in order to assess the role of RNA binding proteins in dendrite morphogenesis. **Methods:** We systematically knocked down expression of genes that have been annotated as translation factors and RNA binding proteins within the *Drosophila* genome using RNA interference, activated specifically within Class IV da neurons by the bipartite Gal4/UAS system. **Results:** The screen uncovered substantial roles in dendrite development for genes encoding translational repressors, eukaryotic initiation factors, as well as genes involved in mRNA splicing. We find that the translational repressor Brain tumor (Brat) and the heterogeneous nuclear ribonucleoprotein Squid are expressed within Class IV da neurons and function in the development of higher order dendritic branching within these neurons. We find that *brat* functions cell autonomously in dendrite morphogenesis in Class IV da neurons. Furthermore, we show that *brat* genetically interacts with the translational repressors *nanos* and *pumilio* in order to promote the generation of complex dendritic trees. **Conclusions:** Our screen highlights an important role for post-transcriptional gene regulation in generating morphological cellular asymmetries during Drosophila neurogenesis.

Morphogenesis of the Intestinal Epithelium during Zebrafish Development.

C. Willenborg[1], S. Casper[2], B. Appel[2], R. Prekeris[1]; [1]Cell and Developmental Biology, Univ Colorado-Denver, Aurora, CO, [2]Department of Pediatrics, Univ Colorado-Denver, Aurora, CO

Proper sorting and targeting of endocytosed proteins is necessary for the maintenance of epithelial cell polarity and apical lumen formation. FIP5, a Rab11 effector protein, is known to be involved in apical-directed transport in polarized cells and is thought to act as a scaffolding protein that recruits and binds effectors of endocytosis. Recently, using 3D culture assays, we have shown that FIP5 is an integral mediator of the formation of the epithelial lumen by cavitation in MDCK cells, with the knock-down of FIP5 resulting in the formation of multiple lumens. Additionally, we demonstrated that FIP5 regulates the formation and scission of endocytic carriers in vivo.

Following these data obtained in cell culture, we propose that FIP5 is also involved in the regulation of polarity maintenance and lumen formation in vivo, and have focused our studies on the zebrafish model. In zebrafish, the cavitation model of lumen formation allows for the lumenal opening of the intestinal mesoderm. Moreover, the proper formation of the intestinal tract within zebrafish is highly regulated, with the polarized integrity of the gut's neighboring epithelial structures, the lateral plate mesoderm (LPM), being required for the proper formation and localization of the intestinal precursor during development. Here, using morpholino antisense oligonucleotides directed against FIP5, we characterize the role of FIP5 in the morphogenesis of the zebrafish intestinal tract, along with the ability of the LPM to effect the asymmetric localization of the gut at early stages of development. We propose that FIP5 mediates the positioning of the intestinal tract, as well as the formation of the gut lumen, during early stages of zebrafish development.

The PKD1 locus encodes an alternative transcript that induces mesenchymal to epithelial transition in COS-1 cells.

R. L. Bacallao[1,2], W. Xu[1]; [1]Medicine, Indiana University, Indianapolis, IN, [2]Medicine, Richard Roudebush VAMC, Indianapolis, IN

Recent evidence from a genome wide cDNA library construction project suggests that the HmPKD1 locus encodes a multiplicity of transcripts (Kimura et al, Genome Research, 2006). We have been characterizing one of the cDNA's generously supplied by Dr. Sagano (Helix Research Institute, Chiba, Japan). We sequenced the entire cDNA clone and found that the start site of the clone is in intron 40 of the HmPKD1 locus. There is also a unique splice between exons 41 and 43. When transfected into COS-1 cells, an SV40 transformed cell line, transfected cells exhibit cobblestone morphology, develop a measurable trans-epithelial resistance (~100 Ohm-cm^2) and increase E-cadherin expression. Furthermore, when transfected COS-1 cells are plated in 3D collagen matrix, the cells form cysts. Control, non-transfected cells do not form any three dimensional, organized structures. This data demonstrates that an alternative transcript from the Human PKD1 locus induces an epithelial phenotype in a mesenchymal cell line.

1830

Effects of Early Disruption in Polarity on Later Development in the Sea Urchin Embryo.

K. Moorhouse[1], H. McKay[1], L. Alford[1], D. Burgess[1]; [1]Biology Department, Boston College, Chestnut Hill, MA

Establishment and maintenance of cell polarity has become an increasingly interesting biological question in a diversity of cell types and has been found to play a role in variety of biological functions. Previously, it was thought that the sea urchin embryo remained relatively unpolarized until the first asymmetric division at the 16cell stage of development. However, there is mounting evidence to suggest that polarity is established much earlier. We analyzed roles of the cell polarity regulators, the PAR complex proteins, and how their disruption in early development affects later developmental milestones such as blastula and gastrula formation. We found that PAR6 along with aPKC and CDC42 localize to the apical cortex (free surface) as early as the 2-cell stage of development and this localization is retained through the blastula stage. These proteins are anchored in the cortex by myosin as disruption of myosin light chain kinase activity with ML-7 resulted in cytoplasmic pooling. Additionally, pulse treatments with ML-7 at the 1 or 2-cell stage prevented the embryos from reaching the gastrula stage. This same pulse disrupted PAR6 localization at the fertilized egg and maintained this disruption through the first cleavage division. Interestingly, aPKC inhibition early in development prevented blastula formation but not normal cleavage divisions. aPKC inhibition did not effect micromere formation at the first asymmetric division. These observations suggest that disruptions of the polarity complex in the early embryo can have a significant impact on the ability of the embryo to reach later critical stages in development. This work is supported by NIH GM093978.

Differential segregation of apical domain markers during chick lens placode elongation.

M. O. Melo[1], R. M. Borges[1], C. Yan[1]; [1]Cell and Development Biology, Universidade de São Paulo, São Paulo, Brazil

Vertebrate lens originates from pre-lens ectoderm, a simple cuboidal epithelium that overlies the optic vesicle. After induction by the optic vesicle, the pre-lens ectoderm cells elongate at their

apico-basal axis, becoming columnar and forming a pseudostratified epithelium known as the lens placode.
We have shown previously that actomyosin contractile filaments are homogeneously distributed along the apico-basal cell sides of the chick pre-lens ectoderm (embryonic stage HH11) and become enriched apically at later stages of the lens placode (embryonic stage HH 13) and during lens placode invagination. Therefore, the actomyosin filaments redistribution to the cell apex accompanies the morphological transition from pre-lens ectoderm to lens placode. Here, we investigate the segregation dynamics of apical proteins during the establishment of the placode´s apico-basal polarity.
Beta-catenin is found in lateral membranes of pre-lens ectoderm and is apically concentrated in elongated placodal cells. In contrast, PAR3 is already apically located in pre-lens ectoderm. PAR3 is a scaffold protein that establishes and maintains epithelial cell polarity in a diverse set of models. Similarly, occlusive junctions (detected by ZO-1 immunolocalization) and aPKC are also apically located in pre-lens ectoderm and remain so with placode elongation.
Taken together, these data suggest that the pre-lens ectoderm has an intrinsic polarity reflected by the apical concentration of PAR3, ZO-1 and aPKC. Thereafter, placodal elongation involves further polarization of additional elements such as acto-myosin network and membrane catenins. This latter step of polarization is required for the onset of placode invagination

1832

Localization of LET-99 during asymmetric division in C. elegans embryos.

E. B. Espiritu[1], J-C. Wu[1], L. S. Rose[1]; [1]Molecular and Cellular Biology, UC Davis, Davis, CA

Positioning of the mitotic spindle during asymmetric divisions is essential for generating cell diversity during development. In several systems, PAR polarity proteins and Gα signaling control spindle positioning. In the C. elegans 1-cell embryo, the Gα complex components, GPR and LIN-5, are asymmetrically localized at the cortex in a dynamic pattern in response to PAR cues. GPR and LIN-5 generate asymmetric cortical pulling forces that move the spindle, possibly by regulating dynein. LET-99, a DEPDC1 family protein, is a key intermediate in this pathway. LET-99 is asymmetrically localized at the cortex in a lateral posterior band pattern. LET-99 in turn inhibits the cortical association of GPR and is needed for asymmetric GPR localization. Quantitative analysis of LET-99 localization in mutant backgrounds shows that PAR-3 inhibits cortical LET-99 localization at the anterior cortex, while a gradient of PAR-1 inhibits LET-99 at the posterior-most cortex. Additionally, cytoplasmic polarity mediators are not required. PAR-3 colocalizes at the anterior an atypical protein kinase C, PKC-3. PAR-1 is a Ser/Thr kinase and associates with LET-99 in immunoprecipitations from embryo extracts and in pull-down assays. These results lead to the hypothesis that phosphorylation of LET-99 by PAR-1 and PKC-3 prevents cortical accumulation. However, PAR-3 also colocalizes at the anterior with PAR-6 and CDC-42. To determine which of the anterior polarity proteins are required to regulate LET-99, we are examining LET-99 localization in embryos depleted for each of the anterior proteins. In vitro kinase assays will be used to test for phosphorylation of LET-99 by PAR-1 and PKC-3. Additionally, we are testing LET-99 interacting proteins for a role in anchoring LET-99 at the cortex.

1833

LET-99, a novel G protein regulator for asymmetric division.

D. H. Park[1], J. A. Milan[1], A. Ye[1], L. S. Rose[1]; [1]Department of Molecular and Cellular Biology, Univ California-Davis, Davis, CA

Asymmetric divisions that generate cell diversity are required for normal development and stem cell maintenance. Spindle positioning is a key aspect of asymmetric division. The mitotic spindle

must be aligned with the axis of cell polarity in order for cell fate determinants to be differentially segregated to daughter cells to give them different fates. The conserved PAR polarity proteins establish cell polarity, and they also regulate spindle movements via a complex involving Gα subunits, GPR and LIN-5. The Gα/GPR/LIN-5 complex is necessary for the cortical forces that pull on astral microtubules, potentially by recruiting regulators of the microtubule motor dynein. In C. elegans one-cell embryos, GPR and LIN-5 first show an overall anterior enrichment during prophase, when pulling forces center the nuclear-centrosome complex and rotate it on to the polarity axis. GPR/LIN-5 enrichment then switches to the posterior during the spindle displacement movements that produce an unequal division. We previously showed that LET-99 is a key component of this pathway and acts downstream of the PAR proteins during both nuclear centration/rotation and spindle displacement. LET-99 antagonizes G protein signaling by inhibiting the localization of GPR at the cortex. The highest levels of LET-99 are present in a posterior-lateral cortical band, which results in the lowest levels of cortical GPR in this region; nonetheless, LET-99 function is also needed for the overall anterior and posterior enrichment of GPR through the cell cycle. To begin to elucidate the mechanism of LET-99 action, we tested LET-99 for interaction with other components of the pathway. In vitro pull down and yeast two-hybrid assays show that LET-99 can interact with GOA-1 and GPA-16, the two Gα subunits used in this system. Direct binding of LET-99 to Gα could directly interfere with formation of a Gα/GPR/LIN-5 complex; alternatively, LET-99 could regulate an upstream step involving other pathway components such as Gβ or RIC-8. To further elucidate the molecular mechanism of LET-99 action, we are carrying out additional genetic and interaction studies with Gβ and Ric-8.

Tissue Development and Morphogenesis II

Morphophysiological Regulation of the Female Prostate by Progesterone Hormone.

R. A. Fochi[1,2], F. A. Santos[3], L. R. Falleiros-Jr[2], R. M. Góes[2], S. R. Taboga[2]; [1]Campinas State University - UNICAMP, Campinas, Brazil, Campinas, Brazil, [2]São Paulo State University - IBILCE, São José do Rio Preto, Brazil, São José do Rio Preto, Brazil, [3]Federal University of Goiás - UFG, Goiânia, Goiás, Goiânia, Brazil

The objective of this investigation was to evaluate the direct effects of hormonal suppression on the female prostate gland, as well as the replacement of progesterone (P4) associated or not with testosterone (T) and estrogen (E2). For this purpose, surgical castration was performed in female gerbil (*Meriones unguiculatus*) at early puberty (45 days). After adulthood (90 days), some of the castrated animals were sacrificed, forming the control group (CCa), while others were treated with subcutaneous doses (1 mg/kg b.w.) of P4 (PCa), E2 plus P4 (PECa) and T plus P4 (PTCa), during 14 days. For the intact control group (NC) non-castrated adult gerbils were used. The surgical castration trigged a diminished glandular development and a reduction in the secretory capacity, as well as decreased the amount of androgen receptor (AR) positive cells, but increased cell proliferation (PCNA) and the number of estrogen receptor cells (ERα). The replacement of P4 unleashed a hyperplastic and hypertrophic process in the epithelial secretory cells, recovering the pattern of glandular secretion with increased number of AR and ERα-positive cells. When P4 was associated with E2, the glandular cellularity became similar to that observed in NC group, occurring however, an intense epithelial hyperplasia associated to a high proliferative rate of stromal and epithelial cells. In the PTCa group, the epithelial hyperplasia was even more evident, presenting an intense immunostaining for AR and ERα and a normal secretion pattern. Furthermore, important hormonal oscillations were observed in the different treatments, with peaks of P4 in the PCa and PECa groups and a testosterone in the

PTCa animals. Thus, the results show the impact of hormonal imbalance on the prostate morphophysiology, highlighting that the female gland is very dependent of androgen and estrogen, but that the progesterone hormone is also a potential regulator of its physiology. Financial support: FAPESP.

1835

Securin is Essential for Mammary Gland Morphogenesis and Tumor Suppression.

R. Hatcher[1], J. Dong[2], Y. Li[2], P. Zhang[1]; [1]Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX, [2]Breast Center, Baylor College of Medicine, Houston, TX

Background & Objective: Securin, also known as PTTG1 (pituitary tumor transforming gene 1), is an inhibitor of separase, a protease catalyzing the cleavage of sister-chromatid cohesions during mitosis. There is strong evidence for securin as a dynamic player involved in gene regulation, organ development and tumorigenesis. However, these earlier reports combined mutations and knockouts of other proteins such p53, Retinoblastoma and p21 with securin. We want to understand how securin directly affects these processes. Our study focuses on the securin loss-of-function effects on mouse mammary gland development, gene regulation and tumorigenesis.

Methods and Results: Our lab generated a securin knockout ($Sec^{-/-}$) mouse model that was normal with no decreased fecundity. Previous *in vitro* studies indicated that securin enhanced promoter activity of specific genes involved in proliferation (c-Myc, Cyclin D3, FGF-2), inhibition (p21) and extra cellular matrix modifiers (MMP2). Using quantitative real-time PCR (qRT-PCR) we analyzed $Sec^{-/-}$ mouse embryonic fibroblasts to reveal a significant reduction of the mRNA transcripts of matrix metalloproteinase 2 (Mmp2) and p21. Preliminary reports demonstrated that Mmp2 knockout mice had a disturbed mammary gland branch network, with increased lateral branching and decreased invasion of the developing ducts. We have completed developmental time points for 4, 7 and 13 wk old mice and our analysis shows that $Sec^{-/-}$ glands have super-numerated secondary and tertiary lateral branching as well as decreased invasion. Using BrdU incorporation to analyze proliferation, we have revealed that 7 and 13 wk old mice have increased proliferation in the branch network. To eliminate the systemic effect of the knockout, we performed mammary gland transplants and found similar results to the $Sec^{-/-}$, indicating that the alteration of the gland is contained within the stem cell niche and not caused by a hormone-signaling imbalance due to the systemic knockout. Analysis of the glands by qRT-PCR reveals similarly low levels of mRNA transcripts in Mmp2 and p21. These $Sec^{-/-}$ mice also develop tumors exclusively in the breast (17%). Current studies are assessing the ability of MMP2-lentivirus to rescue the gland phenotype.

Conclusion: In gland development, securin is more than a regulator of mitosis; it controls the gene expression of both MmP2 and p21. The misregulation caused by the knockout increases proliferation and uncontrolled branching; a factor that is necessary for tumorigenesis. Therefore, securin is essential for gland architecture and tumor suppression.

1836

HIF-dependent upregulation of Bnip3 promotes apoptosis and cavitation during epithelial morphogenesis.

Y. Qi[1], X. Tian[1], J. Liu[1], Y. Han[2], A. Graham[1], C. Simon[3], P. Carmeliet[4], S. Li[1]; [1]Surgery, Robert Wood Johnson Medical School, New Brunswick, NJ, [2]Cardiology, Shenyang Northern Hospital, China, [3]Abramson Family Cancer Research Institute, University of Pennsylvania, Philadelphia, PA, [4]Vesalius Research Center, Leuven, Belgium

Apoptosis is an essential step in cavitation during embryonic epithelial morphogenesis, but the mechanisms are largely unknown. In this study we used embryonic stem cell-differentiated

embryoid bodies (EBs) as a model and found that Bnip3 (Bcl-2/adenovirus E1B nineteen-kDa interacting protein), a BH3-only pro-apoptotic protein, is significantly upregulated during cavitation in a hypoxia-dependent manner. shRNA silencing of Bnip3 inhibits apoptosis of the core cells and delays cavitation. Immunoblot analysis reveals that HIF-2α is selectively increased during EB morphogenesis. Inactivation of HIF-2α but not HIF-1α markedly inhibits Bnip3 elevation and apoptosis. Similarly ablation of HIF-1β, the common β subunit of HIF-1 and -2, completely abolishes Bnip3 upregulation and delays cavitation, whereas overexpression of Bnip3 in HIF-1β-deficient EBs rescues apoptosis and cavitation. These results uncover a mechanism of cavitation through hypoxia-induced apoptosis of the core cells mediated by HIFs and Bnip3.

1837

NF-kappa B Activation Promotes a Phenotype Shift in Fetal Mouse Lung Macrophages.

A. Hipps[1], F. Yull[1], T. Blackwell[1], L. Prince[1]; [1]Vanderbilt Univ, Nashville, TN

Objective: Macrophages are present in multiple embryonal tissues and may play key roles in morphogenesis. We have previously shown that NF-□B activation in fetal lung macrophages inhibits airway morphogenesis and may play a role in neonatal lung disease. The role of NF-□B activation on fetal lung macrophage phenotype remains unknown. We hypothesized that NF-□B signaling in fetal macrophages drives an M1, pro-inflammatory phenotype, which may be detrimental to normal lung morphogenesis.
Methods: Macrophage marker expression was measured by real time PCR and immunostaining. A fetal lung explant model was used to study saccular stage airway branching. In addition to LPS treatment, we tested the effects of NF-□B activation in macrophages using a transgenic mouse model with a macrophage-specific, tet-inducible constitutively active IKKβ mutant (IKFM).
Results: To determine macrophage phenotype in the fetal lung, we measured expression of pro-inflammatory, M1 markers and alternative activation, M2 markers in fetal and adult lung sections. Compared to adult cells, fetal lung macrophages had increased expression of the M2 marker CD206. Isolated macrophages from fetal lung tissue were still able to mount an M1 response to LPS, expressing IL-1β, TNF-α, and the M1 markers CXCL-10 and CCL-3. LPS had no effect on M2 marker expression in isolated cells. In contrast, the T_H2 cytokines IL-4 and IL-13 increased expression of the M2 markers CCL-17, CD206, and Ym1 in isolated macrophages, while decreasing expression of M1 markers. When tested in fetal lung explants, LPS also inhibited expression of Mgl1/2, suggesting a more M1 phenotype. We have previously shown than LPS inhibits airway branching in fetal lung explants. Adding IL-4 or IL-13 prevented the effects of LPS on branching and maintained expression of the M2 marker Mgl1/2. When constitutive NF-□B activation in fetal lung macrophages was tested using doxycycline-treated IKFM macrophages, we again measured increased expression of IL-1β, TNF-α, and CCL-3 and decreased CD206 and Ym1. IL-4 and IL-13 increased CD206 and Ym1 expression in activated IKFM macrophages, but did not decrease expression of CCL-3, IL-1β, and TNF-α.
Conclusions: These results demonstrate that NF-□B activation in fetal lung macrophages stimulates an M1 versus M2 cell phenotype. This shift may play a role in the altered lung morphogenesis seen with exposure to inflammation, as suppression of the M1 phenotype and maintenance of the M2 phenotype with IL-4 or IL-13 can preserve airway branching.

1838

PTEN-dependent upregulation of Bnip3 mediates apoptosis and cavitation during embryonic epithelial morphogenesis.

Y. Qi[1], J. Liu[1], X. Tian[1], A. Graham[1], P. Pandolfi[2], S. Li[1]; [1]Surgery, Robert Wood Johnson Medical School, New Brunswick, NJ, [2]Harvard Medical School, Boston, MA

Gene targeting experiments have demonstrated that the tumor suppressor phosphatase and tensin homolog (PTEN) is essential for mouse early embryogenesis. To elucidate the role of PTEN in embryonic epithelial morphogenesis and the underlying mechanisms, we employed embryonic stem cell-differentiated embryoid bodies (EBs), which are epithelial cysts consisting of an outer endoderm, an underlying basement membrane, and the epiblast epithelium encompassing a proamniotic-like cavity. We found that PTEN is upregulated during EB morphogenesis in parallel with decreased Akt activation and increased inner cell apoptosis, the latter is essential for EB cavitation. Genetic ablation of PTEN in EBs causes over-activation of Akt and inhibition of apoptosis-dependent cavitation. However, pharmacological inhibition of Akt fails to induce cavitation in PTEN-null EBs. Additionally, overexpression of myristoylated, constitutively active Akt in wild-type EBs only slightly inhibits apoptosis and cavitation, suggesting the existence of an Akt-independent mechanism. Our previous study showed that hypoxia-induced upregulation of Bnip3, a pro-apoptotic BH3-only protein, contributes to EB cavitation. To test whether Bnip3 mediates PTEN-dependent cavitation, we analyzed Bnip3 expression in wild-type and PTEN-null EBs. PTEN inactivation inhibits Bnip3 elevation during EB differentiation and in response to hypoxia. Furthermore, overexpression of Bnip3 restores the apoptosis of core cells in PTEN-null EBs. Lastly, reconstitution of PTEN-null EBs with wild-type PTEN or the G129E mutant, which lacks the lipid phosphatase activity, completely rescues Bnip3 expression and cavitation, whereas expression of the C124S mutant, which lacks both the lipid and protein phosphatase activities, restores Bnip3 expression and apoptosis but not cavitation. These results suggest that PTEN facilitates hypoxia-induced Bnip3 upregulation and apoptosis independently of its phosphatase activity. Yet its protein phosphatase activity is required for the clearance of apoptotic corpse and cavitation.

Genome-wide mapping of Sox6 binding sites reveals coordinated regulation of sarcomere protein gene expression by Sox6 in developing skeletal muscle.

C-I. An[1], Y. Dong[1], N. Hagiwara[1]; [1]Internal Medicine, University of California, Davis, Davis, CA

The molecular mechanisms underlying the terminal differentiation of vertebrate skeletal muscle are not well understood. Our laboratory investigates the role of the transcription factor Sox6 in fiber type (slow-twitch vs. fast-twitch) specification in mammalian skeletal muscle and has previously reported that Sox6 functions as a transcriptional suppressor of the slow fiber gene program during skeletal muscle development. [Objective] The objective of the current study is to identify genome-wide binding sites of Sox6 and uncover the functional role(s) of Sox6 during terminal differentiation of skeletal muscle. [Methods] We conducted ChIP-seq, conditional inactivation of the Sox6 gene in mouse muscle, and reporter gene assays of the newly identified Sox6 binding cis-regulatory sequences using muscle primary cultures. [Results] We report that: (1) A total of 1,066 Sox6 peaks were identified by ChIP-seq using mouse fetal myotubes and were assigned to 867 RefSeq genes. Gene ontology analysis of the Sox6 peak-associated genes revealed that the categories relevant to muscle functions, muscle development, and transcriptional regulation were significantly enriched. The genes encoding slow fiber-specific sarcomere proteins and transcription factors highly expressed in muscle were found to be frequently associated with Sox6 peaks; (2) The majority of the Sox6 peak-associated genes were classified as transcriptionally inactive based on Pol II ChIP-seq data, suggesting that the

main function of Sox6 is transcriptional suppression; (3) This notion was confirmed by the phenotype of Sox6 conditional knockout muscle, which exhibited a significant increase in the expression of slow fiber, cardiac, and embryonic isoform genes (associated with Sox6 peaks), accompanied by a major decrease in the expression of fast fiber-specific genes; and (4) Sox6 binding sites were found in the previously reported slow fiber-specific Tnni1 and Tnnc1 enhancer regions. These Sox6 binding sites stifled the enhancer activity, suggesting that transcriptional levels of muscle fiber type-specific genes may be dictated by the combination of modular cis-regulatory elements, which exert positive or negative influence on transcription. [Conclusions] Our data indicate that Sox6 plays a critical role in fiber type specification of skeletal muscle. The main function of Sox6 is transcriptional suppression of developmentally regulated genes, whose combinatorial expression determines the physiological maturity of skeletal muscle.

Tissue Geometry Regulates the Axis of Cell Division in Epithelial Tissues.

J. P. Gleghorn[1], C. M. Nelson[1,2]; [1]Chemical & Biological Engineering, Princeton University, Princeton, NJ, [2]Molecular Biology, Princeton University

Control of the orientation of cell division is critical for regulating normal tissue structure and function. Misorientation of the axis of cell division can cause organ malformation and tumorigenesis. Recent studies examining the biophysics of single cells have revealed that cell shape and cell-matrix interactions can act as significant determinants for the orientation of the plane of cell division. Spatial patterns in cell behavior emerge when groups of cells interact, in part through endogenous mechanical stresses transmitted between cells. Here we investigated the influence of these emergent biophysical signals on the axis of cell division within epithelial tissues. Microlithography was used to engineer epithelial sheets of defined geometry. The axis of cell division was recorded within these microscale tissues, and composite maps of division axis were correlated with computational predictions and experimental validations of the patterns of endogenous mechanical stresses. Cell proliferation correlated with the magnitude of mechanical stress, with increased proliferation in regions of high mechanical stress. In contrast, the axis of cell division was largely perpendicular to the gradient of the endogenous stress. Additionally, the axis of cell division was influenced by the global geometry of the tissue and the local motions of neighboring cells. These data implicate emergent mechanical signals that arise from tissue multicellularity as key determinants of the orientation of cell division, and suggest another mechanism through which tissue geometry might control patterns of morphogenesis.

Inhibition of Sp1-Mediated FGF-10 Expression by Sp3 and NF-κB.

B. Carver[1,2], J-H. Liu[3], A. Stinnett[3], R. van der Meer[4], T. Blackwell[5], L. Prince[3]; [1]Cell and Developmental Biology, Vanderbilt University, Nashville, TN, [2]Program in Developmental Biology, Vanderbilt University, Nashville, TN, [3]Pediatrics, Vanderbilt University, Nashville, TN, [4]Pathology, Vanderbilt University, Nashville, TN, [5]Medicine, Vanderbilt University, Nashville, TN

Objective: Microbial products and inflammatory mediators that activate NF-κB can inhibit branching morphogenesis of the fetal lung, and may lead to developmental lung disease. A key mechanism in this process appears to be the NFκB mediated suppression of FGF-10 expression in the fetal lung mesenchyme. The transcriptional mechanisms for this inhibition are unknown. We hypothesize that NF-κB activation interferes with normal transcriptional regulation of FGF-10 expression.

Methods: We measured FGF-10 promoter activity using an FGF-10 luciferase reporter plasmid in CHO cells. NF-κB activation was modulated by either IL-1β addition or overexpression of a constitutively active IKKβ; (cIKKβ). NF-κB was also blocked using a dominant-negative IκB (dnIκB). ChIP was performed on LPS-treated primary fetal mouse lung mesenchymal cells using antibodies against Sp1, Sp3, and the NF-κB subunit RelA.

Results: Both IL-1β and cIKKβ expression inhibited FGF-10 promoter activity. Conversely, inhibiting NF-κB activation by transfecting cells with dnIκB increased FGF-10 promoter activity above basal levels. The effect of NF-κB on the FGF-10 promoter appeared to be indirect, as deletion a predicted NF-κB binding site in the FGF-10. This result suggested that NF-κB might inhibit the function of other transcription factors at the FGF-10 promoter. Following in silico identification of several GC boxes within the FGF-10 promoter, we next tested if Sp family transcription factors regulated FGF-10 transcription. Overexpressing Sp1 increased FGF-10 promoter activity. Sp1 also co-immunoprecipitated with RelA, suggesting physical interaction. The stimulatory effect of Sp1 was inhibited by co-expression with Sp3. Interestingly, only the two longest translational isoforms of Sp3 inhibited Sp1-mediated FGF-10 promoter activity. NF-κB activation may promote the recruitment of Sp3 to the FGF-10 promoter, as ChIP from LPS-treated cells measured increased RelA and Sp3 promoter association. Co-transfection with dnIκB blocked the inhibitory effects of Sp3, suggesting that NF-κB activation and nuclear translocation may be required for Sp3 to block FGF-10 transcription.

Conclusions: These data suggest that inflammatory signaling through NF-κB inhibits FGF-10 expression by altering the normal transcriptional activities of Sp1 and Sp3 at the FGF-10 promoter. NF-κB might therefore use this a novel mechanism to disrupt normal developmental regulation of FGF-10 in the fetal lung mesenchyme.

1842

PI3K/Akt1 plays a pivotal role in retinal angiogenesis.

J. Ha[1], S. Yun[2], E. Kim[2], Y. Kim[2], I. Jin[2], D. Woo[2], H. Lee[2], C. Kim[2], S. Bae[2]; [1]MRC for Ischemic Tissue Regeneration and Medical Research Institute, Department of Pharmacology, College of Medicine, Pusan National University, Yang-san, Republic of Korea, [2]MRC for Ischemic Tissue Regeneration and Medical Research Institute, Department of Pharmacology, College of Medicine, Pusan National University, Yangsan Republic of Korea

Phosphoinositide 3-kinase (PI3K) and Akt, downstream target molecule of PI3K, regulate multiple cellular functions including cell proliferation, cell cycle progression, tumor growth, and angiogenesis. Disruption of Akt1 in mice shows reduced organism size and endothelial dysfunction. Blood vessels comprise endothelial cells, mural cells. During angiogenesis, mural cells are recruited to sprouting endothelial cells and stabilizing newly formed vessels. In this study, we investigated the role of Akt in endothelial cells or in mural cells during retinal angiogenesis. Vascular endothelial growth factor (VEGF)-induced capillary-like tube formation was significantly abolished in Akt1 knock-down human umbilical vein endothelial cells (HUVECs), whereas Akt2 knock-down cells were not affected. Moreover, retinas from WT or Akt1 deficient mice were stained with endothelial cell marker, CD31 and smooth muscle cell marker, SM22a. Interestingly, retinas from Akt1 knock-out mice showed tortuous, irregular and clustering retinal vessels compared to that of WT mice. It represented that loss of Akt1 caused vascular morphological alterations. Given these results, we suggest that Akt1 plays an important role during retinal angiogenesis.

1843

Role of Pinin in Alternative pre-mRNA Splicing during Epithelial Differentiation.

J-H. Joo[1], G. P. Correia[2], M. Jiang[1], J. G. Ambut[1], A. Pandey[1], S. P. Sugrue[1]; [1]Anatomy and Cell Biology, University of Florida, Gainesville, FL

Pinin (Pnn) is a member of the SR proteins, which comprise a large portion of the non-snRNP spliceosomal proteins. Our previous investigations have revealed that Pnn plays essential roles in the differentiation and maintenance of epithelial cells. To further investigate Pnn's function during epithelial differentiation and to explore the potential underlying mechanism, we now focus on Pnn's role in alternative pre-mRNA splicing. Conditional inactivation of Pnn in multiple types of developing epithelia by utilizing Shh-Cre and Pax6-Cre mouse lines resulted in significant disruption of alternative splicing pattern of Fibroblast growth factor receptor 2 (Fgfr2), leading to the aberrant ratio between IIIb (epithelial-type) and IIIc (mesenchymal-type) isoforms, while not affecting total Fgfr2 transcript level or the alternative splicing of other genes such as Pyruvate kinase isozyme type M2 (Pkm2). Further alternative splicing-specific RT-PCR analyses revealed that other epithelial patterns of pre-mRNA splicing such as Cd44, p120-Catenin (CtnnD1), and enabled homolog (Enah), were also markedly altered in Pnn depleted epithelial cells. It has been demonstrated that epithelial-specific alternative splicing may to a great extent be mediated by Epithelial splicing regulatory proteins 1 and 2 (ESRP1 and 2). Furthermore, ESRPs have been shown to be crucial for the epithelial differentiation and maintenance. Notably, our recent co-immunoprecipitation assays revealed that PNN is in a complex with ESRP1, along with other SR Proteins, SF3b155 and U2AF65. Finally, consistent with our gene inactivation studies in mice, inducible shRNA-mediated knockdown of either PNN or ESRP1 in human corneal epithelial cells led to the similarly decreased levels of epithelial-type FGFR2 isoform, IIIb. Taken together, our study suggests that Pnn is involved in the regulation of epithelial-specific alternative splicing of Fgfr2, Cd44, CtnnD1, and Enah, and Pnn may act through modulating alternative pre-mRNA splicing, possibly through coordination with ESRP proteins, during epithelial cell differentiation. 1844

Developmentally Regulated Expression of Intracellular Fgf11-13, Hormone-like Fgf15 and Canonical Fgf16, -17, and -20 mRNAs during Odontogenesis.

K. Luukko[1], T. Furmanek[1], R. CHAULAGAIN[1], P. Kettunen[1]; [1]Dept. Biomedicine, University of Bergen, Norway

Objective: To investigate and compare the cellular expression of nonsecreted Fgf11-14 and secreted Fgf15-18 and -20 mRNAs during tooth formation. Material and methods: mRNA expression was analyzed from the morphological initiation of the mouse mandibular first molar development to the onset of crown calcification using sectional in situ hybridization. Results: We found distinct, differentially regulated expression patterns for the Fgf11-13, -15-17 and -20, in particular in the epithelial-mesenchymal interface whereas Fgf14, and 18 mRNAs were not detected. Fgf11, -15, -16, -17, and -20 were seen in the epithelium whereas Fgf12 and -13 signals were restricted to the mesenchymal tissue component of the tooth. Fgf11 was observed in the putative epithelial signaling areas, the tertiary enamel knots and enamel free areas of the calcifying crown. Fgf15, Fgf17, and -20 were transiently colocalized in the thickened dental epithelium at E11.5. Later Fgf15 and -20 were exclusively expressed in the epithelial enamel knot signaling centers. In contrast, Fgf13 was present in the dental mesenchyme including odontoblasts cell lineage whereas Fgf12 appeared transiently in the preodontoblasts. Conclusions: The expression of the Fgf11-13, -15, -17 and -20 in the epithelial signaling centers and/or epithelial-mesenchymal interfaces at key stages of the tooth formation suggest important functions in odontogenesis

1845

Mitochondrial development of the *in vitro* hepatic organogenesis model with simultaneous cardiac mesoderm differentiation from murine ES and iPS cells.

M. Tamai[1], Y. Tagawa[1]; [1]Tokyo Institute of Technology, Yokohama, Japan

Induced pluripotent stem (iPS) cells, resembling embryonic stem (ES) cells in many phenomena, including differentiation potential, colony morphology, and the expression of specific representative markers, were generated from differentiated somatic cells. In recent, the mitochondria of iPS cells were reported to be rejuvenated to that of ES cells, however it is not known if the mitochondria have same potential for differentiation as ES cells. We investigated mitochondrial energetic potentials during the differentiation process of iPS and ES cells. We have established the murine ES/iPS cell-derived in vitro hepatic organogenesis model, consisting of not only hepatocytes but also endothelial networks together with cardiac mesoderm differentiation, previously. Mitochondrial energetic potentials can be followed by measuring the oxygen consumption rate (OCR) and extracellular acidification rate (ECAR). OCR is an indicator of mitochondrial respiration, and ECAR is the concentration of acids in the medium, predominantly lactic acid. The assay for mitochondrial energetic potentials was performed using an XF24 Extracellular Flux Analyzer. By measuring OCR and ECAR in the culture medium, we compared the mitochondrial energetic potentials of both ES and iPS cells during the hepatic differentiation. The mitochondrial energetic potentials of the in vitro hepatic organogenesis from iPS cells accorded with each differentiation steps, from proliferation stage as the initiation, spontaneously beating cardiac differentiation in the next, and finally liver tissue-formation, as well as that from ES cells. Our results indicate that the mitochondrial energetic potentials of the *in vitro* hepatic organogenesis model derived from the ES and iPS cells correspond to the proliferation stage in the initiation, spontaneous beating cardiac and hepatic differentiation. Both ES and iPS cells were differentiated into liver-like tissue with similar mitochondrial development.

1846

Epicardial TGFb Signal Is Required for Myocardial Maturation Before the Onset of Coronary Circulation.

M. Takahashi[1], N. Yanagawa[1], M. Kai[1], T. Yamagishi[1], Y. Nakajima[1]; [1]Anatomy and Cell Biology, Osaka City University Graduate School of Medicine, Osaka, Japan

Developing epicardium originates from the proepicardial organ (PE) and spreads over the external surface of myocardium. Thereafter the epithelial epicardium seeds mesenchyme into the subepicardial space to form a multi-potent progenitor for cardiac fibroblasts, coronary smooth muscle and endothelial cells. Surgically ablated PE-deficient hearts in chick embryos as well as mutant mice hearts with defective epicardium show a thin myocardial compact layer before the onset of coronary circulation. Using a chick model with mechanically ablated PE, we investigated mechanisms that lead to thin compact myocardium. In ED6 hearts with defective epicardium, myocardial compact layer was significantly thinner than that of sham-operated hearts. Neither BrdU incorporation nor immunostaining for Phospho-Histone H3 indicated that there was significant difference in the mitotic index between the epicardium deficient myocardium and control hearts. Immunohistochemical detection for sarcomeric proteins showed that myofibrillogenesis was established in epicardium-deficient myocardium, but the average distance between the Z-lines was shorter than that in control. In addition, cell density in epicardium-deficient compact myocardium was significantly higher than that in controls. Western blot analysis showed that PSmad2, but not PERK or PSmad1/5/8, was decreased in epicardium-deficient hearts. In organ culture, primitive ventricle without epicardium from ED2.5 heart was co-cultured with or without PE. After 2 or 3 days of incubation, cultured myocardium

without PE established striated myofibrils, however the average space of Z-lines was shorter and the cell density was higher in comparison with those in co-cultured ventricles. The immaturity and hypotrophy seen in the cultured ventricle without PE were reversed by treatment of conditioned medium harvested from PE culture or recombinant TGFb protein. Co-cultured ventricle treated with LY364947 (TGFb type I receptor kinase inhibitor) showed shortened spaces of Z-lines and hypotrophic cardiomyocytes. These results suggest that the thin compact myocardium in the epicardium-deficient hearts is attributed to impaired cardiomyocyte hypertrophy in the developing myocardium, and myocardial maturation is facilitated by epicardium-secreted trophic factors such as TGFb before the onset of coronary circulation.

1847

Heparanase-1 knock-down delays lumen formation during rat ventral prostate morphogenesis in the first postnatal week.

G. O. Barbosa[1], R. Nunes[1], T. M. Augusto[1], A. Bruni-Cardoso[1], H. F. Carvalho[1]; [1]State University of Campinas, Campinas, Brazil

Branching morphogenesis is an important step in ventral prostate (VP) development. This event occurs in rats after the initiation of bud formation that happens during the last few days of gestation and in the first three postnatal weeks. The testosterone surge around birth is important for stromal and epithelial differentiation through andromedins in a paracrine way. FGF-10 is one of the candidate andromedins. We reported previously that cell death is associated to luminal epithelial cell polarization during the epithelium canalization process in the VP development. Extracellular matrix (ECM) remodeling is also necessary in this process. Matrix metalloproteinase-2 (MMP-2) was shown to contribute to organ growth and morphogenesis. Heparanase-1 (HPSE1) is an endoglucuronidase that has been reported on the releasing of heparan sulfate (HS) fragments and growth factors from ECM stores. It is also known that HPSE1 expression is compensated by MMP expression, as showed for different organs of HPSE1 knock-out mouse. Previous results demonstrated that Hpse1 is expressed mainly by epithelial cells during the first post natal week of VP development and its knock-down by siRNA delays VP epithelial outgrowth and branching morphogenesis. Thus we hypothesized that HPSE1 might be involved in VP morphogenesis of epithelial tubes. In order to test this hypothesis, we have cultured PND 0 (postnatal day zero, the day of birth) rat VP in a membrane floating system with siRNA against Hpse1 (siRNA against Gfp was used as control) and followed the development every two days until PND6 for organ and epithelial area measurements and tips counting. These VP were further processed in historesin for morphological analysis. We also dissected PND10 rat VP and isolated the cells with collagenase followed by trypsin/EDTA digestion and cultured the cells on growth factor-reduced matrigel with the same knock-down treatment described above. This material was labeled with phalloidin-TRITC and DAPI for spheroid analysis under confocal microscopy. Counting of luminated epithelial structures on PND2 demonstrated a 6.2-fold decrease in the 50 nM siHPSE (1.8%) as compared to the 100 nM siGFP control (11.3%), while the 100nM siHPSE resulted in completed absence of lumen formation. This was associated with reduced pERK1/2, which is thought as a first evidence for compromised FGF-10 signaling in this process. Spheroid cultures showed a decrease on the percentage of lumen-bearing spheroids in the group treated with siHPSE (100 nM siGFP control [62%]; 50 nM siHPSE [40%] and 100 nM siHPSE [39%]). These results indicate that HPSE1 plays a role in epithelial tube morphogenesis. It will be interesting to dissect the mechanism through which HPSE exerts this effect focusing on the FGF10 pathway, as it has been explored by others that it may act through an enzyme activity-dependent pathway by releasing HS and the bound growth factors or through an activity-independent pathway by clustering syndecan on cell surface and acting on Rac1 pathway that acts on epithelial cell polarity. Funding by FAPESP (Proc.09/16150-6).

Aurora Kinase-A deficiency impairs skin stratification.

E. C. Torchia[1], L. Zhang[1], A. J. Huebner[1], S. Sen[2], D. Roop[1]; [1]Dept. of Dermatology and Center for Regenerative Medicine and Stem Cell Biology, University of Colorado Denver Anschutz Medical Campus, Aurora, CO, [2]Dept. of Molecular Pathology, University of Texas M.D. Anderson Cancer Center, Houston, TX

Aurora Kinase-A (Aurora-A) is a mitotic regulator that promotes the timely entry into mitosis, centrosome maturation and formation of bipolar spindles. Although highly studied as an oncogene implicated in epithelial cancers, its role in developing skin or tissue homeostasis remains poorly understood. To characterize the role of Aurora-A in skin development, we deleted Aurora-A by interbreeding *K14.Cre* mice with mice containing a floxed Aurora-A allele (*Aurora-A^{fl}*). *Aurora-A$^{fl/fl}$;Krt14.Cre* mice died shortly after birth. The skin of these mice was translucent and histological evaluation showed the epidermis was thin, lacked hair follicles and displayed areas of frank erosion. Although marker analysis revealed the expression of basal layer markers, Krt5 and Krt14 and differentiation markers, Krt1, Krt10, and loricrin in *Aurora-A$^{-/-}$* skin, there was a marked reduction in the number of basal and suprabasal layers and dye exclusion assays showed defects in barrier function. To further characterize the effects of Aurora-A deficiency, we examined embryonic skin between 13 to 14 dpc at the stage when the epidermis begins to stratify. Unlike wildtype cells, *Aurora$^{-/-}$* basal progenitors were delayed in forming two layers as revealed by histological examination and by the late appearance of Krt1 and Krt10 positive subrabasal cells. We observed a concomitant increase in cells in mitosis as well as induction of apoptosis. Furthermore, *Aurora-A$^{-/-}$* keratinocytes were polyploid, indicating that proliferating cells did not complete mitosis but exited prematurely. *Aurora-A$^{-/-}$* keratinocytes also displayed centrosome abnormalities including apparent monopolar spindle structures. At later stages of development, the position of the nuclei relative to the centrosome appeared random, instead of the predominant perpendicular orientation to the dermis of basal keratinocytes seen in *Aurora-A$^{+/+}$* skin. Thus, the deletion of Aurora-A in the developing epidermis may alter the polarity of basal cells and markedly impaired their ability to divide and stratify.

1849

EB1, p150Glued and Clasp1 control apical polarization of acetylated tubulin during vascular tube formation in 3D matrices.

D. KIM[1], L. Martinez-Lemus[1], G. E. Davis[1]; [1]Medical Pharmacology and Physiology, University of Missouri-Columbia, Columbia, MO

Endothelial cell (EC) polarity is a necessary aspect of vascular morphogenesis. However, the molecular mechanism of vascular endothelial cell polarity during this event remains elusive. Here, we show that microtubule tip complex proteins are fundamental regulators of EC lumen formation by affecting EC apical-basal cytoskeletal polarity and tubulin post-translational modifications which are necessary for these events in 3D matrices. Using confocal microscopy, we find a striking cytoskeletal polarity during this process whereby filamentous actin is oriented basally while tubulins including acetylated and detyrosinated tubulin are oriented apically. Also, acetylated and detyrosinated tubulins are strongly induced during lumen formation. Furthermore, elevated SIRT2 and histone deacetylase 6 levels leads to reduced EC lumen formation and concomitant loss of acetylated tubulin while siRNA suppression of SIRT2 leads to increased lumen formation. These observations motivated the hypothesis that a primary mechanism for EC lumen formation is the establishment of asymmetric EC polarity which creates a polarized cytoskeleton that differentially supports the apical (microtubule-rich) versus basal (actin-rich) plasma membrane. siRNA suppression of EB1, p150Glued and Clasp1 leads

to marked blockade of vascular lumen formation, including inhibition of a Src, Pak, Raf and Erk protein kinase cascade. In addition, there is marked blockade of tubulin acetylation and detyrosination which accompanies a loss in EC apical-basal cytoskeletal polarity in 3D collagen matrices. In addition, we observe sub-apical co-localized staining for p150Glued and Clasp1. Re-expression of EB1 fully restores vascular tube formation in EB1 siRNA treated ECs but EB1 mutants fail to rescue this phenotype. We, therefore, propose that EB1, p150Glued and Clasp1 regulate vascular morphogenesis by affecting tubulin acetylation and apical-basal endothelial cell polarization.

1850

Roles of Noggin, a BMP antagonist, in proper development of the mammalian notochord and foregut.

S. Fausett[1], J. Klingensmith[2]; [1]Cell Biology, Duke University, Durham, NC

The mammalian trachea and esophagus, parallel tubes with distinct identities and functions, arise during development from a single anterior foregut tube. Although malformations of the trachea and esophagus are common human birth defects (~1:3,000 live births), the morphogenetic and cellular processes that govern anterior foregut development are understudied. A growing number of rodent models now exist with which to study both the normal compartmentalization of the trachea and esophagus, and the abnormal development that leads to foregut malformations. One model, the Noggin (*Nog*) null mouse, very closely recapitulates the common foregut malformation esophageal atresia with tracheo-esophageal fistula (EA/TEF) with 75% penetrance. This particular malformation consists of an esophagus that ends rostrally in a blind pouch, and a communication between the trachea (or lungs) and the stomach. NOG is a secreted Bone Morphogenetic Protein (BMP) antagonist, but the mechanism by which loss of *Nog* causes EA/TEF is unknown. One possibility is that *Nog* expressed near the time of foregut compartmentalization is essential for this process. Another, arising from the fact that *Nog* mutants have large and disorganized notochords, is that resolution of the notochord from the dorsal foregut endoderm (future esophagus) early in embryogenesis can impact the potential of the foregut to compartmentalize later. Therefore, there are two *Nog* expression domains that conceivably play a role in the proper compartmentalization of the anterior foregut into the trachea and esophagus: 1) the dorsal foregut endoderm, and/or 2) the notochord. We have used tissue- and time-specific manipulation of *Nog* and the BMP pathway in mouse embryos to determine the spatio-temporal requirements for BMP antagonism in the process of foregut compartmentalization. Our results indicate a key role for NOG secreted from early axial structures in attenuating BMP signaling within these axial structures, rather than only in the developing foregut. In conjunction with other published results and careful histological and immunological observations of the *Nog* mutant notochord, these data suggest that an early embryological event, the improper resolution of the notochord from the dorsal foregut endoderm, can cause EA/TEF. Ongoing and future work aims to determine the cell biological consequences of abnormally high BMP signaling on notochord cells as they resolve from the dorsal foregut endoderm.

Could a Malformed Feather be a Melanocytes' Immune Response?

L. C. Straker[1]; [1]IBCCF, UFRJ, Rio de Janeiro, Brazil

Avian feathers are very complex epidermal appendages (Lucas & Stettenheim, 1972). During its development longitudinal cell planes will form barb ridges and barbule plates in the follicle (Maderson *et al*, 2009). Between these plates, supporting cells are source of cellular structures for the adult feather. Structures such as melanosomes are produced by the supporting cells

(melanocytes) and distributed to the barb ridge and barbule cells (keratinocytes) at early stages of the feather development (Maia *et al*, 2011). The melanosomes are rod or spherical structures composed primarily by melanin, although during its development it is possible to observe many internal membranaceous structures (Durrer & Villiger, 1967). Thus, in a Transmission Electron Microscopy (TEM) micrograph it is possible to see that the melanosome is not equally electron dense, there is some internal organisation. The use of Scanning Transmission Electron Microcopy (STEM) enhances the perception of an internal texture. In a simple coloured feather, melanosomes will not differ greatly, therefore similar texture and density is seen in its melanosomes. Another aspect of melanocytes, other than the production of melanosomes, is its capability to respond to an inflammation or a microbial infection (Mackingtosh, 2001). Melanogenesis is stimulated and further production of melanin is a signal of an immune response (Le Poole *et al*, 1993). As any tissue, feathers are subjected to inflammation or microbial during its development. We prepared flight feather barbs of Procellariiformes for TEM following Shawkey *et al* (2003) and observed it in STEM. Inflammatory-like tissue showed melanosomes different to barb melanosomes. This shows that in birds, melanocytes may have immune system properties, as observed in reptiles (Jonhson *et al*, 1999). The melanosomes present in such outgrowth showed different internal texture and different morphology. Some melanosomes were greatly fused, not being possible to distinguish them as rod or spherical. Even the ones that could be individualised were larger than those observed in the barb. Differently from the normal barb melanosomes, these had a random orientation. Therefore, it is possible to speculate that inflammatory responding melanocytes will produce melanosomes with different characteristics than melanocytes which produce melanosomes for the feather tissue. Further investigation on melanocytes of deformed or microbial-attacked feathers will help to understand the role of melanocytes in feather development.

Connective Tissue Growth Factor Expression in Post-natal Epididymal Development.

R. B. Johnson[1], A. Lucchese[1], J. Riddle[1], P. S. Howard[1]; [1]Anatomy and Cell Biology, University of Pennsylvania School of Dental Medicine, Philadelphia, PA

Objective: To determine epididymal cell type, region and segment specific expression of the connective tissue growth factor (CTGF) gene promoter and protein throughout murine post-natal development.
Methods: CTGF-enhanced green fluorescent protein (CTGF-EGFP) transgenic male mice were sacrificed at 7, 14, 21, 28, 35, 42, 49, and 56 days post natal (DPN) and analyzed by fluorescence microscopy. CTGF promoter activity was determined by presence of EGFP. CTGF protein, aquaporin 9 protein (AQP9) – a principal cell marker, and vacuolar proton ATPase subunit B2 (B2) protein - a clear cell marker, were detected by immunofluorescence. CTGF mRNA expression was assessed by in situ hybridization (ISH).
Results: At 7 DPN, weak CTGF promoter activity was detected in 80 ± 2% of luminal epithelial cells (LECs) in all epididymal segments. CTGF promoter activity diminished in LECs of only the initial segment and corpus in a time dependent manner beginning at 14 DPN, decreasing to 5 ± 4% of LECs at 56 DPN. In contrast, EGFP staining intensified in the caput and cauda, with 80% of the LECs staining. However, segments 5 and 8 were characterized by a small reduction in the number of positively stained LECS, (35-60%). A large number of cells which were positive for EGFP also exhibited apical AQP9 protein staining, marking these LECs as principal cells. Clear cells expressed B2 protein, but lacked CTGF promoter activity. CTGF protein was detected at the apical surface of LECs and in peritubular muscle of all regions. ISH of 7 and 28 DPN tissue revealed CTGF mRNA expression in LECs in a region and segment specific pattern.

Conclusions: CTGF promoter activity appears to be tightly regulated in principal cells in different epididymal regions and during the stages of sexual maturation. The increased intensity of EGFP staining post 21 DPN in principal cells of the caput and cauda along with apical CTGF protein accumulation coincides with LEC differentiation. This, plus the gradual loss of CTGF promoter activity in the initial segment and corpus with increasing development, possibly indicates a role for CTGF in establishing divergent states of differentiation in principal cells of different segments. CTGF promoter activity was observed in a vast majority of principal cells in the caput and cauda, but not in clear cells. mRNA expression appeared to mimic promoter activity.

Ectoderm mediated nitric oxide signaling regulates early skeletal muscle (myotome) formation in somites of chicken embryos.

F. Ghamsari[1], W. Denetclaw[1]; [1]Biology, San Francisco State University, San Francisco, CA

Nitric Oxide (NO), a short-lived messenger molecule, plays significant roles in animal physiology. NO is produced by nitric oxide synthases (NOS), utilizing L-arginine with oxygen and NADPH, and signals primarily by the NO/sGC/cGMP pathway. In adult muscle, NO stimulates activation of muscle stem cells in muscle fiber regeneration and regulates myoblast differentiation. In the chicken embryo, dynamic NO increases were previously reported in the ectoderm layer, but its role is unknown in the regulation of skeletal myogenesis (or primary myotome formation) in somites. To investigate, the ectoderm layer of chicken embryos was treated with 50-100 mM L-NAME, a competitive inhibitor of NOS, for a brief 6-hr period with subsequent myotome formation assessed by titin immunofluorescence and confocal microscopy. The L-NAME treatment period allowed formation of 4 new somites and embryos tested had between 6-38 somites (Hamburger and Hamilton stages 8-20). L-NAME treated embryos (n=53) produced delays in the start of myotome formation by 1-3 somites over the control embryos (n=87) in the range of embryos tested. The trends for both populations with best-fit line equation was y=1.233x-12.18, R^2=0.99 for control and y=1.223x-13.40, R^2=0.96 for L-NAME, with x and y representing embryo age in somite numbers and last somite level expressing titin, respectively. Embryos between 11-14 somites expressed myotome for the first time and only in the 3 cranial-most somites (n=15). Myotome formation in control and L-NAME treated embryos was also biphasic for titin expression in somites and contrasted with previously reported triphasic myotome expression in somites based on desmin immunofluorescence. A comparison of quantitative analysis of titin and desmin expression revealed that titin is expressed earlier than desmin by one somite level. We conclude that NO signaling in the embryo ectoderm layer regulates early myotome formation in somites and myogenesis is a biphasic event being prevented until HH 10-11 and later activated in the 3 cranial-most somites then progressing caudal-ward by 1.2 somites with every new somite produced. SJJ2, as a Novel Cardiac Factor, involved in Myocardial Differentiation and early embryonic heart development.

S. Jeon[1], C-J. Lim[1], G. Oh[1]; [1]Laboratory of Cardiovascular Genomics, Division of Life and Pharmaceutical Science,Ewha Womans University, Seoul, Korea, Seoul, Korea

Despite several advances in identification of cardiac transcription factors, there are still needs to find new molecules that directly control cardiomyogenesis from ESCs (embryonic stem cells) to highly efficient myocardial differentiation. To identify novel cardiac factor, we performed Illumina expression microarray. SJJ2 was significantly increased in the mESCs (mouse ESCs)-derived

cardiomyocytes, and characterized as a cardiac factor in myocardial differentiation and early embryonic development. First, we generated mESCs expressing eGFP (enhanced green fluorescent protein) under direction of ¥á-MHC (¥á-myosin heavy chain) gene promoter that specifically works in functional cardiomyocytes. After established GFP expressing mES cell line, we screened novel cardiac factors in ESCs-derived cardiomyocytes using Illumina expression microarray. 276 genes were upregulated (¡Ã 4 fold) in mESCs-derived cardiomyocytes compared undifferentiated ESCs. Among them, SJJ2 is one of the novel signaling molecule candidates, and its function has not yet been analyzed. We confirmed that SJJ2 expression is increased at the initial stage of ESCs differentiation into functional cardiomyocytes. Also, the level of SJJ2 transcription and translation were transiently increased on C2C12 myoblast differentiation into myotubes. Interestingly, we found that the secreted form of SJJ2 can have a potential to be a signaling molecule. Furthermore, we confirmed that SJJ2 is expressed in the developing heart at 9.5-11.5d.p.c embryos. Taken together, our results indicate that SJJ2 was expressed during myocardial differentiation and early embryogenesis. Through which, SJJ2 has the potential to serve as an important factor in early embryonic heart development.

1855

Rncr3 (retinal non-coding RNA 3), which encodes miR-124a, is required for hippocampal axon development and retinal cone photoreceptor survival through Lhx2 suppression.

R. Sanuki[1], T. Furukawa[1]; [1]Developmental Biology, Osaka Bioscience Institute, Suita, Japan

MiRNAs are small RNAs that regulate gene expression by base-pairing to mRNAs. Interestingly, miR-124a is completely conserved at the nucleotide level from worms to humans, and estimated to be the most abundant miRNA in the brain. In our screen identifying functionally important molecules in the retina, we isolated a mouse Rncr3 Rncr3 (retinal non-coding RNA 3) cDNA which is highly expressed in the retina, and found a stem loop of precursor microRNA-124a-1 (pre-miR-124a-1), which is encoded on an Rncr3 exon.To address the function of miR-124a in vivo, we generated Rncr3 knockout mice by replacing all Rncr3 exons with the PGK-neo cassette.We detect that miR-124a was reduced in the Rncr3$^{-/-}$ mouse central nerves system (CNS), especially in the retinal presumptive photoreceptor cell layer (PPL), where cone photoreceptor neurogenesis occurs, and the hippocampal dentate gyrus. Rncr3$^{-/-}$ mutant mice exhibit abnormalities in the CNS, including small brain size, axonal mis-sprouting of DG granule cells, and retinal cone cell death. We found that Lhx2 is an in vivo target mRNA of miR-124a. We also observed that LHX2 down-regulation by miR-124a is required for prevention of apoptosis in the developing retina and proper axonal development of hippocampal neurons. These results suggest that miR-124a plays an essential role in maturation and survival of DG neurons and retinal cones by repressing Lhx2 translation.

1856

Gender differences in social interaction but not crooked tail phenotype in prenatally valproic acid exposed rats.

P. Kim[1,2], K. C. Kim[2], S. J. Jeon[1,2], S-Y. Han[3], C. Y. Shin[1,2]; [1]School of Medicine, Konkuk University, Seoul, Korea, [2]SMART Institute of Advanced Biomedical Sciences, Konkuk University, Seoul, Korea, [3]College of Pharmacy, Gyeongsang National University

Both in human and rodents, exposure to valproic acid (VPA) during fetal developmental period causes teratogenic effects on developing nervous system and produces autistic behavioral symptoms. VPA induced autistic-like behavior such as reduced sociability and social preference as well as reduced threshold against electroconvulsive seizure only when it administered to pregnant rats during the short critical periods (E12). Prenatal exposure to VPA also induced crooked and shortened tail, which might be regarded as the mildest form of neural tube defects.

Interestingly, the altered social behavior is most prominent in males with crooked tail phenotype compared with female animals even though there was no gender difference in the occurrence of crooked tail. Regardless of the occurrence of crooked tail, rat offsprings did not show any defects in motor coordination suggesting that the crooked tail phenotype is not related to the gross motor defects. These results suggest that male rats are more vulnerable to defects in social interaction compared to female animals even with similar neural tube defects phenotype. VPA animal model of autism may provide excellent animal model to study the molecular basis of gender differences of autistic behavior.

1857

Tissue-specific stiffening of embryos parallels myosin and matrix expression and dynamically matches cell function: a focus on embryonic heart.

S. F. Majkut[1], J. Swift[2], D. E. Discher[2]; [1]Physics and Astronomy, University of Pennsylvania, Philadelphia, PA, [2]Chemical and Biomolecular Engineering, University of Pennsylvania

During development, the establishment of mature tissue mechanics at the proper time and place is essential for cellular differentiation and function. Here we study the maturation of embryonic cardiac and neural tissue mechanics in parallel with the effects of extracellular mechanics on individual cell function and structure throughout early development. We used micropipette aspiration to measure local and bulk elastic moduli (E) of embryonic avian heart and midbrain tissue from days 2-12. We observe stiffening of the early heart tube from E = 1 kPa at day 1 to E = 2 kPa at day 4, reaching neonatal values by day 14. Brain tissue does not stiffen and behaves viscoelastically. Treating the tissues with blebbistatin led to ~30% decrease in E for heart and ~50% decrease in E for brain, indicating a significant but partial actomyosin contribution to mechanics at these stages. Treating tissues with collagenase softens heart tissue significantly, but has no effect on neural tissue mechanics, indicating the important role or ECM in establishing cardiac mechanics even at early stages. We performed a quantitative proteomic analysis of HH 3-5 embryos along with 2-4 day heart tubes and midbrains by mass spectrometry to and find that many cytoskeletal protein and collagen levels follow these mechanical trends. Isolated cardiomyocytes from 3-4 day chick embryos were cultured on collagen-coated PA gels of various stiffnesses. Beating magnitude and cytoskeletal organization was modulated by substrates with E~2 kPa, similar to physiological E at those stages.

1858

ROCK 1-directed basement membrane positioning coordinates epithelial tissue polarity.

W. P. Daley[1,2], S. W. Centanni[1], K. M. Gulfo[1], D. A. Nelson[1], M. Larsen[1]; [1]Biological Sciences, University at Albany, SUNY, Albany, NY, [2]Graduate program in Molecular, Cellular, Developmental, and Neural Biology

The basement membrane underlying epithelial cells is critical for epithelial tissue organization and function. However, the mechanisms by which the basement membrane is restricted to the basal periphery of epithelial tissues are not well defined, and basement membrane-mediated signals regulating coordinated tissue organization remain poorly understood. Here, we report that a Rho kinase (ROCK)-mediated, myosin-independent pathway controls coordinated tissue organization by restricting basement membrane to the epithelial basal periphery in the developing submandibular salivary gland (SMG). This ROCK-mediated pathway coordinately aligns individual cell polarity within the tissue via basal basement membrane positioning, and yet is not required for designation of an apical membrane in individual epithelial cells. PAR-1b functions downstream of ROCK 1 to regulate tissue polarity and is specifically required for basement membrane positioning since inhibition of PAR-1b kinase activity with either targeted siRNA knockdown or overexpression of a kinase dead PAR-1b construct prevents basement

membrane deposition and disrupts overall salivary gland epithelial tissue organization. Significantly, culture of salivary epithelial cells and organ explants in the presence of exogenous basement membrane (Matrigel) rescues epithelial organization in the presence of ROCK 1 and PAR-1b inhibition. This basement membrane-mediated, outside-in signal requires functional integrin beta1 to maintain epithelial cell adhesions since they are partially disrupted with integrin beta1 function-blocking antibodies. Taken together, these studies indicate that a ROCK 1/Par 1b pathway is required to maintain tissue polarity in developing epithelium through regulation of basement membrane placement.

Stem Cells and Pluripotency

Post-Translational Regulation of Microtubules during Human iPS Reprogramming.

C. Simerly[1], C. Easley IV[1], C. Redinger[1], J. Barringer[1], D. McFarland[1], G. Schatten[1]; [1]Division of Developmental and Regenerative Medicine, Department of Obstetrics, Gynecology, and Repro, University of Pittsburgh, Pittsburgh, PA

Induced pluripotency (iPS) with human stem cells provides unique patient-specific, disease-bearing pluripotent cell lines (PSCs) important to biomedical investigations, and yet the underlying molecular mechanisms responsible for iPS have not been fully elucidated. Notwithstanding the progress in understanding the roles of transcription factors and epigenetic chromatin modifications being made, research on the cytoplasmic mediators of reprogramming remain largely unexplored. Here, we present evidence that post-translationally modified microtubules (PTM), including those which comprise the centrioles in the mitotic spindles poles of human pluripotent stem cells (hPSCs), are relevant to human iPS derivation. α-Tubulin can be acetylated at lysine 40 and monoclonal antibodies to acetylated α-tubulin detect centrioles of human somatic and pluripotent stem cells at mitosis, with only weak localization in spindle pole or cytoplasmic microtubules. Cold and drug depolymerization of microtubules does not abolish centriole acetylated α-tubulin, while microtubule enhancement with paciltaxel dramatically increases cytoplasmic microtubule staining with concomitant loss at the centrioles. Rescue experiments from microtubule depolymerization show unique cold and drug resistant microtubule cables distinct from the first dynamic microtubules that reassemble from the centrosomes, which are not acetylated. While the epigenetic regulation of chromatin by post-translationally modifying histones through histone acetyltransferases (HATs) and histone deacetylases (HDACs) are well known, cytoplasmic counterparts have not been explored. HDAC6 is unique in not residing within the nucleus but being localized mainly to the cytoplasm where it functions in the deacetylation of cytoplasmic targets like acetylated-microtubules, heat-shock protein (HSP)- 90 and cortactin. Tubastatin-A (TubA; 5nM-10µM), an inhibitor to HDAC6, induces the loss of centriole acetylation with a massive increase in spindle microtubule acetylation in all human PSCs but without detectable affects on histones, HSP90, or cortactin as observed by Western blots. Furthermore, TubA prevents iPS reprogramming by blocking PSC colony formation as observed by morphology and no live cell SSEA-4 pluripotency marker expression. These investigations focus on the role of the cytoplasm and cytoskeleton in mediating the events of nuclear reprogramming, and demonstrate tight cooperation between nuclear dynamics and cytoskeletal plasticity. We conclude that post-translational modifications of microtubules, in addition to transcriptional regulation, are essential for iPS derivations and represent an unappreciated example of ‘**Cytoplasmic Post-Translational Reprogramming**.

Migration of aberrantly persisting neural stem cells in Drosophila.

S. Siegrist[1], I. Hariharan[1]; [1]MCB, UC Berkeley, Berkeley, CA

Neuroblasts are the neural stem cells of the developing Drosophila brain and divide asymmetrically to produce all neurons present in the adult brain. Unlike mammals and even some insects, no new neurons are generated in the adult brain of Drosophila and neuroblasts do not persist. Previously, we determined that two pathways function in parallel to ensure that a subset of neuroblasts are properly eliminated during development, which is essential for ensuring proper adult brain size and inhibiting excess neuron production(1). Insulin/PI3 kinase signaling, which is a highly conserved cellular and organism growth signaling pathway, becomes attenuated in neuroblasts prior to the time of their disappearance, which then primes growth impaired neuroblasts for elimination via an apoptotic-dependent cell death program. Unexpectedly, we observe that some of the apoptotic-inhibited brain neuroblasts that aberrantly persist into adulthood migrate to a brain region rich in neurosecretory neurons, including those that secrete insulin-like peptides. This is unusual since neuroblasts are not migratory and are never found in this brain region. Once positioned here, aberrantly persisting neuroblasts have increased proliferation rates and survive longer than neuroblasts failing to migrate, suggesting this region may provide an environment permissive for neuroblast growth and survival. Currently we are investigating whether diffusible factors attract neuroblasts to the neurosecretory region, and if so, what these factors may be.

Midbodies contribute to cellular reprogramming and tumorigenicity by evading autophagy.

T-C. Kuo[1], C-T. Chen[1], D. Baron[1], T. T. Onder[2], S. Loewer[2], C. M. Weismann[1], G. Q. Daley[2,3], S. Doxsey[1]; [1]Molecular Medicine, UMass Medical School, Worcester, MA, [2]Stem Cell program, Children's Hospital Boston, Boston, MA, [3]Howard Hughes Medical Institute, Chevy Chase, MD

The midbody (MB) is a nonmembranous organelle formed between daughter cells during cell division and is required for the final cell separation event in late cytokinesis. Over 500 proteins comprise the MB, many of which are required for cytokinesis, cell fate determination, and chromosome segregation. After cell division, the post-mitotic MB, or midbody derivative (MBd), can be retained and accumulated in cells. However, the fate and function of these MBds have not been elucidated. In this study we investigated the nature of cells that accumulate MBds, the mechanisms by which MBds accumulate, and the effects of MBd enrichment. By immunohistochemical and immunofluorescence analyses, we found that MBds selectively accumulated in stem cells, induced pluripotent stem cells (iPSCs), and potential cancer 'stem cells' (CSCs) in vivo and in vitro. While in normal proliferating non-cancer, non-stem cells MBd-accumulation was not observed. Remarkably, MBds were reduced upon differentiation of human embryonic stem cells, and increased upon induction of pluripotency in fibroblasts. By modulating protein degradation pathways, we found that MBd-accumulation was mainly controlled by receptor-mediated autophagy. In differentiating and normal dividing cells possessing high autophagic activity, MBd degradation occurred soon after cytokinesis and was mediated by binding of the autophagic receptor, NBR1, to the MB protein Cep55. In contrast, stem cells and cancer cells exhibited low autophagic activity, thus MBds evaded

autophagosome encapsulation and were accumulated. To address MBd function, we first enriched MBd+ cells by depleting NBR1. This enhanced reprogramming of fibroblasts to iPSCs and increased in vitro tumorigenicity of cancer cells. Similarly, high MBd+ cell populations enriched by FACS-isolation also formed more colonies on soft agar compared to low MBd+ populations. Together, our data suggest new roles for post-mitotic MB in maintaining or enhancing pluripotency in stem cells and CSCs. These findings also reinforce the idea of autophagy as a cell makeover process, in which MBds are a target that requires autophagic removal upon loss of pluripotency.

1863

Ectopic expression of *Lhx2* in muscle satellite cells inhibits their myotube differentiation.

Y. Kodaka[1,2], K. Kitajima[1], R. Matsuda[2], T. Hara[1]; [1]Stem Cell Project Group, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan, [2]Graduate School of Arts and Sciences, The University of Tokyo, Tokyo, Japan

Despite of many efforts, a clinically promising therapeutic method against congenital muscular dystrophy has not been established yet. Transplantation of muscle satellite cells derived from immunologically compatible human induced pluripotent stem cells (iPSCs) is a recently proposed strategy. Muscle satellite cells are tissue resident stem cells to replenish myoblasts to regenerate functional skeletal muscle fibers in response to muscle damage. However, only a limited amount of satellite cells can be induced from iPSCs by currently available protocols. To overcome this problem, we attempted an ectopic expression of LIM-homeobox transcription factor Lhx2, which has been recently proven effective for robust amplification of transplantable hematopoietic stem cells from mouse embryonic stem cells (ESCs) and iPSCs *in vitro*. (Blood, 117: 3748-3758, 2011). We employed the previously established *in vitro* differentiation method for ES-derived muscle satellite cells: i.e. embryoid body formation followed by subculture in matrigel-coated plates. Retroviral infection of *Lhx2* gene in differentiating mouse ESCs resulted in increased frequency of satellite cell marker positive cells. In addition, we found that overexpression of *Lhx2* completely inhibited myotube differentiation of C2C12 cells and primary culture of muscle satellite cells isolated from adult mice. Expressions of Myogenin and Myosin heavy chain were severely suppressed in *Lhx2*-transduced C2C12 cells under the culture condition for differentiation, whereas transcription of *Msx1* and *Msx2* genes encoding de-differentiation inducing homeobox transcriptional repressors was initiated. These results demonstrate that ectopic expression of *Lhx2* is effective for blocking terminal differentiation of muscle stem cells by changing the genetic program related to skeletal muscle specification in mesenchymal cell lineage. Stage-specific expression of *Lhx2* could be utilized for obtaining relatively larger amount of skeletal muscle satellite cells from differentiating iPSCs.

1864

FGFR2 Mediates Rapid and Reversible Nanog Repression through the Proximal Promoter Region.

K. E. Santostefano[1], T. Hamazaki[1], N. Terada[2]; [1]University of Florida, Gainesville, FL

Nanog-positive epiblasts and Gata6-positive primitive endoderm cells co-exist and are convertible to each other within the inner cell mass of murine early blastocysts and their in vitro counterpart embryonic stem (ES) cells. Previous studies identified fibroblast growth factor receptor 2 (FGFR2) is responsible for triggering Nanog gene downregulation and subsequent differentiation into PE; however the underlying molecular mechanism responsible for reversible and fluctuating cell fate is poorly understood. Using an inducible FGFR2 dimerization system, we demonstrate that FGFR2 downregulated Nanog gene transcription rapidly within 1 hour in

ES cells, reaching about 90% inhibition within 6 hours. This downregulation of Nanog was accompanied by accumulation of RNA Polymerase II at the transcription start site and occurred without an increase in repressive histone methylation marks, implying regulation is likely in the early and transient phase of gene repression. Moreover, the proximal promoter region of Nanog containing the minimum Oct4/Sox2 binding site was sufficient for Nanog transcriptional downregulation by FGFR2 using insulated and integrated reporter constructs. Interestingly, using chromatin immunoprecipitation, we found Oct4 and Sox2 transcription factors, which are essential for positive Nanog transcription, remain bound to the proximal promoter region. Taken together, these data support a model of reversible Nanog repression at this stage. Consistent with this, addition of a specific inhibitor of FGFR readily reversed Nanog repression induced by FGFR2 dimerization. These findings illustrate well how FGFR2 induces rapid but reversible Nanog repression during early embryonic development.

1865

Syndecan-3 in the Muscle Stem Cell Niche: Implications for Tissue Maintenance, Regeneration and Muscular Dystrophy.

A. Pisconti[1], B. B. Olwin[1]; [1]MCD-Biology, University of Colorado at Boulder, Boulder, CO

Adult skeletal muscle maintenance and regeneration is carried out mainly by a population of resident stem cells named satellite cells, which can remain quiescent in their niche for long periods of time. In response to injury satellite cells activate, proliferate and differentiate to regenerate the damaged tissue in addition to self-renew in order to maintain the muscle stem cell pool throughout an entire life. In muscular dystrophy repeated cycles of degeneration/regeneration eventually exhaust satellite cells leading to progressive loss of regenerative capacity and to muscle wasting. Satellite cells express syndecan-3 that is required for Notch processing and signaling. Syndecan-3 null (Sdc3-/-) satellite cells show impaired proliferation and self-renewal, however Sdc3-/- muscles retain full regenerative capacity in response to up to three subsequent rounds of injury-induced regeneration. When Sdc3-/- mice are crossbred to dystrophic mice, syndecan-3 loss in dystrophic mice leads to improved muscle tissue integrity and function. A number of observations strongly suggest that syndecan-3 loss leads to long-term maintenance of a population of transit-amplifying muscle progenitors that accounts for enhanced regenerative response and resistance to disease progression in dystrophic mice. Syndecan-3 is a component of the satellite cell niche and our results show that manipulation of the satellite cell niche can dramatically impact satellite cell homeostasis and muscle regeneration, providing a promising model to study the molecular mechanisms that regulate satellite cell “stemness”. Furthermore, our studies represent a powerful platform to design new therapeutic strategies to treat conditions where muscle regeneration is impaired, such as: ageing, muscular dystrophy, cancer-induced cachexia and severe trauma.

1866

Dichotomic role of NAADP/two-pore channel 2/Ca2+ signaling in regulating neural differentiation of mouse embryonic stem cells.

Z. Zhang[1], J. Yue[1]; [1]Department of Physiology, University of Hong Kong, Hong Kong

The mobilization of intracellular Ca^{2+}stores is involved in diverse cellular functions, including cell proliferation and differentiation. At least three endogenous Ca^{2+}mobilizing messengers have been identified, including inositol trisphosphate (IP_3), cyclic adenosine diphosphoribose (cADPR), and nicotinic adenine acid dinucleotide phosphate (NAADP). Similar to IP_3, NAADP can mobilize calcium release in a wide variety of cell types and species, from plants to animals. Moreover, it has been previously shown that NAADP but not IP_3-mediated Ca^{2+}increases can potently induce neuronal differentiation in PC12 cells. Recently, two pore channels (TPCs) have

been identified as a novel family of NAADP-gated calcium release channels in endolysosome. Therefore, it is of great interest to examine the role of TPC2 in the neural differentiation of mouse ES cells. We found that the expression of TPC2 is markedly decreased during the initial ES cell entry into neural progenitors, and the levels of TPC2 gradually rebound during the late stages of neurogenesis. Correspondingly, perturbing the NAADP signaling by TPC2 knockdown accelerates mouse ES cell differentiation into neural progenitors but inhibits these neural progenitors from committing to the final neural lineage. Interestingly, TPC2 knockdown has no effect on the differentiation of astrocytes and oligodendrocytes of mouse ES cells. Overexpression of TPC2, on the other hand, inhibits mouse ES cell from entering the neural lineage. Taken together, our data indicate that the NAADP/TPC2-mediated Ca^{2+}signaling pathway plays a temporal and dichotomic role in modulating the neural lineage entry of ES cells; in that NAADP signaling antagonizes ES cell entry to early neural progenitors, but promotes late neural differentiation.

1867

High-throughput screening identified chemical compounds regulating human embryonic stem cell pluripotency.

Y. Geng[1], Y. Zhao[2], E. Zelin[1], Y. Xu[3], H. Lu[3], D. Lynn[1], B. Feng[1], K. Austin[1], J. Stoklosa[1], J. Morrison[1], M. Tyl[1], J. Cheng[4], B. Freeman[1], J. Liao[2], F. Wang[1]; [1]Department of Cell and Developmental Biology, University of Illinois at Urbana-Champaign, Urbana, IL, [2]Department of Bioengineering, University of California, Riverside, [3]Department of Materials Science and Engineering, University of Illinois at Urbana-Champaign

The application of high-throughput screening (HTS) to the research of human embryonic stem cells (hESCs) has been hampered by many technical difficulties. In order to use HTS to improve our understandings of the molecular mechanisms underlying hESC pluripotency and differentiation while by-passing technical challenges associated with the hESC platform, we developed a human embryonal carcinoma cell-based assay suitable for discovering chemical compounds that induce hESC differentiation. Use of this assay has led to the identification of 122 chemical compounds (out of 170,000 screened) that directed differentiation of hESCs. One of the molecules specifically targeted the constitutively expressed heat-shock protein HSC70; shRNA knock-down confirmed HSC70 as an essential regulator of hESC pluripotency. Our results demonstrate feasibility of a new and improved method for adapting HTS to hESC research, and provide a pool of novel candidates of chemical compounds for manipulating hESC fate.

1868

A Conserved Program for Stem Cell Dormancy.

L. Margaretha[1,2], D. C. Jones[3], C. Song[1], A. Nelson[1], B. H. Mecham[4], R. N. Wilson[1], J. Shendure[5], C. B. Ware[4,6], W. L. Ruzzo[3,5], C. A. Blau[4,7]; [1]Institute for Stem Cell and Regenerative Medicine, University of Washington, Seattle, WA, [2]Graduate Program in Molecular and Cellular Biology, University of Washington, Seattle, WA, [3]Department of Computer Science and Engineering, University of Washington, Seattle, WA, [4]SAGE Bionetworks, [5]Department of Genome Sciences, University of Washington, [6]Department of Comparative Medicine, University of Washington, [7]Department of Medicine/Hematology, University of Washington

The ability to reversibly transition to a state of quiescence allows tissue specific stem cells to persist lifelong, and cancer stem cells to resist therapy. However the mechanisms that underlie stem cell quiescence are poorly understood. Here we outline the molecular framework of stem cell quiescence in a mouse model of delayed blastocyst implantation, also known as diapause. We performed RNA sequencing to characterize the transcriptional profiles of pluripotent stem

cells extracted from embryos at three distinct developmental stages: pre-implantation, post-implantation, and during diapause. Our analysis of diapause-associated gene expression points to a program for stem cell quiescence that links the coagulation and metabolic sensing pathways with calcium influx, autophagy, cholesterol synthesis and the induction of Runx1. Portions of these same pathways support dormancy in lower organisms and quiescence in other stem cell types.

1869

Comparison of autophagy in mesenchymal stem cells derived from bone marrow and chorionic plate in placenta by hypoxia.

Y. Lee[1], J. Jung[1], J. Gong[1], J-W. Park[2], G. Kim[1]; [1]Department of Biomedical Science, CHA University, Seoul, Korea, [2]Department of Pharmacology, Seoul National University College of Medicine

Hypoxia triggers physiological and pathological cellular fate such as proliferation, differentiation and death in several cell types. Mesenchymal stem cells (MSCs) derived from several tissues have potentials for self-renewal activity and differentiation towards multiple lineages. However, it should be overcome that the lower yields of MSCs isolated since the rate of self-renewal and differentiating capacity decrease with age of the donor in cell therapy. Recently, it has been reported that hypoxic condition induces the balance between survival and death by hypoxia-induced autophagy, however, the underlying mechanism is not clear. Therefore, the objectives of this study are to analyze the prolifertion in bone marrow-derived mesenchymal stem cells (BM-MSCs) and chorionic plate-derived mesenchymal stem cells in placenta (CP-MSCs) under hypoxia and investigate the regulation mechanisms of self-renewal in each MSC under hypoxic condition. Furthermore, we compared the difference between PDSCs and BM-MSCs by hypoxia-induced autophagy. The effect of hypoxia on the self-renewal of PDSCs and BM-MSCs was performed by RT-PCR, FACS analysis and Western blot against self-renewal factors. Also, we carried out monodansylcadaverine (MDC) staining and immunofluorescence against LC3 for detection of autophagosomes in MSCs exposed to hypoxia. The expression of self-renewal markers (e.g. Oct4, Nanog, Sox2) was expressed in both cell lines. The expression of Oct4 was more increased in BM-MSCs than CP-MSCs under hypoxic condition. In FACS analysis, the rates of S phase in CP-MSCs and BM-MSCs under hypoxia were 8.77 % and 4.85 %, respectively. In addition, the expression of PI3K was gradually increased in CP-MSCs, otherwise, it was remarkably downregulated in BM-MSCs by hypoxia. The expressions of p-ERK and p-mTOR were induced by hypoxia compared to normoxia in CP-MSCs. The expression of LC3 II, which is a component of autophagosome and the hoof-shaped autophagosome in CP-MSCs were more rapidly progressed than BM-MSCs under hypoxia. Taken together, hypoxia triggers autophagy in CP-MSCs and BM-MSCs and autophagy more activated in CP-MSCs than in BM-MSCs.

1870

The Effect of Type-1 Diabetes on Differentiation of Rat Mesenchymal Stem Cells.

J. J. Prince[1], D. P. Gray[1], F. Conyers[1], A. Peister[1]; [1]Department of Biology, Morehouse College, Atlanta, GA

According to the American Diabetes Association, 23.6 million, eight percent of the United States population, suffers from diabetes. Diabetes has a well-documented increased healing time for fracture healing (two to three times the normal rate). This delay also increases the risk of complications, such as delayed union or non-unions. The decreased bone formation may be due to an increase level of TNF-α seen in diabetes. High levels of TNF-α has been linked to an

accelerated loss of cartilage in fracture healing. Mesenchymal stem cells, or MSCs, are the source of stem cells for bone healing.
The overall objectives of this research thrust is to characterize and quantitatively compare the functionality of the MSCs from diabetic rats, as compared to non-diabetic littermates, to determine if a loss of MSC function is responsible for the decreased bone repair noted in Diabetes. The MSCs have an immunomodulatory effect and under normal conditions can decrease the levels of TNF-α in the body. We hypothesize the impairment of bone healing in diabetes is due to both a decrease in MSC function from being in a diseased environment as well as a decreased immunomodulatory effect leading to an increase in TNF-α. The function of the MSCs will be determined by quantifying the bone, fat and cartilage differentiation capabilities.
In this experiment, mesenchymal stem cells (MSCs) were isolated from diabetic rats (Streptozotocin-induced type I diabetes) and their healthy littermates for comparison. MSCs were isolated from diabetic and control-treated rats 6 weeks after Streptozotocin administration. Currently, the differences in differentiation abilities of the MSCs from diabetic rats are being compared to the MSCs from sham-treated littermates. Specifically, differentiation of bone and fat will be examined and quantified. Changes in gene expression will be analyzed during the differentiation.
Eight lines of diabetic and control rat mesenchymal stem cells have been isolated, purified and expanded. The results thus far show the diabetic MSCs have a similar if not slightly increased potential for adipogenic differentiation. Conversely, the diabetic MSCs have a decreased potential for differentiation into osteoblasts, demonstrated by a decreased mineralized matrix production and an attenuated gene expression response.

1871

Effect of Korean mistletoe for self-renewal activity in placenta-derived stem cells.

J. Choi[1], H. Lee[1], S. Lyu[2], W-B. Park[3], G. Kim[1]; [1]Department of Biomedical Science, CHA University, Seoul, Korea, [2]Department of Pharmacology, Sunchon National University, [3]College of Natural Sciences, Seoul Women's University

Mesenchymal stem cells (MSCs) derived from various tissues are powerful sources for cell therapy in the degenerative medicine although there are obstacles to overcome their limited self-renewal. Recently, placenta-derived stem cells (PDSCs) have been reported as an alternative source to bone marrow–derived mesenchymal stem cells (BM-MSCs) due to the characteristics of multilineages, immunosuppressions and self-renewal. Korean mistletoe, which is a natural product isolated from hemi-parasitic plants, has been known to have cytotoxicity in cancer cells. However, there are still unknown whether Korean mistletoe in stem cells has cytotoxicity or not. Therefore, the objectives of the study were to analyze the effects of Korean mistletoe in the cultivation of MSCs, compare the difference according to the cell types (e.g. naïve PDSCs, immortalized PDSCs by hTERT over-expressing), and evaluate the correlation between Korean mistletoe and self-renewal of PDSCs. The cytotoxicities of naïve PDSCs, immortalized PDSCs, and HepG2 cells exposed to Korean mistletoe (1~10,000pg/ml) were analyzed using MTT assay. The cytotoxicities of HepG2 and immortalized PDSCs were induced at 1pg/ml of the mistletoe, while the proliferation of naïve PDSCs were significantly increased at low concentration of the mistletoe (1pg~10pg/ml) without cytotoxicity ($p<0.05$). Also, the expressions of cyclin D1 and phosphorylated ERK were increased in naive PDSCs exposed to the mistletoe. From these results, Korean mistletoe have cytotoxicity in cancer cells including immortalized PDSCs, however, they also enhance the self-renewal in PDSCs through the ERK signaling. Therefore, Korean mistletoe could be used as an anti-cancer drug in cancer as well as a supplement for the cultivation of MSCs to enhance self-renewal activity.

MafA Restoration Improves the Expression Profile of Genes Specific for Islet β-Cells in Mouse Embryonic Progenitor-derived Insulin-producing Cells.

S. Shao[1], J. Zhang[1], G. Li[1]; [1]Dept of Clinical Research, Singapore General Hospital, Singapore, Singapore

Derivation of functional insulin-producing cells from stem cells is a promising approach to develop transplantation therapy for curing insulin-dependent diabetes. We generated a dozen of expansible and glucose-responsive insulin-producing cell lines (e.g. MEPI and ERoSHK) by differentiating mouse embryonic stem or progenitor cells. Though these cells could correct hyperglycemia after transplanted into diabetic animals, they revealed features of immaturity displaying higher un-regulated insulin release and moderate mitotic activity in vivo. MafA (v-maf musculoaponeurotic fibrosarcoma oncogene homolog A) is a master transcription factor implicated in controlling islet β-cell development and glucose responsiveness; its expression was significantly lower in our insulin-producing cells in comparison with isolated mouse islets. In this study, MafA levels in mouse embryonic progenitor-derived insulin-producing (MEPI)-1 cells were largely restored by transfecting vectors expressing MafA, as confirmed by real-time RT-PCR, immunofluorescence staining and immunoblotting. MafA restoration significantly enhanced (2-5 fold) expression of genes for proteins important for β-cell development and functions which are expressed low in MEPI cells. These include Nkx6.1 (a transcription factor playing an important role in pancreatic β-cell development), glucagon-like peptide-1 (GLP-1) receptor [GLP-1 is a powerful incretin protecting β-cells, promoting β-cell growth and enhancing glucose-stimulated insulin secretion (GSIS)], Ins1 and Ins2 (both for insulin biosynthesis), PCSK1 (encoding a key prohormone convertase required for processing of proinsulin into mature insulin), Glut2 (important for glucose transportation across cell membrane, the first step in GSIS), glucokinase (an essential hexokinase that catalyzes glucose metabolism to generate ATP and serves as a principal controller for insulin secretion in response to rising levels of glucose), and Kir6.2 (a major subunit of ATP-sensitive inwardly rectifying potassium channel involved in a key signaling scenario that couples glucose metabolism to GSIS). Moreover, microarray analysis of gene expression profile in MafA-restored MEPI-1 cells revealed recovering of altered levels of several transcripts for proteins involved in the signalling pathways for susceptibility to diabetes onset and development, e.g. casitas b-lineage lymphoma (Cbl), FK506 binding protein 12-rapamycin associated protein (Frap) 1/mammalian target of rapamycin (mTOR), CCAAT/enhancer binding protein (CEBP)-β, FBJ osteosarcoma oncogene (Fos) and Kruppel-like factor 10 (Klf10). Importantly, the expression of p27, an inhibitor of cyclin-dependent kinases controlling cell cycle and proliferation, was significantly enhanced by 1.5 fold in MEPI-1 cells after MafA up-regulation. Thus, our data suggest that MafA can optimize embryonic stem cell-derived insulin-producing cells and enhance their functions by improving gene expression profile resembling primary islet β-cells.

Tumor Invasion and Metastasis

1873

In Vivo Imaging of Tumor Associated Collagen Signatures.

J. Szulczewski[1], P. A. Young[1], D. Inman[2], P. J. Keely[2], K. W. Eliceiri[1]; [1]LOCI, University of Wisconsin, Madison, WI, [2]Molecular Biology, University of Wisconsin, Madison, WI

Stromal reorganization has been associated with the progression of breast cancer. The importance of the stroma and specifically the extracellular matrix (ECM) has been highlighted

through the identification of mechanical signaling pathways in which cell-ECM adhesion points have increased the activity of RhoGTPases and thus cell contractility and motility. These associations have implicated that stromal reorganization, and more specifically changes in collagen alignment, are a potential biomarker for the invasion and progression of breast cancer. Non-linear optical techniques, including Second Harmonic Generation (SHG) and Multiphoton Laser Scanning Microscopy (MPLSM), have been a useful tool in studying disease progression and ECM reorganization. These imaging modalities are not only compatible with genetically tagged fluorescence markers and intrinsic signatures such as that from collagen but can also detect these changes non-invasively with cellular scale resolution deep within intact tissue. Thus together MPLSM and SHG are powerful non-invasive methods to study cancer cell and collagen architecture interaction. Recently we have been able to identify Tumor Associated Collagen Signatures (TACS) in vivo by use of MPLSM, SHG, and a Mammary Imaging Window (MIW). These intravital imaging techniques allow us to optically section approximately 300 microns into a progressing breast tumor in vivo in our mouse model. We have also been able to map out the entire collagen layout in excised breast tumor slices from the mouse models through stitching multiple fields of view together into one large image montage. These new techniques are helping to elucidate the role that ECM reorganization has in the invasion and progression of breast cancer.

1874

Role of stiffness and force response in integrin mediated signaling and metastasis.

V. Swaminathan[1], K. Mythreye[2], C. Guilluy[3], E. O'Brien[3], G. C. Blobe[4], K. Burridge[3], R. Superfine[3]; [1]NHLBI, NIH, Bethesda, Md, [2]Dept. of Medicine, Duke University, [3]University of North Carolina, Chapel Hill, [4]Duke University

In cancer, changes in cellular phenotypes are characterized by altered cytoskeletal architecture as well as disruption of signal transduction pathways controlling proliferation, angiogenesis and apoptosis. Recent studies have shown that mechanical properties of the cytoskeleton as well as its force sensing capability are critical in maintaining
normal functions and the mechanism for this balance is currently an active area of research.We recently showed that in ovarian cancers, mechanical stiffness of cells show an inverse relationship with their invasive potential and by altering this relationship, we can alter the phenotype. We also have shown that the Rho signaling pathway is critical in force sensing and recently discovered 2 RhoGEFs, LARG and GEFH1 which regulate the mechanical stiffness and response to force on integrins. Here we combine the 2 systems to show that it is GEFH1 that regulates the mechanical stiffness dependent cell invasion behavior in ovarian cancer cells and by selectively targeting this pathway, we can alter the metastatic behavior in these cells. Our results show that the GEFH1-RhoA pathway may be a critical pathway in loss of mechanotransduction associated with cancer and a potential target for therapy.

1875

Lamin A/C Directs Nuclear Stiffness, 3D Cell Migration and Tumor Propagation.

T. Harada[1], J. Swift[1], D. Discher[1]; [1]Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA

Cancer cell migration is an essential process of tumor propagation and metastasis, and therefore has significant contribution to its malignancy. The efficiency of cell migration in tissue is determined by several factors such as contractile force generated by actomyosin activity, ability to secrete enzymes remodeling extracellular matrix, and importantly mechanical properties of migrating cell. In the present study, we hypothesized that cell nucleus, the biggest and stiffest cell organelle, plays an essential role in determining cell mechanics in the context of

migration through physically constraining environment. Here strong emphasis is placed on the expression of inner nuclear membrane-associated protein lamin A/C, which is known to be a major determinant factor for nuclear stiffness. Lamin A/C down-regulation by short interfering RNA (siRNA) in A549 lung carcinoma cells resulted in softening of their nuclei and increased migration efficacy through 3 m-sized pores in the presence of nutrition gradient, whereas wound scratch healing assay showed that lamin A/C knockdown had no remarkable effect on 2D migration on cell culture dish. Furthermore, fluorescent-labeled A549 cells with initial lamin A/C knockdown by 40% were injected in immuno-deficient mice along with control cells to compare the difference in growth and expansion of tumor over 4 weeks. A549 tumors with initially decreased lamin A/C expression showed higher proliferation rate than control tumors up to 2 weeks, which nicely matched with the duration of temporal siRNA knockdown observed *in vitro*. Importantly, although lamin A/C-knockdown and control cells did not show a significant difference in protein expression profile before injection to mice, proteomic analysis revealed that A549 cells acquired new phenotype after growing as a tumor for 4 weeks *in vivo*.

1876

Physical mechanisms in cancer: the transition to metastasis.

P. Lee[1,2], C. W. Wolgemuth[1,2]; [1]Department of Cell Biology, University of Connecticut Health Center, Farmington, CT, [2]Center for Cell Analysis and Modeling, University of Connecticut Health Center, Farmington, CT

In cancer, one of the most significant factors that influence the prognosis for a patient is whether or not the cancer is metastatic. The transition from a non-metastatic tumor to a metastatic one is accompanied by a number of changes in the proteins that are expressed within the tumor cells. These changes must somehow conspire to produce a behavioral change in cell, and even multi-cellular, behavior: cells that were happy staying in one place begin to move, often as a group. Here we ask the question of what cell-level biophysical changes are sufficient to transition a static tumor to a metastatic one. We use a mathematical model developed to describe the biophysics of epithelial tissue to explore this problem. We find that moderate increases in cell-ECM adhesion accommpanied by a decrease in cell-cell adhesion can cause a group of cells to break free from a tumor and spontaneously migrate. This result may explain why some metastatic cells have been observed to up-regulate integrin and down-regulate cadherin.

1877

Autophagy supports migration, invasion, and differentiation driven by oncogenic Ras.

R. Lock[1], C. Kenific[1], J. Debnath[1]; [1]Pathology, University of California, San Francisco, San Francisco, CA

The pro-tumor functions of autophagy, a tightly controlled cellular self-digestion process, have been largely attributed to its ability to promote tumor cell survival. Here, we demonstrate a previously unrecognized requirement for autophagy in facilitating extracellular matrix (ECM) invasion and tumor cell motility in cells transformed with oncogenic Ras. RNAi-mediated depletion of critical autophagy genes (ATGs) profoundly inhibits the invasive behavior of H-Ras^{V12} MCF10A cells in three-dimensional (3D) culture. This reduction in invasive capacity correlates with a partial restoration in cell-cell junctional integrity and polarized secretion of the basement membrane protein, laminin 5. In addition, H-Ras^{V12} MCF10A cells and MDA-MB-231 cells, a K-Ras mutant breast cancer cell line, display reduced motility following ATG knockdown. Importantly, the invasive behavior of Ras-transformed epithelial cells is associated with an epithelial-mesenchymal transition (EMT), and ATG knockdown partially reverses Ras-driven mesenchymal differentiation, by enhancing the expression of *e-cadherin* and *keratin 14*, and reducing *fibronectin* and *vimentin* expression. Interestingly, upon co-culture with autophagy

competent cells, the invasive capacity of autophagy deficient cells in 3D is restored; indicating decreased secretion of pro-invasive factors in ATG knockdown cells. In support of this finding, we observe decreased transcription of *wnt5a* and *mmp2* and reduced MMP2 activity in conditioned media following autophagy inhibition. Both factors are critical mediators of this phenotype as treatment of H-Ras^{V12} MCF10A 3D structures with an MMP-2 inhibitor was sufficient to suppress invasion, and the addition of recombinant Wnt5a rescued the invasive capacity of autophagy depleted H-Ras^{V12} cells. Our results reveal new roles for autophagy in supporting tumor cell migration, invasion, and differentiation, and we propose autophagy may facilitate dissemination and metastasis during the later stages of tumorigenesis.

1878

Cortactin phosphorylation regulates cell invasion through a pH dependent pathway.

M. Magalhaes[1], D. Larson[1], C. Mader[2], J. Bravo-Cordero[1], H. Gil-Henn[2], M. Oser[1], A. Koleske[2], J. Condeelis[1]; [1]Anatomy and Structural Biology and Gruss Lipper Biophotonics Center, Albert Einstein College of Medicine of Yeshiva University, Bronx, NY, [2]Department of Molecular Biophysics and Biochemistry and Department of Cell Biology, Yale University

Invadopodia are invasive protrusions with proteolytic activity uniquely found in tumor cells. Recent work has shown that cortactin phosphorylation is a key step during invadopodium maturation, regulating Nck1 binding and cofilin activity. The precise mechanism of cortactin-dependent cofilin regulation and the roles of this pathway in invadopodium maturation and cell invasion are not fully understood. We show that cortactin:cofilin binding is regulated by local pH changes at invadopodia that are mediated by the sodium-hydrogen exchanger NHE1 (NHE1). Furthermore, cortactin tyrosine phosphorylation mediates the recruitment of NHE1 to the invadopodium compartment where it locally increases the pH to cause the release of cofilin from cortactin. In particular, we show that this mechanism involving cortactin phosphorylation, local pH increase and cofilin activation regulates the dynamic cycles of invadopodium protrusion and retraction and is essential for cell invasion in 3D. Together, these findings identify a novel pH-dependent regulation of cell invasion.

1879

Invadopodia formation and microvesicle release are required for cancer cell extravasation in vivo.

H. S. Leong[1], A. Robertson[1,2], C. MacMillan[1,3], A. Ablack[1], V. McPherson[1], E. A. Turley[1], A. F. Chambers[1,2], J. D. Lewis[1,2]; [1]Oncology, London Health Sciences Centre, London, ON, Canada, [2]Medical Biophysics, University of Western Ontario, London, ON, Canada, [3]Pathology, University of Western Ontario, London, ON, Canada

During the metastatic process, cancer cells must undergo trans-endothelial migration from the vessel lumen into underlying tissue in a process known as extravasation. Little is known about the dynamic mechanical aspects of this process. To address this, we performed real-time, sub-cellular resolution intravital imaging of human cancer cells during arrest, intravascular migration and extravasation using a shell-less avian embryo xenograft model. We find that extravasation occurs at endothelial junctions and that the majority of extravasation events occurred during the 12 hours subsequent to the intravenous injection of cancer cells. In the majority of extravasation events, long cytoplasmic extensions identified as invadopodia were observed prior to extravasation which breached underlying endothelium. We observed the release of microvesicles during these invadopodial extension events prior to extravasation, and this resulted in a ~40% reduction in cell volume post-extravasation. Based on this, we hypothesized that invadopodia are required for extravasation, and that cancer cell extravasation could be abrogated by inhibiting factors required for invadopodia function. We found that treatment with

Src kinase inhibitors significantly reduced invadopodia formation in vivo and resulted in a ~60% decrease in extravasation events when compared to vehicle treated controls. In conclusion, we determined that 1) extravasation occurs at junctions between adjacent endothelial cells, 2) cancer cells form invadopodia that breach the endothelial layer prior to successful extravasation and 3) cancer cells undergoing extravasation release cancer microparticles into both the vessel lumen and tissue interstitium with a corresponding decrease in cell volume. Pharmacological inhibition of invadopodia by Src kinase inhibition reduces cancer cell extravasation, revealing an important mechanism of action against metastatic cancers.

1880

Cytoskeletal Regulation of Transendothelial Tumor Cell Migration.

M. Roh-Johnson[1], S. Alford[2], F. Gertler[2], J. Condeelis[1]; [1]Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, [2]Koch Institute For Integrative Cancer Research, MIT, Cambridge, MA

Most cancer patients die as a result of metastasis. Spread of metastatic cancer cells by blood circulation is responsible for most of the distant metastases, thus it is important to understand the molecular mechanisms that regulate intravasation. Tumor cells and endothelial cells dynamically alter their cytoskeletons and adhesive properties during this process. Previous results have shown that rat mammary adenocarcinoma cell lines that express an invasive isoform of Mena (MenaINV), a key regulator of the actin cytoskeleton, exhibit a dramatic increase in transendothelial migration in vitro in the presence of macrophages (Roussos et al. JCS, 2011). MenaINV has also been shown to localize to invadopodia, actin-rich structures that degrade matrix. To determine whether the formation of invasive structures such as invadopodia is required for efficient transendothelial migration, we took advantage of the high incidence of transmigration exhibited by cells expressing MenaINV. We imaged transmigration in real-time by co-opting an organotropic assay (Nakatsu and Hughes. Methods Enzymol, 2008) to grow blood vessels in a 3-dimensional matrix. We found that human breast cancer cells form protrusions that exhibit oscillatory movements as the tumor cells probe the surface of the endothelium. We also found that MenaINV is enriched in the protrusions at the site of tumor cell-endothelial cell contact, and that these protrusions penetrated through the endothelium into the blood vessel. These results suggest that tumor cells form invadopodia to break through the endothelial barrier during intravasation. Further studies exploring this hypothesis as well as addressing adhesion dynamics are on-going.

1881

Dynamin 2 Potentiates Invasive Migration of Pancreatic Tumor Cells through Stabilization of the Rac GEF Vav1.

G. Razidlo[1], Y. Wang[1], J. Chen[1], D. Billadeau[2], M. McNiven[1,3]; [1]Center for Basic Research in Digestive Diseases, Mayo Clinic, Rochester, MN, [2]Department of Immunology, Mayo Clinic, Rochester, MN, [3]Department of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN

Tumor cell migration is an important component of the metastatic process. The large GTPase Dynamin 2 (Dyn2) has recently been identified as a potent activator of pancreatic cancer cell dissemination (Eppinga, et al., Oncogene 2011), and is also known to play a role in the Rac-mediated formation of lamellipodia. The mechanisms by which Dyn2 might modulate Rac activation to upregulate the migratory process are undefined. In this study we have found that Dyn2 is required for Rac activation in pancreatic cancer cells, and that this activation is mediated through a direct interaction with the Rac GEF Vav1. Importantly, Vav1 has been shown to be expressed ectopically in pancreatic cancers, and this expression correlates with

tumor invasion and lethality (Fernandez-Zapico, et al., Cancer Cell 2005). We have identified a direct binding between Dyn2 and Vav1 in pancreatic cancer cells, and subsequently observed that disrupting this interaction markedly impairs both Rac activation and the subsequent formation of lamellipodia that are required for migration of these neoplastic cells. Surprisingly, disruption of the Dyn2/Vav1 interaction dramatically reduces Vav1 protein stability and subsequently attenuates Rac activation. The effects of Dyn2 on Vav1 protein levels and Rac activation are independent of Dyn2 enzymatic activity and identify a novel structural role for Dyn2 in Rac activation and lamellipod protrusion. Thus, the large GTPase Dyn2 can regulate the activation of a small GTPase, Rac, through a previously unreported effect on GEF protein stability, and is a potent mechanism by which pancreatic cancer cells upregulate the migratory and metastatic program. This study was supported by CA104125 to M.A.M. G.L.R. was supported by T32 CA148073.

1882

Pituitary tumor transforming gene 1 (PTTG 1) regulate invasion activity of human oral squamous cell carcinoma via integrin-mediated FAK signal.

S. Lee[1], J. Choi[2], W-H. Kim[3], J. Kim[4], S-K. Lee[1]; [1]Department of Oral Pathology, College of Dentistry, Gangneung-Wonju National University, Gangneung, Korea, [2]Department of Biomedical Science, CHA University, [3]Department of Pathology, College of Medicine, Seoul National University, [4]Department of Oral Pathology, College of Dentistry, Yonsei University

Human pituitary tumor-transforming gene 1 (PTTG1), which is a newly identified proto-oncogene, overexpress in many nonendocrine-related tumors as well as endocrine-related cancers. Also, PTTG1 has been known to involve in the regulation of cell-cycle via securin function and in progression of tumor. However, the function and the regulation mechanism of PTTG1 in oral squamous cell carcinoma (SCC) remain still unclear. The objectives of the study are to analyze the expression of PTTG1 in oral SCC and evaluate the mechanism for invasion of oral SCC cell lines (YD-10B and YD-15) depends on PTTG1 expression by siRNA. The expressions of PTTG1 in oral SCC tissues and oral SCC cell line were analyzed by immunohistochemistry and Western blot, respectively. The expression of invasion-related factors (e.g. MMP2/-9, integrins, TIMPs) and the invasion activity in oral SCC cells transfected siRNA-PTTG1 were measured by Western blot and Metrigel assay system. The expression of PTTG1 in oral SCC tissues was mainly observed in cytoplasm, although it partially localizes in the nucleus in oral SCC. The invasiveness of oral SCC cells using Metrigel was significantly increased after PTTG1 plasmid transfection comparing to Mock ($p<0.05$). There is no difference expression for MMP-2 regardless of PTTG1 siRNA treatment. However, the enzyme activity of MMP-9 was significantly decreased. In addition, migration activities of oral SCC cells were significantly decreased after PTTG1 siRNA treatment ($p<0.001$). In addition, down-regulated PTTG1 induced alterations of integrins in oral SCC cell lines through the phosphorylations of FAK1 and mTOR. These results suggest that alteration of PTTG1 could be regulated invasion activity of human oral SCC via integrin-mediated FAK signaling. Therefore, these findings provide useful guideline for the migration mechanism of oral SCC by PTTG1 expression.

1883

Phosphorylation Regulates TWIST1-mediated Breast Cancer Cell Invasion.

Y. Teh[1,2], Y-H. Lin[1,2], S. Li[2], G. Lowe[2], C. Glackin[2], J. Liu[1]; [1]Biological Sciences, California State Polytechinc University, Pomona, Pomona, CA, [2]Neurosciences, Beckman Research Institute, City of Hope, Duarte, CA

TWIST1 belongs to the family of basic helix-loop-helix (bHLH) transcription factors. The regulatory role of TWIST1 in mesodermal tissue development has been well established in

Drosophila and mouse models. We and others have shown that TWIST1 plays an important role in cell invasion and TWIST1 expression level is aberrantly high in metastatic breast cancer cells. Phosphorylation of TWIST1 has been reported to stabilize TWIST1 protein, inhibit p53-mediated apoptosis in response to DNA damage, and regulate nuclear localization of TWIST1. We hypothesized that phosphorylation of TWIST1 regulates TWIST1-mediated cell invasion. To address our hypothesis, we mutated a conserved threonine (T) residue into alanine (A) or aspartic acid (D) to generate a phosphodeficient (T148A) or phosphomimic (T148D) TWIST1.

Our previous results demonstrated that TWIST1 promotes cell invasion by inducing the expression of Interleukin-8 (IL-8). This IL-8 induction is mediated by the physical association between TWIST1 and RELA in the NF-κB transcriptional complex. In addition, we observed changes in the cell invasive properties in response to overexpression of T148A and T148D mutants. Therefore, to investigate whether phosphorylation at T148 affects the association between TWIST1 and RELA that leads to changes in cell invasion, we performed co-immunoprecipitation (Co-IP) experiments using T148A and T148D mutants in comparison with wild-type TWIST1. Co-IP results showed significant changes in binding affinity of TWIST1 and RELA as a result of the mutations, and these results were confirmed by additional IL-8 promoter activity assays.

In conclusion, our results suggested that phosphorylation at T148 is essential for TWIST1-mediated cell invasion by regulating the physical interaction between TWIST1 and RELA. This study provides valuable information on the relationship between post-translational modifications of TWIST1 and the onset of cancer cell invasion. Knowledge gained from this study may lead to the identification of therapeutic targets that affect TWIST1 function and will be useful for developing novel anti-metastatic drugs for advanced breast cancer.

1884

Distinct effects of EGF and LPA on cell migration dynamics during breast cancer progression.

M. Weiger[1], V. Vedhem[1], C. Stuelten[1], K. Shou[1], M. Herrera[2], W. Losert[2], C. Parent[4];
[1]Laboratory of Molecular and Cellular Biology, National Cancer Institute, NIH, Bethesda, MD, [2]Department of Physics, University of Maryland, College Park, MD, [4]Laboratory of Molecular and Cellular Biology, National Cancer Institute, NIH, Bethesda, MD

During cancer progression, subsets of cancer cells break away from the primary tumor and invade distal sites within the body. This process of metastasis is associated with alterations in the migratory potential of cancer cells. Direct observation of migration behaviors of cancer cells as they progress towards metastasis is still lacking. Using an established cell-line model for breast cancer progression, we assessed the impact of both cancer progression and extracellular stimuli on the migratory abilities of cancer cells. Specifically, we focused on the consequence of activated receptor tyrosine kinase (EGF-EGFR) and G-protein coupled receptor (LPA-EDG2) signaling on cell migration. Using live-cell imaging and particle image velocimetry analysis, we monitored and measured the migration dynamics of an epithelial sheet (normal, early tumor, pre-metastatic, and metastatic cells) as it migrates into open space with or without uniform stimulation (EGF or LPA). Under basal conditions, early tumor and pre-metastatic sheet-edges infiltrate into open space at the highest rates (0.81 ± 0.11 and 0.49 ± 0.18 µm/min, respectively). Surprisingly, both normal and metastatic cells infiltrate at lower rates (0.26 ± 0.15 and 0.25 ± 0.18 µm/min, respectively). We also found that normal breast epithelial cells and early tumor cells exhibited directional and collective sheet migration, while independent and random motions were prevalent in more metastatic cells. In response to uniform EGF stimulation, both normal and metastatic cells exhibited increases in migration rate (80% and 53%, respectively),

while pre-metastatic cells showed only a modest rise (18%) and early tumor cells remained unchanged. The motion dynamics of migration in all four cell-types remained largely unchanged under EGF stimulation. LPA treatment induced a more spread morphology in all cell-types and again lead to an increases in the migration rate of normal, pre-metastatic and metastatic cells as compared to basal conditions (90%, 23% and 41%, respectively). Interestingly, some metastatic cells treated with LPA appeared to abandon their random movements and instead migrated as a cohesive sheet similar to normal breast epithelial cells. Western blotting and immunofluorescence studies suggest that differences in E-cadherin and β̃catenin expression and localization may contribute to the distinct migration behaviors observed. Together, we demonstrate that the migration dynamics of epithelial cells dramatically changes as they transition from a normal to metastatic state. In addition, our data highlight how different external cues can distinctly regulate migratory behaviors.

1885

Phosphatase dysregulation mediates EGF sensitivity in Mena^{INV}-positive breast cancer cells.

S. Alford[1,2], M. Kai[1], L. Ritsma[3], I. Shapiro[1], E. Arwert[4], J. Wyckoff[4], R. Eddy[4], J. van Rheenen[3], J. Condeelis[4], D. Lauffenburger[1,2], F. Gertler[1]; [1]Koch Institute for Integrative Cancer Research, Massachusetts Institute of Technology, Cambridge, MA, [2]Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA, [3]Hubrecht Institute, Netherlands, [4]Anatomy and Structural Biology, Albert Einstein College of Medicine

Approximately 90% of human breast cancer deaths are due to metastasis of the original tumor. An ‘Invasion Signature’ has been reported for breast carcinoma cells collected *in vivo*, and includes a significant upregulation of the cytoskeletal associated protein Mena, a member of the Ena/VASP family of actin regulatory proteins. In particular, an alternatively spliced isoform of Mena, Mena^{INV}, significantly increases metastasis and the ability of carcinoma cells to respond to epidermal growth factor (EGF) *in vivo* and *in vitro*. The aim of this study was to determine the mechanism underlying Mena^{INV} induced metastatic behavior. We found that ectopic expression of Mena^{INV} in human breast cancer cell lines increases EGF sensitivity at the level of actin polymerization (lamellipodial protrusion) and 3D collagen invasion, extending our past work in rodent carcinoma models. The elevated sensitivity to EGF initiates with an increase in EGF receptor (EGFR) phosphorylation and is propagated through the PLCγ/cofilin pathway as measured biochemically and using live- and fixed-cell FRET imaging. Concomitant with increased growth factor response, EGFR-targeted therapeutics are less effective in Mena^{INV} positive cells. We found that the increase in EGF sensitivity cannot be accounted for by a significant increase in total or surface levels of EGFR or pre-clustering of the receptor, as measured biochemically and with electron microscopy. Alternatively, expression of Mena^{INV} facilitates mis-localization of a novel Mena interacting partner, the EGFR-targeted tyrosine phosphatase PTPN1 (PTP1B). Inhibition of PTP1B activity increases lamellipodial protrusion, 3D collagen invasion and EGFR signaling pathway activation in vector control cells, phenocopying the expression of Mena^{INV}. Additionally, ectopic expression of Mena^{INV} limits the access of PTP1B to EGFR upon EGF stimulation as measured by proximity ligation assay, providing a mechanism for decreased PTP1B activity. Finally, we found that inhibition of PTP1B significantly increased the EGF sensitivity of chemotaxing MTLn3 carcinoma cells *in vivo* like that measured upon ectopic expression of Mena^{INV}. These results demonstrate that phosphatase dysregulation is a key component of Mena^{INV}-mediated metastasis. We are currently using mass spectrometric approaches, combined with signaling network analysis, to determine how PTP1B dysregulation rewires the EGF-stimulated signaling pathway upon Mena^{INV} expression.

1886

Fibronectin matrix-mediated cohesion suppresses invasion of prostate cancer cells.

D. Jia[1], I. Entersz[1], C. Butler[1], R. Foty[1]; [1]Surgery, UMDNJ-Robert Wood Johnson Med Sch, New Brunswick, NJ

Invasion is an important early step in the metastatic cascade and is the primary cause of death of prostate cancer patients. To invade, cells must first detach from the primary tumor. Cell-cell and cell-ECM interactions are important regulators of cohesion, a property previously demonstrated to mediate cell detachment and invasion. The studies reported here propose a novel role for α5β1 integrin, the principle mediator of fibronectin matrix assembly (FNMA), as an invasion suppressor of prostate cancer cells. Using a combination of biophysical and cell biological methods, and well-characterized prostate cancer cell lines of varying invasiveness, we explore the relationship between cohesion, invasiveness, and FNMA. We show that cohesion is inversely proportional to invasive capacity. We also show that more invasive cells lack the capacity for FNMA and that this is associated with decreased α5β1 integrin expression. We generated cells over-expressing either wild-type α5 integrin or an integrin in which the cytoplasmic domain of α5 was replaced with that of α2. This construct does not promote FNMA. We show that only wild-type α5 integrin was able to promote aggregate compaction, to increase cohesion, and to reduce invasion of aggressive cells. These effects could be blocked by the 70 kDa fragment of fibronectin. This suggests that the mechanism of invasion suppression involves a fibronectin matrix-mediated increase in intercellular cohesion that reduces tumor cell detachment. This is a first demonstration that the fibronectin matrix can act as an invasion suppressor of prostate cancer cells. Restoring FNMA may discourage invasion and subsequent metastasis.

1887

Delta-catenin promotes angiogenesis in prostate cancer cells.

Y. He[1], H. Kim[2], H. Lee[1], Q. Lu[3], K. Kim[1]; [1]Chonnam Natl Univ, Gwangju, Korea, [2]Sunchon Natl Univ, Korea, [3]East Carolina Univ

δ-Catenin has been well known to be abundantly expressed in brain being implicated in the regulation of dendrogenesis and cognitive function. It has also been proved by accumulated evidence to express in a variety of cancer tissues, especially in prostate tumors. Recently, it has been found to express in vascular endothelium being involved in pathological angiogenesis. The discoveries above led us to ask whether δ-Catenin overexpressed in prostate tumor cells is able to induce angiogenesis contributing to the prostate tumor growth. In this study, we discovered that, similar to what has been found in endothelium, δ-Catenin overexpressed in prostate tumor cells was able to induce angiogenesis as well. We found that not only did δ-Catenin stimulate new blood vessel formation but also it accelerated tumor growth in CAM assay. We also observed that δ-Catenin increases the expression of Vascular Endothelial Growth Factors (VEGF) and promotes the secretion of VEGF protein into the media where tumor cells grew through increased HIF-1a protein expression. Furthermore, we found that -Catenin nuclear localization is increased in δ-Catenin over-expressed prostate tumor cells compared with in control prostate tumor cells under both normoxia and hypoxia condition. Taken together, our findings suggest that δ-Catenin may contribute to prostate tumors growth by inducing angiogenesis through increasing β-Catenin nuclear localization to function on HIF-1a mediated transcription or on VEGF directly. Our current study adds the novel evidence to the involvement of δ-Catenin in prostate cancer progression and also provides better understanding about how δ-Catenin promotes prostate tumors growth.

1888

Glutamate Effects on 2-Dimensional and 3-Dimensional Brain Tumor Cell Cultures.

K. Cotton[1], B. Karumuri[1], C. Agashe[1], M. Pawar[1], J. McNamara[1], S. Kanakamedala[1], M. A. DeCoster[2]; [1]Biomedical Engineering; IFM, Louisiana Tech University, Ruston, LA

Gliomas account for approximately three-fourths of all malignant brain tumors. Gliomas release the neurotransmitter glutamate by the X-c system, a sodium independent cystine-glutamate exchanger. Glutamate is also known to act as an autocrine signaling mechanism for gliomas, believed to result in tumor expansion. We have shown that glioma cells in vitro release a greater amount of glutamate compared to normal brain astrocytes, and that cystine stimulates glutamate release from glioma cells by 6.4 fold more than from astrocytes by using a novel glutamate biosensor. Here we are measuring the effect of glutamate on intracellular calcium concentration ([Ca2+]i) dynamics of 2-dimensional (2D) glioma cells in real-time, metabolic analysis of glioma cells in response to high levels of glutamate, and long term effects of 1mM and 3 mM glutamate treatments on 3-dimensional (3D) glioma spheroids. Induction of [Ca2+]i oscillations with glutamate in 2D glioma systems correlate with past publications; however, when the same concentrations of glutamate are introduced in 3D spheroid, 2D cultures undergoing deadhesion, or 2D glioma cultures over 24 hours, we observed retardation of growth, [Ca2+]i quenching, and a decrease in metabolic activity, respectively. While neurons in mixed neuronal/glial cell cultures responded with [Ca2+]i increases when stimulated with glutamate concentrations as low as 100 nM, glioma cells in culture treated with glutamate as high as 5 mM demonstrated only variable [Ca2+]i oscillations over the same time period of recording, 10 minutes. However, high concentration glutamate treatment of glioma cultures for 24 hours was toxic to these cells, resulting in a 50% toxicity effect (EC-50) of 2.6 mM glutamate. Using a novel 3D model for brain tumor growth, we have successfully demonstrated that glioma spheroids using this model grow over 400% in area over 8 days in vitro; however, subjecting spheroids to repeated additions of 1mM glutamate appear to sustain or increase spheroid area, while 3mM glutamate inhibited spheroid growth by 50% compared to controls. Using confocal microscopy combined with the vital dye calcein, we observed that mature glioma spheroids in vitro have an outer, viable cell shell with an internal necrotic region. Combined with in vivo observations and our data presented here, this raises the possibility that high concentrations of glutamate for sustained periods in brain tumors may account for necrotic core regions.

1889

Hypoxia-inducible factor 1 alpha expression and its correlations with p53, c-Myc and CD31 in glioma.

A. Zhang[1], M. Frolkis[1], J. Wu[1], P. Li[1]; [1]Epitomics,Inc., Burlingame, CA

As a key regulator of the cellular response to hypoxia, hypoxia-inducible factor-1 alpha (HIF-1 alpha) is a well-known transcriptional factor that controls genes important for the growth and metabolism of tumors. In this study, we investigated the expression of HIF-1 alpha in glioma cells and glioma tissues utilizing western blot (WB) and immunohistochemistry (IHC). We also examined the relationships of HIF-1 alpha with p53, c-Myc and CD31 in the same cell and tissue samples. WB analysis of various glioma cell lines showed a high expression of HIF-1, whereas no HIF-1 alpha expression was detected in normal brain lysate. Similar results were found with p53 expression in glioma cells. Glioma cells displayed weak expression of c-Myc. To determine whether HIF-1 alpha expression associates with glioma progression, we also performed IHC analysis of paraffin-embedded human glioma tissues of different histological grades (#14). The IHC results showed that 90% of grade 3-4 gliomas displayed strong HIF-1 alpha staining of cancer cells, compared to only 40% of grade 2 gliomas which showed HIF-1 alpha expression. As the marker of microvessels density, CD31 exhibited a high level of

expression in the late stages of glioma tissues. IHC staining of gliomas did not show a direct correlation of HIF-1 alpha with c-Myc in vivo. In summary, our results suggest that HIF-1 alpha expression strongly correlates with glioma progression and invasion, supporting the reports that HIF-1 alpha could be a potential target for glioma therapeutic research. Our data also indicated a high correlation between HIF-1 alpha and apoptotic marker p53 in glioma cells. IHC analysis on CD31 demonstrated that HIF-1 alpha affects angiogenesis in gliomas by increasing microvessels density. In the contrary to the recent HIF-1 alpha-c-Myc axis reports, we did not detect any significant HIF-1 alpha-c-Myc correlation.

1890

Fra-1 Mediated Regulation of CD44 Expression in Malignant Brain Tumor Cells.

R. D. Edmondson[1], P. Cagle[1], T. Raines[2], D. Gibo[3], W. Debinski[3], P. Martin[1]; [1]Biology, North Carolina A&T State University, Greensboro, NC, [2]University of Virginia, [3]Wake Forest University

Glioblastoma multiforme (GBM) is the most common form of primary brain tumors. It is a highly aggressive tumor, characterized by an increased proliferation rate and a high capacity to invade surrounding tissues. Currently, GBM treatment includes surgical resection followed by radiation and/or chemotherapy. However, these therapeutic options often do not alter the infiltrative and migratory capacity of GBMs. The invasive migration of glioblastoma multiforme has been associated with CD44, a cell surface glycoprotein and the principle receptor for hyaluronic acid (HA). The molecular basis of CD44 regulation regulated in GBM is not fully understood. However, CD44 regulation has been shown to be by an AP-1 transcription factor family member, fos-related antigen (Fra-1) in an equally aggressive cancer, mesothelioma. To better understand how Fra-1 regulates cell adhesion and migration, we performed adhesion and wound healing assays on human GBM cell lines. To determine whether malignant brain tumor cell adhesion is mediated by Fra-1 expression, we analyzed GBM cell adhesion to HA. U-1242 MG cells were transfected with siRNA directed against Fra-1 and treated with epidermal growth factor (EGF, 20 ng/ml). Adherence to HA increases in U-1242 MG cell lines following growth factor simulation, but was inhibited when the cells were transfected with Fra-1 siRNA. Using another GBM cell line A-172, and its clones, A-172 MW6 (Fra-1 dominant negative) and A-172 MW12 (Fra-1 overexpressors) we examined the migratory capacity of these cells. A-172 MW6 cells exhibit a slower migration rate than cells with higher levels of Fra-1 expression. Collectively, our results suggest that Fra-1 regulates CD44 expression in human GBM cells, which in turn affects GBM cell adhesion and migration.

1891

TWIST WR Domain Induces NF-κB Transcriptional Activity and Promotes Cellular Invasiveness through IL8 Production.

S. Li[1], S. Kendall[1], R. Raices[1], M. Covarrubias[1], Z. Liu[1], G. Lowe[1], Y-H. Lin[1,2], Y. Teh[1,2], V. Leigh[1], S. Dhillon[1], S. Flanagan[1], K. Aboody[1], C. A. Glackin[1]; [1]Beckman Research Institute City of Hope, Duarte, CA, [2]California State Polytechnic Institute

Metastasis is the primary cause of death for cancer patients. TWIST, an evolutionarily conserved basic helix-loop-helix (bHLH) transcription factor, was shown to promote metastatic spread to the circulatory system in a mouse model and displays elevated expression in many advanced human carcinomas. However, the molecular events triggered by TWIST to cause cancer cell dissemination are not completely understood. Here we show a novel mechanism by which TWIST induces the production of interleukin 8 (IL8), which signals autocrinely to cause metalloproteinases activation and cell invasion, key feature of a metastatic cancer. In this mechanism, the TWIST carboxy-terminal WR (Trp-Arg) domain stimulates the IL8 promoter, which is independent of the TWIST bHLH DNA binding domain. Unexpectedly, the TWIST WR

domain forms a transcriptional complex with the NF-κB subunit RELA (p65/NF-κB3) and activates the transcriptional activity of NF-κB. This protein complex associates with the IL8 promoter and increases the DNA binding affinity of RELA, thus inducing IL8 expression. Suppression of IL8 or inhibition of its receptors resulted in reduced invasiveness of breast epithelial and cancer cells. Taken together, these data demonstrate that the TWIST WR region is a functional domain that controls the activity of NF-κB and promotes cellular invasiveness.

1892

Urokinase plasminogen activator receptor induced non-small cell lung cancer invasion and metastasis requires NHE1 expression and transport activity.

J. J. Provost[1], M. A. Wallert[1]; [1]Center for Biopharmaceutical Research and Production, North Dakota State University, Fargo, ND

Non-small cell lung cancers (NSLC) are aggressive cancers that are insensitive to chemotherapies and accounts for nearly 33% of all cancer deaths in the United States. Two hallmarks of cancer that allow cells to invade and metastasize are sustained proliferation and enhanced motility. In this study we investigate the relationship between urokinase plasminogen activator (uPA)/uPA receptor (uPAR) signaling and Na^+/H^+ exchanger isoform 1 (NHE1) expression and activity. The addition of 10nM uPA increased the carcinogenic potential of three NSCLC cell lines, NCI-H358, NCI-H460, and NCI-H1299. The rate of cell proliferation was increased in an NHE1-dependent manner 1.87, 1.76, and 1.63 fold respectively for the three cell lines. The percentage of cells displaying stress fibers was also increased by uPA addition 3.17 (H358), 3.05 (H460), and 3.09 (H1299). In each case this increase was blocked when the experiments were performed with NHE1 inhibited by 10 μM EIPA (ethylisopropyl amiloride). Similarly, uPA increased anchorage-independent growth as measured by a soft-agar assay 2.0, 1.84, and 1.64 fold respectively for H358, H460, and H1299 cells. To further evaluate the role of uPA/uPAR and NHE1 in tumor progression we completed two additional studies. First, evaluating signaling events using full-length uPA compared to the uPA amino terminal fragment (ATF). Second using two new cell lines, one with reduced NHE1 expression (H460 NHE1 K/D) and one with reduced uPAR expression (H460 uPAR K/D). When comparing uPA and ATF signaling in H460 cells, we found that both uPA and ATF increased stress fiber formation 2.00 and 1.94 fold respectively, while uPA increased matrix metalloproteinase 9 (MMP9) activity 5.44 fold compared to 2.81 fold for ATF. Using the K/D cell lines we found that neither uPA nor ATF could stimulate stress fiber formation or MMP9 activity in cells with dramatically decreased NHE1 or uPAR expression. Finally, using *in vivo* tumor formation studies in athymic mice we found that when mice were injected with H460 cells 80% of mice formed tumors with an average volume of 390 mm^3. This was compared to 20% of H460 uPAR K/D injected mice forming tumors with an average volume of 15 mm^3 and 10% of H460 NHE1 K/D injected mice forming tumors with an average volume of 5 mm^3. Taken together, these data demonstrate that uPA/uPAR-mediated tumor progression and metastasis requires NHE1 in NSCLC cells and suggests a potential therapeutic approach to blocking cancer progression. Cell fusion between cancer cells induces chromosomal instability.

M. Do[1,2], I-H. Kwak[2], M-D. Kim[2], I-J. Lee[2], J-H. Lee[1,2]; [1]Department of Molecular Science and Technology, Ajou University, Suwon, Korea, [2]Department of Biochemistry and Molecular Biology, Ajou University School of Medicine, Suwon, Korea

Recent studies suggested the possibility that tetraploid cells induce aneuploidy, one of the major characteristics of most cancer cells. One of the ways to tetraploidy formation is cell fusion,

which eventually leads to a wide range of chromosomal aberrations. Notably, cell fusion increases chromosomal instability which probably is involved not only in tumorigenesis but in tumor progression. We tested whether cell fusion between cancer cells induces chromosomal instability, and whether fused cells get more aggressive phenotypes. HeLa cells were fused by electric fusion. After fusion, about 90 percent of the fused cells eventually died within 1 week. However, we could observe increased centrosome number as well as enhanced multi-polar spindles during mitosis. Therefore, the fused cells showed increase of chromosome segregation defects that are major cause of chromosomal instability. Moreover, Giemsa staining and interphase fluorescence in situ hybridization (FISH) revealed high frequency of alteration in chomosomal number, evidencing the presence of chromosomal instability. Regarding tumor progression, agarose colony generation assay and in vivo tumorigenesis assay showed wide variation between stable colonies of fused cells, but not overt increase of tumor progression. However, wound-healing assay showed 2 fold increase of cell migration in fused cells, suggesting the possibility that fusion between cancer cells can contribute cancer progression possibly via enhancement of cell migration.

1894

High-fat diet-induced obesity increases solid tumor growth and metastasis of melanoma cells in C57BL/6 mice.

J. Jung[1], S. Her[2], J. Park[1]; [1]Department of Food Science and Nutrition, Hallym University, Chuncheon, Korea, [2]Division of Bio-Imaging, Chuncheon Center, Korea Basic Science Institute, Chuncheon, Korea

Epidemiological evidence indicates that overweight and obesity increase the risk of developing several types of cancers, including colon, breast, liver cancer, and melanoma. In this study, in an effort to evaluate the effect of high-fat diet (HFD)-induced obesity on the progression of malignant melanoma, the solid tumor growth and metastasis of B16-F10 mouse melanoma cells were monitored in syngeneic C57BL/6N mice. Mice were fed on an HFD or control diet (CD) for 16 weeks and subdermally injected with B16-F10 cells into the right rear flank. The body weights and the growth of solid tumors were markedly increased in mice fed on HFD. In order to determine whether obesity stimulates cancer cell growth in mice, B16-F10-luciferase cells stably expressing firefly luciferase were injected into mice and luciferase activity was monitored using an in vivo imaging system. The mean intensity of the bioluminescence signal emitted from the B16-F10-luciferase cells was significantly higher in mice fed on the HFD as compared to those fed on CD. Immunofluorescence staining results of tumor tissue sections revealed that HFD feeding increased the protein expression levels of Ki67, CDK4, cyclin A, cyclin D1, VEGF, and VEGF receptor 2. Western blot analysis results demonstrated that the protein levels of COX-2, iNOS, p-Akt, p-ERK1/2, p-p38 MAPK, p-SAPK/JNK, p-STAT3, p-p65, p-c-Jun, and HIF-1(were increased in the tumor tissues of mice fed on the HFD. Furthermore, HFD feeding increased the number of F4/80- and PECAM-positive cells in tumor tissues. In order to determine whether HFD feeding increases metastasis, the subcutaneously injected cells were allowed to grow and establish themselves as a solid tumor for 3 weeks, and the tumor was subsequently surgically removed to prevent the rapidly growing primary tumor from causing an end-point termination of the experiment. 3 weeks later, the mice evidenced lung and lymph metastasis, which was increased in the mice fed on HFD. The serum levels of pro-inflammatory cytokines/chemokines were increased significantly in mice fed on the HFD. The results of this study demonstrate that HFD-induced obesity stimulates melanoma growth and metastasis in mice, which may be mediated via the induction of inflammation and angiogenesis.

Viability screens in cancer cells with pooled shRNA libraries identify potential therapeutic targets and synergistic lethal interactions.

D. Tedesco[1], K. Bonneau[1], M. Makhanov[1], G. Frangou[2], A. Chenchik[1]; [1]Cellecta, Inc., Mountain View, CA, [2]Fred Hutchinson Cancer Research Center, Seattle, WA

Genes modulating proliferation and survival in oncogenic cells have been identified using pooled lentiviral-based libraries expressing many thousands of shRNAs. A viability assay with leukemic and prostate adenocarcinoma cell lines transduced with these shRNA libraries targeting thousands of genes identified a few hundred essential genes for each panel of cells. Subsequent validation using single shRNA-expressing constructs showed that about 80% of the shRNAs identified in the complex library screen did in fact lead to cell death when transduced in cells. Analysis of the identified essential genes for known biological interactions revealed several non-random clusters of interacting proteins that provide some insight into signaling pathways and protein networks specific to these cancers. Also, we have recently adapted the approach to combinatorially screen shRNA sequences targeting hundreds of genes to discover additive and synergistic combinations that generate a synthetic-lethal phenotype. Analysis of the lethal combinations indicates redundant, complementary, and compensatory responses in cancer cells. This presentation will provide an overview of the screening platform, our approach to shRNA library design, and results from the screens for cancer cell-specific lethal and synthetic-lethal genes.

1896

Automated morphometric analysis of spheroid cultures.

O. Dery[1], S. Kessel[1], K. Hohenstein Elliott[1], C. Peterson[1], F. Kamme[1]; [1]Cyntellect, San Diego, CA

Spheroid cultures are very important *in vitro* models in the field of cancer research, and are believed to better represent three-dimensional cell behavior as compared with conventional two-dimensional monolayer cultures. Morphometric analyses of tumor spheroids are of particular interest in oncology research to identify new drug candidates for chemotherapy-induced apoptosis and reduction of metastasis. Morphometric analysis of these large, non-adherent multi-cellular objects is predominantly done by manual visual inspection, typically on a small subset of the total sample population. This subjective approach is slow, very inconsistent, not scalable to large samples, not amenable to high-throughput analyses (e.g., screening), or analysis over extended periods (e.g., kinetics). To address these issues, a Colony Counting application was developed on the Celigo Adherent Cell Cytometer featuring uniform full-well brightfield imaging via rapid scanning mirrors with slow gentle plate movements to reliably image spheroid cultures in multi-well (96-well to 6-well) plates and novel software for high throughput brightfield image analysis (e.g., <15 min to scan and analyze an entire 12-well plate). Results showed successful imaging and characterization of mammospheres created from several different breast cancer cell lines. Spheroid counts, sizes, and growth tracking over time were used to evaluate spheroid forming efficiency, tumorigenicity, and self-renewal of a variety of breast cancer tumor-initiating cells. In addition, the effects of several cytotoxic drugs, including doxorubicin and paclitaxel, were evaluated by repeated non-destructive and non-invasive brightfield imaging of serially-passaged mammospheres. The Colony Counting application on Celigo therefore provided an efficient, reproducible, and automated method for

imaging and assessing the number, size, and morphology of non-adherent spheroids within multi-well plates.

1897

Differentiation of Reactive Stroma in a Novel 3D Organoid Culture Model.

M. L. Stephens[1], S. Ressler[1], D. R. Rowley[1]; [1]Baylor College Medicine, Houston, TX

Prostate cancer is a disease that is prevalent among older men. The tumor microenvironment in prostate cancer is inhabited by different types of cells, such as cancer epithelial cells and stromal myofibroblasts. The mechanism whereby the interactions of these different cells promote the growth and progression of a tumor is not fully understood. Therefore, the primary objective is to better understand how the differentiation of normal stromal cells to myofibroblasts can lead to the formation of a tumor microenvironment. Our hypothesis was that there was an over-expression of certain stromal markers, within LnCAP (prostate cancer) organoid model compared to PNT1A (human prostate tissue). To test our hypothesis, normal human prostate tissue, PNT1A organoids, and LnCAP organoids were stained, using immunohistochemical techniques, to identify specific epithelial and stromal markers. These stromal markers consisted of AR (androgen receptor), which can be found in both the epithelial and stromal cells, tenascin C, vimentin, SMA (smooth muscle alpha-actin), and FAP (fibroblast activating protein); while pan-cytokeratin is an epithelial marker. After performing immunohistochemistry for cytokeratin, a control protein, our results showed that in PNT1A and LnCAP organoids, the epithelial cells made up the outer lining of the organoid, and the stromal cells were found in the inner part of the organoid. Although both organoids have epithelial cells and stromal cells within, the structure of LnCAP organoids were far less uniform than PNT1A which creates different expression standards between the two organoids. With this immunohistochemical data, identification of each of these stromal markers is feasible. Therefore, these data may help us understand the mechanism by which prostate cancer cells interact with myofibroblasts, thus leading to new treatments that could control or eradicate prostate cancer.

1898

Breast Cancer Cell Interactions.

N. E. Georgoulia[1], T. J. Mitchison[2]; [1]Systems Biology /SEAS, Harvard, Boston, MA, [2]Systems Biology, Harvard, Boston, MA

In this study, a cell culture approach is employed to identify patterns of pair-wise interaction between cancer cells over a panel of 20 established epithelial breast cancer cell lines. It is our hypothesis that different clones within a tumor, as well as different cell lines in cultured conditions, interact in one of two ways: a) by competitive growth or, b) by synergistic growth. We investigate this by culturing cell lines in serum-free conditioned medium (CM), i.e. medium which has already been used on other cell lines. Cell population growth is monitored by incubating cultures with 5-Ethyl-2'-deoxyuridine (EdU). Cell apoptosis is obtained by labeling fixed cultures with a cleaved Poly ADP Ribose Polymerase (c-PARP) monoclonal antibody. Results yield two 20x20 matrices of cell to CM interaction, and confirm that cancer cells interact through secreted substances in the medium. In an effort to trace these phenomenological interactions back to specific biochemical pathways, the interaction matrices are correlated to gene expression data available for these cell lines. Furthermore, the experiment reveals two cell lines, HCC38 and BT20, whose media produce a strong apoptotic and strong anti-proliferative effect respectively. By employing molecular weight fractionation, we attempt to isolate specific components from these media retaining the strong interaction activity.

1899

Finding novel chemical compounds with selective cytotoxic activity on human cancer cell lines using automated cellular imaging.

Y. Santiago-Vazquez[1], C. Lema[1], A. Varela-Ramirez[1], R. J. Aguilera[1]; [1]University of Texas at El Paso, El Paso, TX

Hematological malignancies are a life-threatening group of neoplastic diseases that affect a large population from children to adults. This situation is more aggravated by the fact that cancer cells develop resistance to the drugs used for their currently undergoing treatments. Moreover, drug therapies are known to cause serious side effects on patients, especially due to their non-selective activity. For these reasons, more efficiency and effectiveness therapies are needed to improve the patient's quality of life, reduce mortality, and contribute to the fields of cell biology and cancer research. The main goal of this study was to discover novel drugs with selective cytotoxicity on lymphomas, exhibiting minimal side-effects on normal cells. As proof of concept, a small library of novel chemical compounds was tested on a panel of human B- and T-lymphoma cell lines, as well as human non-tumorigenic control cells. A recently developed Differential Nuclear Staining (DNS) high throughput screening technique and flow cytometry were used to perform the analyses in triplicate using Propidium iodide to quantify loss of membrane integrity. The mode of action of the most promising cytotoxic compounds was subsequently elucidated via flow cytometry. Interestingly, the majority of experimental compounds were found to induce apoptosis with moderate specificity toward either T or B lymphomas. Ongoing experiments should reveal the cell death pathway(s) activated after compound treatment.

1900

Exploring novel diagnostic marker for breast cancer by autoantigen screening.

H. Fujiki[1], H. Takeda[1], K. Matsuoka[1], Y. Miyagi[2], A. Yoshida[3], Y. Endo[1], T. Sawasaki[1]; [1]Cell-Free Science and Technology Research Center, Ehime University, Ehime, Matsuyama, Japan, [2]Molecular Pathology and Genetics Division, Kanagawa Cancer Center Research Institute, Kanagawa, [3]Department of Breast and Thyroid Surgery, Kanagawa Cancer Center Hospital, Kanagawa

Although diagnosis marker has a potential to raise survival rate of breast cancer, no diagnosis marker is applicable for early stage breast cancer. Recently several autoantigen proteins have been found in cancer patients and they attracted attention as a novel diagnosis marker candidate. For global exploration of cancer-specific autoantigens, we developed a high-throughput screening system using AlphaScreen and biotinylated protein library (BPL) expressed by wheat germ cell-free expression system. We conducted the first screening using pooled sera from breast cancer patients, and selected 41 proteins for the second screening. The second screening revealed that seven autoantigens strongly reacted with patient□fs sera. Next, we examined expression of these autoantigens in breast cancer. His-tagged proteins were synthesized by wheat germ cell-free system, purified, and immunized to mice. Finally we obtained polyclonal antibodies for Five autoantigens. Immunoblotting using these polyclonal antibodies demonstrated that these antigens expressed in MCF-7 cell and two antigens expressed in T-47D cell but not in PrEC (normal human prostate epithelium cell).

1901

Identification of FDA-approved drugs that computationally bind to MDM2.

W. A. Warner[1], R. Sanchez[1], A. Dawoodian[1], L. Esther[1], J. Momand[1]; [1]Biochemistry, California State University, Los Angeles, Los Angeles, CA

The integrity of the p53 tumor suppressor or its pathway is compromised in the majority of cancers. In 7% of cancers, p53 is inactivated by abnormally high levels of MDM2, an E3 ubiquitin ligase that polyubiquitinates p53, marking it for degradation. The p53 protein binds to a hydrophobic cleft of MDM2 and blockage of that cleft can re-establish p53 tumor suppressor activity. Some small molecule MDM2 inhibitors have been developed but de novo drug development is marked by high costs and a lengthy timeframe. This report describes an approach for the identification of FDA-approved compounds that are suitable candidates repurposing as lead drugs for MDM2 inhibition. To this end, 241 conformers of 1,125 FDA-approved drugs were generated computationally. Drug conformer similarities to 41 computationally generated conformers of MDM2 inhibitor Nutlin 3a were ranked by shape and charge distribution. Tanimoto combo scores ranged from 0.716 to a high of 0.801 for Bepridil. In silico docking of the drugs to MDM2 was used to calculate binding energies and to visualize contacts between the top-ranking drugs and the MDM2 hydrophobic cleft. We present a subset of FDA-approved drugs that are predicted to inhibit p53/MDM2 interaction.

1902

S100A4 Inhibition: An Approach for the Prevention of Metastatic Disease.

A. R. Bresnick[1]; [1]Biochemistry, Albert Einstein College of Medicine, Bronx, NY

The leading cause of mortality in cancer patients is the consequence of malignant cells leaving the primary tumor, traveling to distant sites within the body and forming secondary tumors. From a clinical standpoint, the prevention or inhibition of metastasis is vital to the treatment of cancer. S100A4 is a member of the S100 family of calcium-binding proteins that regulates tumor cell motility via interactions with myosin-IIA and has a direct role in promoting metastatic disease. These observations suggest that S100A4 is an attractive candidate for therapeutic development. We developed three assays to screen for S100A4 inhibitors; a novel fluorescent biosensor (Mero-S100A4) that reports on the conformational rearrangements associated with Ca^{2+}–binding and S100A4 activation, a fluorescence polarization assay that monitors the interaction of S100A4 with a peptide derived from the minimal S100A4 binding site on the myosin-IIA heavy chain and a turbidity assay that directly reports on S100A4-mediated depolymerization of myosin-IIA filaments. These approaches allowed us to screen a small library of FDA-approved compounds, the LOPAC and MayBridge Hitfinder collections and approximately 20,000 ChemDiv compounds. We identified small molecules that disrupt S100A4 function by a variety of mechanisms, including small molecule-induced oligomerization and covalent modification. Our studies demonstrate that small molecule approaches can be used to disrupt the S100A4/myosin-IIA protein-protein interaction.

1903

Association of Polymorphisms and Expression of ERCC1 and XPA with the Response of Patients with Testicular Germ Cell Tumors treated with Cisplatin.

J. R. Mendoza[1], C. A. Hernández Hernández[2], E. Fabian[1], M. D. Pérez Montiel[3], C. Castro[1], J. D. Díaz[1], R. González-Barrios[1], J. Martínez[4], M. Á. Jiménez[5], L. A. Herrera[1]; [1]Biomedical Research, National Cancer Institute Mexico, Mexico City, Mexico, [2]Oncology, Hospital Regional de Alta Especialidad Mexico, Mexico city, Mexico, [3]Pathology, National Cancer Institute Mexico, Mexico city, Mexico city, [4]Oncology, National Cancer Institute Mexico, Mexico city, Mexico, [5]Surgery, National Cancer Institute Mexico, Mexico city, Mexico

Testicular germ cell tumors (TGCT) are the most common solid tumors among young men. Cisplatin-based chemotherapy cures over 80% of metastatic TGCT; nucleotide excision repair (NER) is one of the factors that modify the sensitivity to this anticancer drug. In the present study we analyzed the influence of two single nucleotide polymorphisms, which occur in two genes that codify proteins involved in NER, ERCC1 (8092C>A) and XPA (5'UTR), in the response of 101 TGCT patients treated with cisplatin (CPt). In addition, we determined the effect of these polymorphisms in the expression of ERCC1 and XPA using real time PCR in tumor samples from 31 patients. We analyzed 101 TGCT patients; DNA was extracted and genotyped by RFLP's method. The expression of ERCC1 was analyzed by Real Time PCR. We found a statistically significant association between the ERCC1 8092C>A polymorphism and the sensitivity to CPt (p=0.02); the A allele was associated with an under-expression of ERCC1 (p=0.04). There was no association between the XPA 5'UTR polymorphism and the response to chemotherapy. To confirm the association between ERCC1 and XPA expression and sensitivity to CPt, we determined mRNA levels in CPt-sentitive, and CPt-resistant testis tumor cell lines after treatment with CPt. Our results show that ERCC1 mRNA levels increased after 1h, 15h and 21h post-treatment with CPt in resistant cell lines. There was no significant change in XPA expression. The ERCC1 8092C>A polymorphism has a direct effect in the response of TCGT patients to cisplatin. We hypothesize that this polymorphism may influence the mRNA stability promoting its degradation, and resulting in a diminished DNA repair. It is important to notice that these associations have not been previously described, so the determination of the polymorphism of ERCC1 8092C>A and the ERCC1 mRNA levels could be used as predictive markers of response to CPt-based chemotherapy in TCGT patients. This work was supported by CONACYT 83959 and PAPIIT IN213311-3.

Caspase 8 cleavage is inhibited downstream of p38 MAPK in cisplatin resistant cells.

P. Flynn[1], J. Byerly[1], T. Berner[1], S. Murphy[1]; [1]Biology, University of the Sciences, Philadelphia, PA

Cisplatin is a platinum based anti-cancer drug that is used to treat a variety of cancers such as lung, head and neck, ovarian, and testicular. Although initial responsiveness to cisplatin therapy is high, the majority of patients relapse with development of tumors that are resistant to treatment. Therefore, we wanted to investigate the apoptotic signaling events occurring in cisplatin responsive cells with the goal of determining how these signaling events are inhibited in resistant cells. In this study we examined apoptotic signaling in the *ras* transformed A549 lung carcinoma cell line. Following 48 hour treatment of cells with 10uM cisplatin there was a significant increase in caspase 8 cleavage and DNA fragmentation. These events were independent of one another since inhibiting caspase 8 activity did not prevent DNA fragmentation, but did prevent breakdown of the nuclear envelope. We also determined that caspase 8 cleavage, but not DNA fragmentation, was dependent upon the signaling of the pro-apoptotic mediator p38 MAPK. Interestingly, cisplatin treatment selected for resistant cells that were still able to initiate p38 MAPK dependent signaling, but were unable to cleave caspase 8. Therefore, these data suggest resistance to cisplatin induced breakdown of the nuclear envelope involves inhibition of caspase 8 cleavage downstream of p38 MAPK.

1905

Photodynamic therapy-induced apoptotic cell death is mediated by a transglutaminase 2-dependent mechanism involving the calpain/Bax signaling pathway.

J-O. Yoo[1], Y-C. Lim[1], Y-M. Kim[1], K-S. Ha[1]; [1]Cellular and Molecular Biochemistry, Kangwon National University School of Medicine, Chuncheon, Korea

We investigated the key role of transglutaminase 2 (TG2) in apoptotic cell death induced by photodynamic therapy (PDT) with the chlorin-based photosensitizer DH-II-24 in human gastric adenocarcinoma cells. PDT-induced apoptotic cell death was prevented by cystamine and TG2-specific siRNA, both of which inhibited TG2 activation by PDT. Moreover, overexpression of EGFP-TG2 (wild-type TG2) potentiated apoptotic cell death via enhanced activation of TG2 in response to PDT, while EGFP-[C277S]TG2 (transamidation-defective mutant form of TG2) attenuated apoptotic cell death because of reduced TG2 activation. PDT resulted in translocation of Bax and collapse of the mitochondrial membrane potential that caused the release of cytochrome c and apoptosis-inducing factor (AIF). Released AIF translocated to the nucleus and subsequently led to apoptotic cell death synergistically with the caspase-dependent pathway induced by PDT. Both the caspase cascade and the action of AIF in PDT were mediated by TG2 activation. In addition, PDT-activated calpain was responsible for Bax translocation, the collapse of the mitochondrial membrane potential, caspase-3 activation, and AIF translocation, but not TG2 activation. Together, these results demonstrate that PDT with DH-II-24 targets TG2 by activating calpain-induced Bax translocation, which induces apoptotic cell death simultaneously through both caspase-dependent and AIF-mediated pathways. Moreover, these results suggest TG2 as a possible therapeutic target for PDT treatment of cancer.

1906

The role of beta-tubulin isotypes in microtubule drug resistance.

E. Narvi[1,2], K. Jaakkola[3], C. Oetken-Lindholm[1], P. Halonen[1], S. Winsel[1], L. Kallio[1], M. J. Kallio[1,2]; [1]VTT Technical Research Centre of Finland, Turku, Finland, [2]Centre for Biotechnology, University of Turku and Åbo Akademi University, Turku, Finland, [3]VTT Technical Research Centre of Finland, Finland

Epothilones are a novel group of microtubule binding drugs, of which ixabepilone (Ixempra®) is in clinical use for treatment of breast cancer. In this study we evaluated the importance of various human beta-tubulin isotypes in the epothilone drug response in lung and breast cancer cell lines. Silencing experiments of TUBB2A-C, TUBB3 and TUBB5 showed that reduction of TUBB3 levels significantly sensitized the cells to sagopilone, epothiloneB and ixabepilone. In contrast, diminishment of TUBB2 or TUBB5 did not influence the cellular drug response. TUBB3 deficient cells displayed an increased number of drug induced abnormal multipolar mitotic spindles and a decreased rate of cell proliferation. In addition, reduction of TUBB3, but not TUBB5 isotype stabilized the microtubule dynamics which may, at least partly, explain the increased sensitivity of TUBB3 deficient cells to the microtubule stabilizing epothilones. Exogenous expression of TUBB3 in epothilone resistant A549EpoB40 cell line reversed the drug resistant phenotype most likely by replacing the mutated TUBB5 isotype expressed in these cells. Together, our results indicate that the TUBB3 isotype functions as epothilone binding target and the expression levels of TUBB3 define the cellular response and sensitivity to epothilones.

1907

ATM-NBS1 Interaction Is Essential for Subsequent ATM Functions after Ionizing Radiation.

D. Zhang[1], N. Liu[1], S. Han[2], J. Ma[2], B. Xu[1]; [1]Radiation Oncology, The Methodist Hospital Research Institute, Houston, TX, [2]The First Affiliated Hospital, College of Medicine, Xi'an Jiaotong University, Xi'an, China

The Ataxia-Telangiectasia Mutated (ATM) kinase and the Nijmegen Breakage Syndrome 1 (NBS1) are critical elements in regulation of optimal DNA damage responses. ATM is a major kinase that functions by phosphorylating a number of substrates to facilitate cell cycle checkpoints, DNA repair and apoptosis. NBS1, on the other hand, is a component of the MRN complex required for DNA repair. NBS1 interacts with and recruits ATM to DNA damage sites. The constitutive interaction of ATM with NBS1 at the extreme C-terminus is required for initial ATM autophosphorylation at Serine 1981. However, it is less clear whether the interaction is essential for ATM function at later time points after DNA damage. Using a small inhibitory peptide that can disrupt the ATM-NBS1 interaction, we found that IR-induced ATM activation is significantly delayed in the absence of the interaction. While ATM activation was later restored, disruption of the ATM-NBS1 interaction after IR-induced DNA damage impaired subsequent DNA repair processes, leading to an extended retention of H2AX foci. Abrogation of the ATM-NBS1 complex before IR leads to the loss of the early G2/M checkpoint but sustain functional G2/M accumulation in response to IR. However, a prolonged G2 accumulation with a moderate radiosensitivity was induced when the ATM-NBS1 interaction was disrupted after IR. Together, these observations have highlighted an essential role of ATM-NBS1 interaction in the process of ATM activation as well as radiosensitivity.

1908

Understanding the functions and therapeutic significance of the poly(ADP-ribose) polymerase (PARP) enzyme family.

J. E. Rood[1], M. Chesarone-Cataldo[1], P. Chang[1]; [1]Koch Institute, MIT, Cambridge, MA

Post-translational protein modifications such as phosphorylation and ubiquitination have well-established roles in a range of cellular processes. One less-understood modification is the covalent addition of ADP-ribose groups to proteins, termed ADP-ribosylation. The poly(ADP-ribose) polymerase (PARP) family of proteins synthesizes this modification onto acceptor proteins, using NAD+ as substrate. Human cells express 17 different PARP proteins, which play critical roles in cell division, DNA damage repair and stress responses including stress granule formation and ER stress sensing mechanisms. One sub-family of PARPs has also been linked to the regulation of cell motility. Recently, PARP proteins have proven to be attractive targets for disease therapy, with PARP inhibitors in over 16 clinical trials. For example, inhibitors of PARP-1, which plays critical roles in single strand DNA damage repair, are promising targets for cancer therapeutics, particularly in cancers, such as BRCA-deficient tumors, with genetic lesions in double-strand DNA damage repair, where PARP inhibitors are thought to function via synthetic lethality. Interestingly, PARP inhibitors appear to also be effective in treating specific cancers that lack defects in double-strand DNA damage repair, suggesting that some therapeutic benefits of current PARP inhibitors are due to inhibition of PARPs other than PARP-1. To gain a deeper understanding of the mechanism of PARP function, we identified the major binding partners of each PARP via LC/MS-MS. This analysis suggested novel roles for many of the PARPs and provided support for PARP functions in cell migration. We then developed an assay to test the effects of a variety of PARP inhibitors on the enzymatic activity of each of the 17, full-length PARP proteins purified from human somatic cells and a cell-based assay to explore the effects of PARP inhibitors on cell motility. Our work allows a more complete

comprehension of the cellular effects of PARP inhibitors, and of their functions in cancer therapy.

1909

Identification of Oncogenic Point Mutations and Hyperphosphorylation of

Y-W. Wang[1,2], Y-S. Jou[1]; [1]Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan, [2]Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan

The oncogenic property of anaplastic lymphoma kinase (ALK) plays an essential role in the pathogenesis of various cancers and serves as an important therapeutic target. In this study, we identified frequent intragenic loss of heterozygosity (LOH) and six novel driver mutations within ALK in lung adenocarcinomas. Overexpression of H694R or E1384K mutant ALK leads to hyperphosphorylation of ALK and activation of its downstream mediators STAT3, AKT and ERK resulted in enhanced cell proliferation, colony formation, cell migration and tumor growth in xenograft models. Furthermore, the activated phospho-Y1604 ALK was increasingly detected in 13 human lung cancer cell lines and 263 lung cancer specimens regardless of tumor stages and types. Treatment of two different ALK inhibitors, WHI-P154 and NVP-TAE684, resulted in down-regulation of aberrant ALK signalings, shrinkage of tumor, suppression of metastasis and significantly improved survival of ALK mutant-bearing mice. Together, we identified novel ALK point mutations possessed tumorigenic effects mainly through hyper-phosphorylation of Y1604 and activation of downstream oncogenic signalings. The up-regulated phospho-Y1604 ALK could serve as a diagnostic biomarker for lung cancer. Furthermore, targeting oncogenic mutant ALKs with inhibitors could be a promising strategy to improve therapeutic efficacy of fatal lung cancers.

1910

Comparative effects of TNFR1 and TNFR2 on the early TNF signaling.

C. Ha Rim[1]; [1]Food and Nutrition, University of Nambu, Gwangju city, Korea, Dem People's Rep

Tumor necrosis factora (TNFα) is a proinflammatory cytokine with pleiotropic immunological and biological activities. TNFα signaling is triggered by the engagement of soluble TNFα to two types of cell surface receptors, TNFR1and TNFR2. TNFR1 and TNFR2 resemble each other in their extracellular, cysteine-rich domains. TNFR1 contains a cytoplasmic death domain (DD) that binds to the adaptor TRADD (TNFR-associated death domain). TNFR2 lacks a DD, but has cytoplasmic motif that binds TRAFs (TNFR-associated factors). Upon binding to ligated TNFR1, TRADD recruits the secondary adaptors RIP (Receptor interacting protein), TRAF2 (TNF Receptor associated factor2), FADD (Fas associated death domain), cIAP1, cIAP2. Unlike TNFR1, TNFR2 binds TRAF2 directly and TRAF2 also recruits TRAF1, cIAP1, cIAP2. Because the majority of TNFα signaling events are mediated by TNFR1 and function of TNFR2 is poorly understood, this study is subject to know comparative effects of TNFR1 and TNFR2 on the early TNFa signaling.
First, we purified wild type TNF, TNFR1-specific TNF, TNFR2-specific TNF. Then we show endogenous TNFR-interacting proteins in vivo through wild type TNF, mutant TNF, when both TNF receptors were stimulated simultaneously or respectively. Analysis of data demonstrated that ubiquitin E3 ligase cIAP1 and cIAP2 are associated with TNFR2 constitutively. But, cIAP1 and cIAP2 associated with TNFR2 was not observed, when both TNF receptors were stimulated simultaneously. These means that cIAP1 and cIAP2 could be ubiquitinated or translocated. When HeLa-R2 cells were stimulated with TNFα, endocytosis of TNFR1 occured within 10 min. Unlike this, endocytosis of TNFR2 do not occur after 1hour. These data demonstrated that TRAF2 associated with TNFR2 when both TNF receptors were stimulated simultaneously. We guess that TRAF2 is key mediator to TNFR2 signaling. We show that downregulation of cIAP2

increase cell death of TNF-stimulated cells and TNFR2 accelerates cell death of TNF stimulated cells. Understanding the regulation of TNFα-TNF receptors production and signals transmitted by TNFa is necessary for the development of effective treatments for these diseases.

Angiogenic effects of C-peptide in human umbilical endothelial cell.

Y-C. Lim[1], M. P. Bhatt[1], Y-M. Kim[1], K-S. Ha[1]; [1]Cellular and Molecular Biochemistry, Kangwon National University School of Medicine, Chuncheon, Korea

The pro-insulin connecting peptide, C-peptide is a cleavage product of insulin biosynthesis that is co-secreted with insulin by pancreatic $_{\beta}$-cells following glucose stimulation. Several studies suggest that C-peptide has beneficial effects in a number of diabetes-associated complications, such as prevention of diabetic neuropathy, neuronal apoptosis, vascular dysfunction and atherosclerosis. However, the roles of C-peptide in vascular remodeling and induction of angiogenesis process remain obscure. In the present study, we investigated reactive oxygen species (ROS) and Ca^{2+} as angiogenesis mediators and induction of cell migration, actin reorganization and tube formation by C-peptide in human umbilical endothelial cells (HUVECs), and these responses were compared with those were induced by vascular endothelial growth factor (VEGF). Interestingly, C-peptide is more potent than VEGF in induction of tube formation without generation of ROS, Ca^{2+} and stress fiber. Also, C-peptide increased expression of FXIIIa, which is known regulator of angiogenesis by enhancing cell migration and cell survival. Thus, our results suggest that C-peptide has potential therapeutic application in angiogenesis and prevention of vascular leakage.

1912

Influence of dermatan sulfate in inflammatory response and migration of mononuclear cells differentiated or not into to endothelial progenitor cells after arterial lesion.

J. A. Godoy[1], F. O. Higino[1], C. C. Werneck[1], C. P. Vicente[1]; [1]State University of Campinas/UNICAMP, Campinas, Brazil

Dermatan sulfate (DS) is an antithrombotic and anticoagulant glycosaminoglycan present in extracellular matrix that can be involved in attraction, migration and differentiation of cells after endothelial lesion. Its inflammatory capacity is not yet elucidated. Endothelial progenitor cells (EPC), first described by Asahara 1997, can migrate to lesion site in order to recover damaged endothelium. In this work, we analyzed the effect of DS in the inflammatory process and migration of mononuclear cells (MNC) obtained from mice bone marrow (BM) induced or not to differentiation into EPC, after arterial injury. Lesion was done in the carotid artery using a wire guide probe. DS [20mg/kg] was administered 10 min, 12, 24 and 48 hours after surgery. MNC extracted from BM were cultured or not for 4 days in DMEN containing VEGF, IGF and FGF (differentiation medium). MNC were labelled with PKH26-GL (2 x 10^6 cells) and MNC cultivated (MNCc - 10^6 cells) with PKH26-GL and LDL-FITC and injected 1 and 24 hours after injury. Both treatments were administered intravenously. Arteries were analyzed 7 days after injury to map the presence of these cells in the vessel. We analyzed 4 groups: MNC (1), MNCc (2), MNC + DS (3) and MNCc + DS (4). PKH-26 + cells were higher in groups 3 and 4 when compared to the others (45 or 52,33 vs. 22 or 26,25, $p<0,05$). LDL^+ cells did not differ in any treatment. Inflammatory response was analyzed by western blotting using ICAM-1, eNOS, P-selectin and SDF-1 antibodies. ELISA (TGF-β and IL-6) assays were done 1 day after lesion in injured mice

treated or not; Injured (A), DS (B), MNC (C) and not injured (D). TGF-β levels decreased in B (6571,15 vs. 10259,21 pg/ml (A), p<0,05), IL-6 levels did not differ among groups. Expression of ICAM-1 in group B decreased about 52%, P-selectin 10 times and SDF-1 was abolished in DS treated animals; C increased the expression of ICAM-1 in 20% and eNOS in 133% in relation to A. We observed that DS therapy promoted a significant migration of MNC to lesion site and decreased the expression of proteins related to inflammation, suggesting DS effect can be not only related to inhibition of thrombosis, but also to decrease of inflammation in the injury site promoting a better environment for MNCs adhesion.

Expression of Nampt, an NAD+ regenerating enzyme, in the developing and adult vasculature.

A. Watson[1], Z. Nong[1], Y. Xu[1], G. Pickering[1]; [1]Univ Western Ontario, London, ON, Canada

Pathways that consume NAD+, including those mediated by sirtuins, PARPs, and cADP ribose, have emerged as critical mediators of DNA repair, transcriptional regulation, calcium mobilization, and lifespan. The existence of these NAD+-consuming events has highlighted the importance of pathways that generate NAD+ locally. However, tissue expression of NAD+ biosynthetic enzymes has not been well characterized. Furthermore, there has been controversy over the identity of nicotinamide phosphoribosyltransferase (Nampt), the rate limiting enzyme for NAD+ salvage from nicotinic acid, which has also been proposed to be an adipokine. We undertook RT-PCR screening of adult mouse tissues which revealed that Nampt was expressed in heart, aorta, skeletal muscle, kidney, liver, bladder and brain. Immunostaining revealed that although Nampt was expressed in most tissues, there was cell type variability. This was particularly evident in the vessel wall, where endothelial cells expressed abundant Nampt but expression in the underlying smooth muscle cells was weak. This pattern was observed in the aorta, carotid arteries, and medium and small vessels of the heart, kidney and lung. This gradient was also observed in human aorta, particularly in the adventitial microvessels. Upon injury to the mouse carotid artery induced by distal ligation, Nampt expression was significantly upregulated in the medial SMCs. Mouse embryos revealed strong Nampt staining in the primordial aortic structures at 9.5 dpc and Nampt staining in the endothelial layer was strong throughout embryonic development. In contrast, mural cell expression declined in late embryonic stages, by e18.5. Conclusion: Nampt is a ubiquitously expressed enzyme but in adult blood vessels there is a significant gradient between the endothelial cells and underlying smooth muscle cells, implying differential requirements for NAD+ regeneration within the artery wall. In SMCs, NAD+ consumption may be particularly important during early differentiation in the embryo and following vascular injury in the adult.

1914

HDL reduces the risk of foam cell apoptosis in foam cell associated with PC-FC complex formation.

M. Mori[1], S. Kikuchi[1], R. Motohashi[1], M. Imamura[1], M. Takahashi[1]; [1]Theraputical Pharmacolgy and Cellbiological Pathology, Chiba Institute of Science, Choshi, Japan

[Objective] Phosphatidylcholine (PC)-cholesterol (FC) complex structures, a unique atheroma related antigen associating with foam cell death. To elucidate the role of antigen in the development of atherosclerosis , the relationship among PC-FC complex, cellular FC transport and role of HDL in cultured foam cell were investigated.
[Method] Foam cells were prepared by incubation with various modified LDL for 24hr, then cultured up to 3—6 days in the presence of LPDS +/- HDL. PC-FC complex and Oxidized

Phosholipid were detected by immunofluorescent microscopy using specific monoclonal antibodies. Cell Apoptosis was detected by Annexin V binding.
[Results & Discussion] We succeeded to express PC-FC complex as a cell apoptosis marker on the surface of FC-rich lipid droplets using Hyperlipidemic sera and acetylated LDL. PC-cholesterol complex expression and Foam cell apoptosis significantly reduced by HDL treatment. HDL also reduced CE deposit in lipid droplets formation in foam cell. Whereas, HDL was not effective for decreasing the frequency of foam cell apoptosis in the presence of Probcol or Glyclazide treatment via ABC transporter pathway, closely related with cellular FC transport. Probcol enhanced to express PC-FC complex and FC-rich lipid droplets in foam cells, whereas no significant change of this antigen expression and cell apoptosis with Glyclazide treatment.
This phenomena would be related to the PC-cholesterol complex formation and foam cell death via cellular FC transport. HDL played an important role in PC-FC complex formation.
Expression of PC-FC complex can be related to oxidized lipid production in cultured foam cells. Oxidized lipid accumulation might be also related to the foam cell death. These significantly relationship among the PC-FC complex formation, cellular FC transport, oxidized lipid accumulation and foam cell apoptosis can reflect to development of atherosclerosis in thickened intima.

1915

A1 adenosine receptors are involved in vasa vasorum endothelial cells barrier enhancement in a neonatal model of hypoxia-induced pulmonary arterial hypertension.

N. Umapathy[1], E. Kaczmarek[2], N. Fatteh[1], R. Lucas[1], K. Stenmark[3], A. Verin[1], E. Gerasimovskaya[3]; [1]Vascular Biology Center, Georgia Health Sciences University, Augusta, GA, [2]Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, [3]Department of Paediatrics, University of Colorado, Aurora, CO

In a neonatal model of pulmonary hypertension, hypoxia-induced pulmonary vascular remodeling involves dramatic pulmonary artery (PA) adventitial thickening, accumulation of inflammatory cells and expansion of the adventitial *vasa vasorum* network. However, the molecular and cellular mechanisms underlying these events remain elusive. The main aims of this study were i) to determine the differences in barrier function between VVEC isolated from animals exposed to normoxia or 2-week hypobaric hypoxia (P_B=430Hg), and ii) to investigate the role of adenosine receptors (ARs) in VVEC barrier regulation. The quantitative RT-PCR data indicate that VVEC isolated from control animals (VVEC-Co) express all the ARs (A1, A2a, A2b and A3). Interestingly, A1 and A3 ARs expression is decreased in VVEC isolated from calves exposed to chronic hypoxia (VVEC-Hyp) compared to VVEC-Co. We further demonstrate that the AR ligand, adenosine, strikingly enhanced the barrier function in VVEC-Co, as measured by transendothelial electrical resistance (TER) and to a lesser extent in VVEC-Hyp. Using receptor-specific agonists and antagonists, as well as specific siRNAs we could demonstrate that A1 ARs are responsible for the adenosine-induced TER increase. We subsequently investigated the role of cytoskeletal proteins in the observed barrier enhancement effect of adenosine in VVEC. Our results show that adenosine failed to increase the TER in cytochalasin B (an inhibitor of actin polymerization)-treated VVEC. In contrast, adenosine was able to increase the TER in nocodazole (an inhibitor of microtubule polymerization)-treated VVEC, suggesting a critical role of actin polymerization in VVEC barrier enhancement. Moreover, adenosine significantly increased the cortical actin in the cell-cell junctions in VVEC-Co, but to a lower extent in VVEC-Hyp, possibly due to observed decreased levels of A1 ARs expression in the latter. Further, we showed that TNFα, which is produced in hypoxic vessels, increases the permeability of VVEC-Co, but not VVEC-Hyp, an effect blunted by adenosine pre-treatment in VVEC-Co. In summary, we demonstrate for the first time that Gi-coupled A1 ARs enhance barrier function in VVEC,

probably via actin microfilament remodeling. We propose that A1 ARs are a possible therapeutic target in regulating endothelial barrier function, crucial in pulmonary arterial hypertension.

1916

Myosin-II inhibition leads to functional enrichment of long-term hematopoietic stem cells.

J-W. Shin[1], A. Buxboim[2], D. Discher[2]; [1]Pharmacology, University of Pennsylvania, Philadelphia, PA, [2]Biophysical Engineering Laboratory, University of Pennsylvania

Non-muscle myosin-II (NMM-II) promotes cell division, membrane rigidity and adhesion to a rigid matrix; hence it seems predictable that NMM-II activity is low in dormant hematopoietic stem cells (HSCs) and increased during differentiation. Deletion of NMM-II is known to be embryonically lethal, but its role in adult HSC differentiation is not known. Here, reversible inhibition of NMM-II sustained over several cell cycles enriches long-term HSCs up to ~20 fold by selective elimination of proliferating progenitors. Molecular profiling and functional analyses indicate that NMM-II isoforms may play distinct roles during HSC differentiation. NMM-IIA dictates the early stage of HSC differentiation as indicated by the lower expression in HSCs than committed progenitors, which is consistent with higher membrane elasticity of HSCs. In contrast, NMM-IIB may dictate the late stage of HSC differentiation as indicated by the higher expression in HSCs and progenitors than differentiated CD34- cells – its functional implication in matrix elasticity sensing and migration is under investigation. HSC and progenitor number is sensitive to matrix elasticity in a NMM-II dependent manner, with the maximal number observed on soft and high-density fibronectin matrices. In contrast, the extent of HSC enrichment is more sensitive to matrix density than elasticity under NMM-II inhibition. Deactivating NMM-IIA phorphorylation at the Ser1943 residue is highest in HSCs and decreased during differentiation. Phospho-mimetic mutation of NMM-IIA at Ser1943 shows decreased cytoskeletal integrity and increased membrane elasticity, indicating that physical properties of HSCs can also be regulated by HSC-specific signaling via NMM-II heavy chain phosphorylation. Myosin-inhibited CD34+-derived bone marrow cells maintain functional long-term HSCs in vivo in the marrows of xenografted mice with an added benefit to increase platelet circulation simultaneously. Therefore, NMM-II is a critical node for HSC differentiation.

1917

Defective retinal angiogenesis in isoxanthohumol-treated mice.

D. Duarte[1], R. Costa[1], R. Soares[1], R. Negrão[1]; [1]Department of Biochemistry, Faculty of Medicine, University of Porto, Porto, Portugal

Angiogenesis, the formation of new blood vessels from an established vascular network, occurs in many physiological conditions, such as wound healing or pregnancy. Pathological angiogenesis, conversely, is associated with several diseases, like cancer, diabetes or ischemia. Identification and characterization of dietary compounds, able to modulate angiogenesis may constitute an important strategy for prevention of these pathologies. Isoxanthohumol (IXN), a flavonoid of beer, is one of the main xanthohumol metabolites. Several studies demonstrated anti-inflammatory, anti-oxidant and anti-angiogenic properties.
To further evaluate the effects of IXN on developmental angiogenesis, the neonatal retinal neovascularization model was used. In the developing retina, endothelial sprouting and organization of vascular networks occur in a reproducible temporal and spatial pattern and can be easily imaged to study the interactions of EC with growth factors, astrocytes and mural cells and to analyse several angiogenic steps, namely EC survival, proliferation, migration and vascular pruning and normalization.
C57BL/6 mice pups were injected intraperitoneally with 20µL of 50µM IXN or control (PBS), daily, until post-natal day (P)4. Then, pups were euthanized and eyes enucleated, fixed in 4% p-

formaldehyde overnight, and retinas were dissected out and stained with FITC-conjugated isolectin. Finally, retinal endothelium was visualized using fluorescent and confocal microscopy, photographed and vascular quantification measurements were performed.
At P4, IXN group displayed a significant decrease in the vascular length and increase in the width of the capillary free zone of main arteries and no differences in the number of artery side branches. Furthermore, it was observed a decline in the number of endothelial tip cells and filopodia, and decreased filopodia length in the IXN-treated mice. Taken together these results suggest that IXN negatively modulates EC migration (tip cells and filopodia) and vessel sprouting (vascular length) and endothelial cell survival (with of capillary free areas).
Analysis of IXN treatments on later stages retinal angiogenesis at P5 and P7 pups seems to confirm that IXN modulates tip cells behaviour and vessel morphology.
Altogether, the accumulated evidence proposes IXN as an interesting anti-angiogenic compound that might have therapeutic and preventive applications in angiogenic and inflammation associated diseases.

Analysis of evolutionary repurposing predicts an orally available vascular disrupting agent.

H. Cha[1], M. Byrom[1], P. Mead[2], A. Ellington[1], J. Wallingford[1], E. Marcotte[1]; [1]University of Texas, Austin, TX, [2]St Jude Children's Research Hospital

In the course of systematically identifying genetic modules that are repurposed during the course of evolution (phenologs), we discovered a pathway that was both relevant to restructuring of yeast cell walls in response to stress and at the same time responsible for regulating angiogenesis in vertebrates (1). By analyzing such repurposed networks, we reasoned that small molecule inhibitors targeting the pathway in yeast might act as angiogenesis inhibitors suitable for chemotherapy in vertebrates. We computationally prioritized candidate angiogenesis inhibitors based upon measured synthetic genetic interaction of known drugs. This strategy led to the finding that thiabendazole (TBZ), an orally available antifungal drug in clinical use for 40 years, also potently inhibits angiogenesis. We found that TBZ treatment severely impaired angiogenesis in the frog, *Xenopus*, an accurate and tractable model vertebrate for *in vivo* studies of angiogenesis. We also found that TBZ inhibited angiogenesis in a dose-dependent manner in human cells (HUVECs) *in vitro*. Among various growth factors and cell adhesion molecules, the vascular endothelial growth factor (VEGF) pathway is perhaps the best-characterized signaling pathway associated with angiogenesis. Ectopic VEGF potently induces ectopic angiogenesis in frog embryos, and this effect was blocked by TBZ, suggesting that the drug acts downstream of this key regulatory node. In TBZ treated embryos, we noted disconnected and scattered arrays of cells in which vascular gene expression persisted. The ability of TBZ to disrupt pre-existing vasculature in our subsequent tests suggests such defects in vascular morphogenesis in the absence of changes to vascular cell fates may stem from impairment of junctional integrity in the vasculature. This is especially significant because disruption of more established vasculature may also prove beneficial for cancer therapy, and a new class of drugs called Vascular Disrupting Agents (VDAs). Though promising, no VDAs have as yet been approved for use in humans. *In vivo* time-lapse imaging reveals that TBZ reversibly disassembles newly established blood vessels, marking it as one of the few known vascular disrupting agents. Finally, we also showed that TBZ slows tumor growth in preclinical fibrosarcoma xenografts. Notably, a TBZ dose for these experiments was close to the U.S. Food and Drug Administration-approved maximum recommended daily dose in humans. Thus, the prospects are excellent for human chemotherapeutic use of TBZ. In sum, a

direct test of the evolutionary repurposing of gene networks has revealed a viable therapeutic agent, already approved for human use in other contexts.

Chronic insulin exposure uncovers a tyrosine phosphatase dependent pro-inflammatory phenotype of endothelial cells.

H. Giri[1], I. M[1], R. K[1], M. Dhar[1], U. Ram[2], M. Dixit[3]; [1]Biotechnology, Indian Institute of Technology, Madras, Chennai, India, [2]Sitapati Clinic and Hospital, [3]Indian Institute of Technology, Madras, Chennai, India

Objective: To elucidate intracellular mechanism mediating chronic insulin induced endothelial inflammation.

Methods: Human umbilical vein derived endothelial cells were treated with different concentrations of endotoxin free insulin for varying periods of time prior to performing leukocyte adhesion assays. Endothelial inflammation was assessed by measuring adhesion of PKH26 labelled peripheral blood derived mononuclear cells to insulin treated HUVECs. Changes in gene expression were assessed via reverse transcriptase PCR (RT-PCR) and enzyme activity was measured through immunophosphatase assay.

Results: 48 hours of insulin treatment increased the adhesion of leukocytes to the endothelial monolayer even at sub-optimal concentration of 1nmole/L. This effect of insulin was accompanied by time dependent decrease in intracellular nitric oxide as measured via DAF-2DA imaging. Addition of exogenous nitric oxide through NO donor DETA-NO attenuated insulin-mediated leukocyte adhesion to endothelial cells. These effects were due to intracellular changes in response to chronic insulin treatment and not due to secretion of pro-inflammatory cytokines. Increased leuckocyte adhesion was accompanied by increased expression and activity of protein tyrosine phosphatase PTP1D in a time dependent manner, which in turn induced a time-dependent increase in expression of adhesion molecules E-selectin, ICAM-1 and VCAM-1. Use of NSC87877 and down-regulation of endogenous levels ofPTP1D via siRNA significantly attenuated chronic hyperinsulinemia mediated adhesion of leukocytes to the endothelium.

Conclusions: Chronic insulin exposure elicits inflammatory phenotype in primary cultures of endothelial cells via a mechanism involving increased expression and activity of PTP1D.

1920

The nuclear liver X receptor and its role in smoke exposed rat lungs.

A. Kratzer[1], J. Salys[1], M. Zamora[1], L. Taraseviciene-Stewart[1]; [1]Medicine, UC Denver, Aurora, CO

Background: Chronic obstructive pulmonary disease (COPD) is one of the leading causes of mortality worldwide and currently there are no efficient treatments. Liver X receptor (LXR) plays a role both in lipid metabolism and inflammation. Objectives: To investigate the effects of cigarette smoke (CS) on LXR activation and target gene regulation in vivo and in vitro and to study potential protective effects of LXR activation against CS-induced emphysema. Methods: Sprague Dawley rats were exposed to second hand CS for two months. The lung tissue and bronchoalveolar lavage (BAL) cells were examined for LXR target gene expression and emphysema development was measured by mean linear intercept (MLI). Rat alveolar macrophages (AM) and rat pulmonary endothelial cells (EC) treated with CS extract, LPS or

DMHCA (a steroidal LXR agonist) were examined for changes in LXR target gene and protein expression. Results: Whereas expression of ATP binding cassette transporter A1, a known LXR target gene, was not changed in the lung, it was significantly downregulated in the BAL cells from CS-exposed rat lungs and in AM treated with CS extract. Real-time PCR showed that LXRalpha was significantly downregulated in BALf cells after 1 month of CS exposure and similarly in rat pulmonary micro- and macrovascular cells upon 1% CS extract treatment. Activation of LXR attenuated the expression of LPS-induced genes such as COX2, CCL5 and IL18. We also found that IL18 is increased in BALf cells of CS exposed rats, whereas IL18 binding protein (IL18bp), an endogeneous IL-18 inhibitor, was not changed. Interestingly, activation of LXR lead to upregulation of IL-18BP in AM. Additionally, we saw emphysematous changes in LXR-deficient mice, implying a protective role for this nuclear receptor. Conclusions: CS inhibits regulation of LXR target genes, but activation of LXR attenuated the LPS-induced production of pro-inflammatory cytokines in AM. We also saw an increase in IL18bp, which might be a potential new LXR target gene playing a role in the anti-inflammatory signaling pathway of LXR. Our data suggest that LXR agonist treatment might be beneficial to prevent and treat CS-induced emphysema.

New Technologies for Cell Biology

1921

Encapsulation of functional cytoplasmic extract within giant unilamellar vesicles.

M. D. Vahey[1], M. C. Good[1], A. Skandarajah[1], J. C. Stachowiak[2], R. Heald[1], D. A. Fletcher[1];
[1]University of California Berkeley, Berkeley, CA, [2]Sandia National Laboratories

Cytoplasmic extracts and purified proteins can be used to identify and reconstruct the molecular mechanisms underlying a broad range of cellular behaviors, including mitotic spindle assembly and actin-based motility. Despite the promise of these *in vitro* approaches, many fundamental cellular processes depend on or are influenced by confinement within membranes and are thus challenging to reconstitute. Although giant unilamellar vesicles (GUVs) offer a promising platform for addressing this challenge, traditional techniques for forming GUVs provide limited flexibility for encapsulating protein solutions, often have limited yield, and may produce highly polydisperse or multilamellar vesicles. Here we show that functional cytoplasmic extracts can be loaded into GUVs of controlled size by temporal control of microfluidic jetting-based encapsulation. This technique uses the liquid impulse expelled from a small (~10 μm) nozzle to deform a planar lipid bilayer into spherical vesicles. Because the solution expelled from the nozzle ends up inside the GUV, this technique offers excellent control over the internal composition of vesicles and can be used to create vesicles over a wide range of sizes containing biological solutions up to fourfold higher in viscosity than water, including whole-cell extracts. We achieve this flexibility by shaping the electrical signal that actuates the liquid jet so as to minimize the mechanical stress imparted on the membrane. As a demonstration of this technique, we encapsulated cytoplasm from *Xenopus laevis* eggs and showed that this extract retains its ability to form mitotic spindles in the presence of sperm chromosomes after encapsulation in a GUV. The precise control over microfluidic jetting demonstrated here is a step towards the reconstitution of increasingly complex biological phenomena within membrane compartments.

1922

Sub-cellular scaled multiplexed protein patterns for single cell co-cultures.

J. Collins[1], S. Nettikadan[1]; [1]NanoFabrication Systems, NanoInk, Inc., Skokie, IL

Cell culture studies are hampered by the heterogeneous nature of cell populations. Further, bulk measurement techniques currently average cellular responses and are not capable of discerning whether an observed phenomenon is a result of cell type differences or other variables within a population. Tip-based direct protein printing is a relatively new technique useful for controlling the cellular microenvironment with sub-cellular resolution. Here this technique demonstrates spatial control of multiple cell types at single cell levels on a substrate. Specifically, 3T3 fibroblasts and C2C12 myoblasts and their respective binding dynamics with fibronectin and laminin demonstrate the single cell co-culture concept.

Co-culture studies have been useful for mimicking the in vivo environment and studying effects on stem or progenitor cell function. However there are many experimental variables that cannot be properly controlled and may lead to confounding results. Several different techniques have been developed in an effort to address the heterogeneity of cell populations including single cell analysis. However, most current single cell analysis is just that, analysis of single cells within a population, using high resolution imaging and tracking technologies. Although cell populations can be monitored at the single cell level, it is still difficult to discern the effect of neighboring cells on cell behavior. Newer technologies such as microfluidics have been used to isolate single cells and then analyze their genomic or proteomic contents. However, these are destructive techniques making longitudinal studies and causal-effect relationships difficult to determine.

Tip based lithography is used to control cell morphology, cell cluster size and differential cell binding at single cell levels. Co-culture of NIH 3T3 fibroblasts with C2C12 myoblasts is demonstrated with greater than 70% pattern binding efficiency with 80% of those being single cell patterns. These proof-of-concept experiments demonstrate a single cell co-culture technique which may be useful for studying cell signaling, differentiation and other stem and primary cell interactions.

1923

Uncovering the Diversity of Individual Cells: Protocol for High Throughput Gene Expression Profiling of Single Cells.

K. Datta[1], S. L. Spurgeon[1], A. A. Leyrat[1], A. Hamilton[1], A. Mir[1], K. J. Livak[1]; [1]Fluidigm Corporation, South San Francisco, CA

Fluctuations in gene expression at the single cell level could be key for generating developmental signals and for understanding the progression of tumors. Data needs to be collected from a statistically significant number of single cells in order to determine the range of gene expression present in a population of cells. Furthermore, transcripts need to be quantified for a number of genes in order to obtain meaningful cell signatures.

We describe a new protocol that enables analysis of 96 gene transcripts in 96 individual cells. The method entails collecting single cells directly into reverse transcriptase buffer in a 96-well PCR plate. Following a reverse transcriptase reaction with random primers, multiplex Specific Target Amplification (STA) is performed to enrich samples for the 96 targets of interest. STA retains relative abundance between loci and permits quantitative Cq information to be derived. The 96 individual qPCR assays are then performed for all 96 single cell samples in a 96.96 Dynamic Array™ IFC (Fluidigm). The qPCR assays use DNA binding dye detection in order to

reduce the upfront cost of obtaining 96 assays relative to probe-based assays. The qPCR thermal cycling protocol is immediately followed by acquisition of melting curves (Tm) in order to assess reaction quality.

The results obtained using this protocol demonstrate that individual mammalian cells exhibit a great deal of heterogeneity in transcript levels. For all genes analyzed, transcript levels varied 10- to 100-fold among individual cells even for a homogeneous population of tissue culture cells. These results support the model that eukaryotic transcripts are produced in short but intense bursts interspersed with relatively long intervals of inactivity of random duration. For a population of single cells, this leads to what has been called a lognormal distribution of transcripts but is more accurately described as a Gamma distribution.

1924

KillerRed-Rab7 induces light-dependent cell death in fibroblasts.

E. Serebrovskaya[1], M. Bulina[2], K. Lukyanov[1]; [1]IBCH RAS, Moscow, Russia, [2]Biology department, University of Miami

Objectives:

Phototoxic fluorescent protein KillerRed opens new perspectives for application of a genetically encoded photosensitizer in various fields of experimental biology for light-induced (and thus strictly controlled in space and time) inactivation of target proteins and killing of target cell populations. However, low phototoxic activity impedes wide application of KillerRed and finding sensitive targets for KillerRed-induced phototoxicity is necessary. Lysosomes are known to be an important target for photosensitizer-induced oxidative stress. Cell damage by lysosomotropic photosensitizers is mediated by lysosomal cathepsins. We study phototoxic effects caused by KillerRed localized to the cytoplasmic side of lysosomal membrane.

Methods:

Standard molecular cloning techniques; transient transfection; preparation of cell lines stably expressing KillerRed-Rab7 by lentiviral transduction; wide-field fluorescence microscopy; Hoechst33342, propidium iodide staining;

Results:

We targeted KillerRed to lysosomes by fusing it to the fragment of Rab7 protein. KillerRed-Rab7 (KR-Lyso) fusion co-localized with EGFP-Rab7, a known marker of lysosomal localization. We found that REF52 cells transiently expressing KR-Lyso undergo morphological changes after illumination with KillerRed-activating green light. These cells showed either nuclear fragmentation (as seen after Hoechst33342 staining) and no propidium iodide staining, or normal nuclear morphology and propidium iodide staining. Propidium iodide staining coincided with the loss of EGFP fluorescence in cells co-expressing cytoplasmic EGFP. These changes could be prevented by preincubation with cathepsin inhibitors E-64 and pepstatin A, implying that lysosomal membrane damage is responsible for the KR-Lyso phototoxicity. We further studied the influence of illumination intensity on the mode of cell death that occurs after photosensitization with KR-Lyso. We transiently co-transfected REF52 cells with KR-Lyso and EGFP-Baxα. After 20 min illumination with 77 mW/cm2 EGFP-Bax redistribution from diffuse cytoplasmic fluorescence to punctate loci immediately preceded cell shrinkage. On the other hand, after 5 min illumination with 680 mW/cm2 no Baxα redistribution was observed either before or after cell shrinkage. Also we used FRET-based caspase sensor Casper3-GR to determine whether caspase-3 activation is involved in KR-Lyso-induced phototoxicity. With the same illumination intensity we observed both cells where caspase activation preceded cell shrinkage, and cells where caspase activation wasn’t observed. We conclude that different

modes of cell death occur after photosensitization with KR-Lyso depending on the illumination intensity and other factors, possibly, level of KR-Lyso expression in each particular cell.

1925

Imaging-based proteomic maps of neuron.

T-C. Deng[1], N. Sharifai[2], H. Samarajeewa[1], M. Boulina[1], T. Kagesawa[1], T. Li[1], J. Stoecker[3], A. Chiba[1]; [1]Biology, University of Miami, Coral Gables, FL, [2]Neuroscience, University of Miami, Coral Gables, FL, [3]Computer Science, University of Miami, Coral Gables, FL

We present logistics to conduct systematic surveys of protein-protein interaction networks as they operate in their native environment of a cell. Our isPIN (in situ protein-protein interaction networks) project employs advanced Drosophila genetics, sophisticated molecular imaging technology, and high-performance computation. FRET (Förster resonance energy transfer) offers a visual indication of molecular distance and behavior. Direct association of two interacting proteins brings them typically within 8 nm from each other. When they are each tagged with spectrally matched fluorescent molecules, this nanoscopic distance induces FRET. Because the tagged proteins are not artificially tethered to each other, fluorescent lifetime measurement is the preferred method of FRET quantification. As a starter, we chose to focus on 141 neuronally expressed cytoplasmic proteins. Each protein is tagged in four-ways: with EGFP on the N-terminus, mCherry on the N-terminus, EGFP on the C-terminus, and mCherry on the C-terminus. Resulting GAL4-responsive transgenes are inserted at pre-specified acceptor sites on the second chromosome though PhiC31 integrase-mediated transgenics. These fluorescently tagged proteins are expressed under the control of cell-specific GAL4 drivers, either singly or in pairs, and examined for localization and interactions within model neurons in vivo. Whereas the localization of each protein is assessed through four different tags, the interactions among them are quantified through eight FRET-able tag pairs. Of 9,941 possible interactions among 'humanized' complement of the 141 proteins, only <0.5% are reported in literature. Our project will be able to not only confirm some of these interactions in real-life but also reveal when and where they occur within a single complex cell. Of particular interest are the dynamics of signal convergence and divergence being expected among Rho GTPases and their CRIB effectors. By subdividing the data into twelve functionally distinct subcellular compartments at eight developmental stages, up to ninty-six context-specific proteomic maps will be created for these and many other proteins. While the current phase of the project focuses on well-known pairs of signaling proteins in identified neurons under normal conditions, future experiments may include stress or disease-affected states as well as non-neuronal cells. Ultimately, the project aims to add information-rich contexts to proteomics. Supported by NIH/NINDS.

1926

A photoactivatable small molecule inhibitor for light-controlled spatiotemporal regulation of Rho kinase in live embryos.

A. Morckel[1], H. Lusic[2], L. Farzana[1], J. Yoder[1], A. Deiters[2], N. Nascone-Yoder[1]; [1]Department of Molecular Biomedical Sciences, North Carolina State University College of Veterinary Medicine, Raleigh, NC, [2]Department of Chemistry, North Carolina State University, Raleigh, NC

To uncover the cellular and molecular mechanisms of embryonic development, the ideal loss-of-function strategy would be capable of targeting specific regions of the living embryo with both temporal and spatial precision. To this end, we sought to develop a novel pharmacological agent that can be light-activated to achieve spatiotemporally limited inhibition of Rho kinase activity *in vivo*. A new photolabile caging group, 6-nitropiperonyloxymethyl (NPOM), was installed on a small molecule inhibitor of Rho kinase, Rockout, to generate a “caged Rockout”

derivative. Complementary biochemical, cellular, molecular and morphogenetic assays in both mammalian cell culture and *Xenopus laevis* embryos validate that the inhibitory activity of the caged compound is dependent on exposure to light. Conveniently, this unique reagent retains many of the practical advantages of conventional small molecule inhibitors, including delivery by simple diffusion in the growth medium, and concentration-dependent tuneability, but can be locally activated by decaging with standard instrumentation. Application of this novel tool to the spatially heterogeneous problem of embryonic left-right asymmetry revealed a differential requirement for Rho signaling on the left and right sides of the primitive gut tube, yielding new insight into the molecular mechanisms that generate asymmetric organ morphology. As many aromatic/heterocyclic small molecule inhibitors are amenable to installation of this caging group, our results indicate that photocaging pharmacological inhibitors may be a generalizable technique for engendering convenient loss-of-function reagents with great potential for wide applicability in cell and developmental biology.

1927

SPASM: A novel, genetically encoded technique to systematically regulate protein-protein interactions.

S. Sivaramakrishnan[1], J. Spudich[2]; [1]Cell and Dev Biology, University of Michigan, Ann Arbor, MI, [2]Biochemistry, Stanford University, Stanford, CA

Cellular functions of proteins are strongly influenced by their interactions with other proteins. The frequency of protein-protein interactions, in turn, is a function of the local concentration of two proteins. When two proteins are tethered together, the link between them influences the effective concentration of both and therefore the frequency of their interaction. Currently, in the absence of detailed structural information of the interaction interface, no methods exist to systematically vary the effective concentration within this intramolecular interaction. Here we outline a modular, genetically encoded linker, namely an ER/K single α-helix that can be used to regulate the frequency of interaction between two proteins, or between a protein and a peptide, one at each end. We exploit the wide range of interaction affinities between calmodulin and its binding peptides, combined with Forster's resonance energy transfer (FRET) for a detailed characterization of the role of the ER/K α-helix in regulating protein-protein interactions. We find that regardless of the strength of the bi-molecular interaction, increasing the length of the ER/K α-helix reduces the on-rate of the intramolecular interaction, without significantly affecting the off-rate. We demonstrate a generalized, genetically encoded method to determine the dissociation constant for both moderate (μM Kd) and strong (nM Kd) interactions between proteins, that combines FRET-based detection of protein-protein interactions with an ER/K α-helix linker to make stoichiometric amounts of the two interacting proteins. We apply this technique to develop novel FRET biosensors for signaling proteins and to control auto-inhibition in protein kinases.

1928

An Intein with Genetically Selectable Markers Provides a New Approach to Internally Label Proteins with GFP.

E. Muller[1], R. Ramsden[1], L. Arms[1], T. Davis[1]; [1]Biochemistry, University of Washington, Seattle, WA

Inteins are proteins that catalyze their own removal from within larger precursor proteins. The *Pch* PRP8 mini-intein of *Penicillium chrysogenum* was modified four ways to create inteins that could confer 1) G418 resistance 2) hygromycin resistance or 3) histidine prototrophy in appropriate genetic backgrounds or 4) express the transcriptional activator LexA-VP16. Splicing efficiencies for the modified inteins were high when they were expressed in either *E. coli* or *S.*

cerevisiae. The genetically marked inteins were coupled to GFP at their N-termini. The GFP-intein-marker-intein DNA was used as a template to create a PCR product with ends homologous to the interior of a target gene. Transformation and genetic selection yielded cells with the intein inserted in frame into the target gene. Following expression, protein splicing removed the intein, leaving behind an embedded GFP tag. As a proof of principle the central linker of the yeast calmodulin gene *CMD1* was tagged with GFP and shown to be fully functional.

1929

PSI:Biology-Materials Repository: A Biologist's Resource for Protein Expression Plasmids.

C. Cormier[1], J. Steel[1], J. Park[1], M. Fiacco[1], J. Kramer[1], P. Hunter[1], J. LaBaer[1]; [1]Biodesign Institute, Arizona State University, Tempe, AZ

The Protein Structure Initiative:Biology-Materials Repository (PSI:Biology-MR; MR; http://psimr.asu.edu) sequence-verifies, annotates, stores, and distributes the protein expression plasmids and vectors created by the Protein Structure Initiative (PSI). DNASU (http://dnasu.asu.edu), a freely searchable database, stores the plasmid annotations, which include the full-length sequence, vector information, and associated publications for over 140,000 plasmids created by our laboratory, by the PSI and other consortia, and by individual laboratories for distribution to researchers worldwide. Each plasmid links to external resources, including the PSI Structural Biology Knowledgebase (http://sbkb.org), which facilitates cross-referencing of a particular plasmid to additional protein annotations and experimental data. To expedite and simplify plasmid requests, the MR uses an expedited material transfer agreement (EP-MTA) network, where As of July 2011, over 43,000 protein expression plasmids and 85 empty vectors from the PSI are available upon request from DNASU. Overall, the MR's repository of expression-ready plasmids, its automated pipeline, and the rapid process for receiving and distributing these plasmids more effectively allows the research community to dissect the biological function of proteins whose structures have been studied by the PSI. With the added biological focus in PSI:Biology, the distribution of these materials will help researchers expand the knowledge of the role of proteins both in normal biological processes and in disease.

1930

Cationic carrier-mediated mRNA delivery.

G. Tavernier[1], K. Wolfrum[2], J. Adjaye[2], S. De Smedt[1], J. Rejman[1]; [1]Research Group on Nanomedicines, Gent University, Gent, Belgium, [2]Department of Vertebrate Genomics, Max Planck Institute for Molecular Genetics, Berlin, Germany

We complexed mRNA encoding luciferase (mLUC) to Lipofectamine (LF), DOTAP/DOPE, or to linear poly(ethyleneimine) (linPEI). Luciferase activity after transfecting HeLa cells with the resulting lipo- and polyplexes was determined by a bioluminescent assay. Interestingly, extent and duration of luciferase expression was determined by the type of complex used. Luciferase activity could be determined for over a week if mLUC was complexed with Lipofectamine. We further transfected the cells with an mRNA or pDNA encoding Green Fluorescent Protein (GFP). This allowed us to estimate the number of transfected cells and directly compare the results for the two nucleic acids. mRNA complexed to Lipofectamine or DOTAP/DOPE transfected a substantially larger fraction of cells (>80%) than pDNA (40%).

We also tested the carriers for their ability to deliver mRNA encoding CXCR4, a receptor binding stromal derived factor 1, into mesenchymal stem cells. With the mRNA-cationic

lipoplexes the fraction of CXCR4-positive cells was around 80%, and with the lin-PEI polyplexes about 40%. These results encouraged us to employ this technology to re-program fibroblasts into stem cell-like cells (induced pluripotent stem cells or iPS). To that end we subjected fibroblasts to either a single, double or triple transfection with 4 different mRNAs, each encoding a transcription factor (Oct4, Sox2, Klf4, cMyc). Flow cytometry following immunostaining demonstrated successful transfection of all introduced factors. Moreover, expression of other transcription factors typically up-regulated during the reprogramming process (such as Nanog) was also significantly increased. Preliminary results, based on morphology and immunohistochemistry, confirmed the formation of iPS colonies.

1931

Novel discrete PEG-based crosslinking reagents for conjugation of antibodies and proteins to biotin, fluorochromes, enzymes and gold that eliminate aggregation, improves solubility, reduces non-specific binding and enhances low level detection limits.

A. A. Rampersaud[1], I. Rampersaud[1], Y. Sheikhaldeen[1], R. Brody[1], M. Vermillion[1], A. Pokora[1], D. Moothart[2], P. Davis[1]; [1]Quanta Biodesign Ltd, Powell, OH, [2]American Qualex Antibodies/ Signal Transduction Products, San Clemente, CA

This research describes the preparation of antibodies in which various labels are linked to the antibodies via a short, uniform (> 3) polyethylene glycol (PEG) chain. The PEG substitution for the traditional hydrocarbon linker results in a conjugate that is more resistant to aggregation and has far superior solubility properties.

As one specific example, biotin modification (biotinylation), results in covalent attachment of one or more biotin groups to biomolecules, (e.g. antibodies). Such biotinylated proteins are capable of binding avidin or streptavidin with very high specificity and thus biotin-tagged molecules can be easily detected using an appropriate streptavidin/avidin detection reagent. Biotinylation reactions are widely used for labeling peptides, proteins, antibodies and cell surface receptors. Standard biotinylation procedures can have drawbacks, most notably, aggregation and non-specific interactions with other biomolecules.

One reason for aggregation of biotinylated proteins may be that commercial reagents, such as sulfo-NHS-LC-biotin and NHS-LC-biotin, introduce hydrophobic aliphatic chains along with the biotin tag. Both reagents contain an (amine-reactive) sulfo-NHS ester with a aliphatic spacer region which separates the protein/antibody from the biotin group. The aliphatic chain (LC group) amplifies the tendency of biotinylated proteins to aggregate in aqueous solution and may cause protein precipitation over time. For this reason, hydrophilic PEG-based biotin compounds are a better alternative for maintaining water solubility of modified proteins. We compared sulfo-NHS-LC-biotin with a unique biotinylation reagent, NHS-dPEG12-biotin, in which the LC group is replaced with a short PEG spacer arm. The results of side-by-side biotinylation reactions of immune affinity purified goat anti-rabbit IgG antibodies shows that NHS-dPEG12-biotin requires no special changes in biotinylation conditions and easily substitutes for sulfo-NHS-LC-biotin. The biotinylated proteins are indistinguishable from each other except in streptavidin-accelerated aggregation of antibodies. The NHS-dPEG12-biotin dramatically improved the solubility properties of the Streptavidin-biotinylated IgG complex.

Our results show that dPEG reagents increase the solubility, increase sensitivity and decrease the aggregation of proteins and that these benefits are likely due to an increased hydrophilic character of the modified biomolecules or surfaces.

1932

Quantitative *in situ* Measurement of Target Biomolecules by Metal Nano-Particle Label Sets and "Adaptive SEM" Technology.

H. Kim[1], H. Terazono[1], M. Hayashi[1], H. Takei[1,2], K. Yasuda[1,3]; [1]Kanagawa Academy Sci/Technol, Kawasaki, Japan, [2]Dept Life Sci, Toyo Univ, Japan, [3]Dept Biomed Info, Tokyo Med Dent Univ, Japan

1. Objective

Identification of cellular distributions having different phenotypes in a tissue is essential for understanding functions of the tissue originated each cellular spatial arrangement. One useful way is *in situ* detection of expressed biomarkers for each cell in the tissue using a lot of labels, because each cellular phenotype is generally reflected expression patterns of key biomarkers. However, fabrication and identification of such label sets are still challenging. We propose a new sensing technology, which is a comprehensive development of fabrication and identification of nano-particle (NP) labels for simultaneous *in situ* measurements of a lot of expressed biomarkers in a cell.

2. Methods

The NP labels were fabricated as follows. Various sizes of polystyrene spheres were used as casts of NPs, placed on a substrate, and the size was furthermore processed as desired diameter with oxygen plasma treatment. Next, metals were deposited on the spheres by thermal evaporation. Then, metal NPs composed of various sizes and elements were fabricated. When polystyrene casts were interfering with measurements, UV-excited ozone oxidization was performed, and cup-shaped metal NP shells were also obtained. For the identification of fabricated NPs, field emission scanning electron microscopy (FE-SEM) was used. Both diameters and elements of NPs were identified with observations of secondary electron (SE) and backscattered electron (BE) in the FE-SEM.

3. Results and discussion

By using our fabrication method, more than 400 kinds of NPs were fabricated. Metal shell layers were formed by thermal evaporation; therefore, multi-layered NPs can be easily fabricated with sequential evaporation. We used double-layered NPs; outer layer is Au for easy immobilization of probe molecules to use these NPs as labels of biomarkers, and inner layer is various to apply label varieties. Spatial distributions and diameters of reacted NP labels were identified by SE observation with high spatial resolution, and metal kinds were identified by BE observation as the difference of intensities in the image caused by the difference of atomic number of inner metal. We call it "adaptive SEM" technology (i.e., NP identification is "adaptive" for various samples), and at least six different metals can be simultaneously discriminated by this technology. These results indicate a possibility for quantitative *in situ* detection of expressed biomarkers in a cell by the suggested technology.

1933

Targeted NF-κB Inhibitory Nanoparticle Decreases Melanoma Cell Proliferation by Preventing P65 nuclear translocation.

H. Pan[1], K. Le[2], G. Lanza[2], S. Wickline[2]; [1]Washington University School of Medicine, Saint Louis, MO, [2]Washington University School of Medicine

Although death rates from all cancers are declining in US, the incidence of new cases and deaths from melanoma continue to rise. Malignant melanoma exhibits approximately a 10-20% response rate to conventional chemotherapy. Adjuvant immunotherapy with interferon-α and/or interleukin-2 modestly increases the response rate in a small group of patients, but excessive toxicity from immunotherapy may outweigh the benefit. Therefore, seeking for the alternative therapeutic approaches continues. It has been reported that abnormal activation of NF-κB signaling pathway contributes to the melanoma progression and metastasis. NBD peptide, a NF-κB inhibitory peptide, has been shown to inhibit abnormal NF-κB activation. The NBD peptide delivery has been reported by fusing it to cell penetrating peptide. But lacking cellular specificity calls for a constrained delivery system. In this study, we report a post-formulation technology for generating targeted NF-κB Inhibitory nanoparticle and its application on potential melanoma treatment.
Methods and Results: Targeted NF-κB inhibitory nanoparticles were generated by loading NBD peptide, a NF-κB inhibitory peptide, into $\alpha_\gamma\beta_3$-integrin targeted perfluorocarbon (PFC) nanoparticles by using a linker peptide, which enables post-formulation self-assembling process. Physic characterization of NF-κB inhibitory nanoparticles was performed by measuring particle size and zeta potential. Dose dependent manner of NF-κB nuclear translocation inhibition was demonstrated by ELISA-based transcription factor assay. XTT cell proliferation assay results indicated that proliferation of human melanoma cell (C32) was inhibited by 40%. Moreover, the *in vivo* stability of the NF-κB inhibitory nanoparticles was demonstrated by using both radioactive and magnetic resonance spectroscopy readouts.
Conclusion: This targeted NF-κB inhibitory nanoparticle prevents melanoma cell proliferation by NF-κB signaling pathway inhibition. We anticipate that this new nano-therapeutic system could benefit melanoma management. Moreover, this post-formulation strategy could help to accelerate translation of cell biology findings into clinic applications.

1934

Silicone gels for cell rigidity sensing and traction force microscopy: robust mechanical properties, rigidity sensing assays in a multi-well format, and TIRF microscopy on soft substrates.

E. Gutierrez[1], E. Tkachenko[2], S-A. Lee[2], A. Besser[3], M. Ginsberg[2], A. Groisman[1]; [1]Physics, University of California, San Diego, La Jolla, CA, [2]Medicine, University of California, San Diego, [3]Cell Biology, Harvard Medical School

Substrate rigidity impacts cellular migration, gene expression, development, and tumorigenesis, especially in a range of elastic moduli, *E*, of 0.1 to 100 kPa. Soft substrates commonly used for cell rigidity sensing studies are hydrogels, such as polyacrylamide gels. These gels also enable cell traction force microscopy (TFM), where forces exerted by cells on a substrate with known *E* are evaluated from deformation of the substrate. Elastic moduli of thin gels are usually measured with atomic force microscopy (AFM), which requires expensive equipment. Elastic moduli of hydrogels can change due to drying, swelling, aging, and hydrolysis of molecular bonds. Here, we formulated and tested a series of silicone gels with *E* covering a range from 0.4 to 300 kPa that were all prepared by mixing different proportions of two components of a commercial silicone, Sylgard 184. Silicone pre-polymers were spin-coated onto microscope cover glasses to ~35 um thickness. Mechanical properties of the silicone gel layers were

consistent and robust, with ~3% variability within a batch and ~10% change after 6 months of storage. Elastic moduli of the gels were measured with 5-10% absolute accuracy by tracking displacements of beads on surfaces of the gels, when known hydrodynamic shear stresses were applied to the surfaces using a specially built microfluidic device. We made 6-well plates with gels of different E at the well bottoms. We found that mouse embryonic fibroblasts spread over significantly larger areas on gels with moderate E of 30 kPa than on gels with $E = 0.5$ and 3.5 kPa. Cells were harvested from the wells and analyzed for biochemical changes. Western-blot analysis revealed varying levels of phosphorylated Focal Adhesion Kinase (FAK) in fibroblasts grown on silicone gels with different E.
We also formulated and prepared layers of silicone gels with E from 0.4 to 130 kPa and with refractive index, n, of 1.49. The high value of n made the gels fully compatible with through-the-lens Total Internal Reflection Fluorescence Microscopy (TIRFM) using TIRF objectives with numerical apertures (NA) of up to 1.49. TIRFM enables selective visualization of the dynamics of substrate adhesions, vesicle trafficking, and biochemical signaling at the cell-substrate interface. For TFM, we also covalently bound to gel surfaces 40nm far-red fluorescent beads that were distributed nearly evenly with a high surface density. We plated mouse endothelial cells with fluorescently labeled F-actin on the $n = 1.49$ silicone gels and successfully performed concurrent TIRFM and TFM. We obtained high-quality TIRF images of the cells showing maps of F-actin localization at the substrate and juxtaposed them with high-resolution traction force maps obtained with TFM.

1935

Nanofluidics-based antibody microarray for application of single cell Immunoassay.

Y-L. Lin[1,2], T. Leichle[3], C-F. Chou[4]; [1]Nano Science and Technology, Taiwan International Graduate Program, Institute of Physics, Academia Sinica, Taiwan, Taipei, Taiwan, [2]Chemistry Department, National Taiwan University, Taiwan, Taipei, Taiwan, [3]LAAS-CNRS and University of Toulouse, Toulouse, France, France, [4]Institute of Physics, Genomics Research Center, and Research Center for Applied Sciences, Academia Sinica, Taiwan, Taiwan

Cellular heterogeneity that arises from stochastic transcription and translation processes is a fundamental phenomenon in cell biology. However, demands to quantitatively measure multiple proteins within individual cells beyond current capability of proteomics technology. This may be particularly true for stem cell research. For example, while the study of induced pluripotency frequently rely on experimental assays that average measurements among a large population of cells, the majority of them do not become pluripotent. Although fluorescence microscopy is commonly employed to observe individual stem cells, the number of species can be observed simultaneously is limited to the spectrum overlapping of fluorescent dyes.

For the purpose to quantitatively measure protein contents in single cells, we invented a novel nanofluidic device for immunoassays, combining conventional antibody microarray with state-of-art Lab-on-Chip technology. In our device, antibody spots with diameters of 200 micrometers were imbedded in fluidic channels with depths of less than one micrometer. The binding activity and the specificity of immobilized antibodies were confirmed using target proteins conjugated with fluorescent dye. To characterize the performance of the device, real-time reaction kinetics was studied in experiments using DNA hybridization and ligand-protein (biotin-streptavidin) interactions. The results, combining with theoretical works, show that the shallow depths shorten the diffusion time and thus significantly improve the overall binding efficiency.

To sum up, we present a nanofluidic platform combined with antibody microarray, and thus could identify multiple target proteins from extremely small volume comparable to single or few cells. Not only for better understanding of cellular heterogeneity, this technique should also

contribute to the fields where starting materials are extremely limited, including single cell analysis and stem cell research.

1936

Spatio-temporal profiling of IgE receptor-mediated pathway using an integrated microfluidic platform.

Y. Liu[1], B. Wilson[2], J. Oliver[2], A. Singh[1]; [1]Biotechnology and Bioengineering, Sandia National Labs, Livermore, CA, [2]Department of Pathology, University of New Mexico, Albuquerque, NM

Traditional biochemical techniques for studying cellular behavior rely on multiple manual steps leading to hard-to-reproduce results, loss of sample, and poor temporal resolution. We are developing a microfluidic platform that integrates and automates the various steps required (e.g., cell culture, cell preparation, challenge, and measurement) to systematically interrogate cellular signaling process at a single cell level with high-sensitivity and minimum reagent consumption. The monolithic serpentine microfluidic chip is about 250 m in width and 30 m in depth, which holds up to a thousand cells per chamber. The accessories including pneumatic control units, electronic control valves, digital heaters and optical detectors are assembled into a bench-top, semi-automated platform that maintains cell viability and enables quantitative measurement of signaling events in single cells using high-resolution imaging and on-chip flow cytometry. The platform is being validated using rat basophilic leukemia cells (RBL-2H3), a mast cell model used to understand fundamental mechanisms that lead to allergic responses and asthma. Following on-chip cross-linking of the high-affinity receptor FcεRI for IgE by multivalent antigen, we examined early, intermediate, and late stages of signaling events including protein phosphorylation, calcium mobilization and the release of inflammatory mediators and synthesis and secretion of cytokines, demonstrating the ability of our platform to make quantitative measurements on a cell by cell basis from just a few hundred cells. The new platform enables analysis of the heterogeneity of cellular responses and makes it possible to analyze rare primary cells and tissue samples.

1937

Delivery of Epidermal and Dermal Stem Cells to a Burn Wound via a Spray Device - Exploring Human Fetal Skin Progenitor Cells for Regenerative Medicine Cell Based Therapy.

R. Esteban[1,2], M. Young[1,2], P. Over[1,2], C. Chinnici[3,4], G. Amico[3,4], J. Gerlach[1,2]; [1]Bioreactor Group, McGowan Institute for Regenerative Medicine, Pittsburgh, PA, [2]Pittsburgh University, Pittsburgh, PA, [3]Istituto Mediterraneo per i Trapianti e Terapie ad Alta Specializzazione (ISMETT), Palermo, Italy, [4]UPMC Italy, Palermo, Italy

Introduction

Alternatives to autologous mesh grafting are not available in high demand. Skin progenitor cells derived from human fetal skin tissue are believed to have an interesting potential for regenerative cell-based therapy in acute and chronic skin disease treatment due to their relatively undifferentiated basal nature. We propose to address the need for innovative cell-based therapies by focusing on fetal skin derived (non-embryonic) and adult stem cells for a cell therapy for 2nd and 3rd degree burns.

Materials and Methods

We focus on fetal epidermal progenitor cells for 2nd degree burns as well as a combined treatment using dermal mesenchymal stromal cells (MSC) for 3rd degree burns. Adult cells are used as a control.

In vitro work on cell isolation, cell culture, cell characterization and cell spraying are performed to prepare key proof of concept studies. Further, post-culture and post-cryopreservation FACS analysis are used to determine immunogenicity, proliferative activity and extent of differentiation.

Results

• Cell isolation, cell culture and cryo-preservation methods are established for dermal and epidermal stem cell types.

• Proliferation markers like ki67 confirm feasibility for cell banking.

• Fetal and adult keratinocytes exhibit CK15 marker in later passages, showing their basal keratinocyte cell capability.

• Fetal and adult dermal cells are negative for markers CD34, CD14, CD45 and also for HLA DR and are positive for CD90, CD105, CD73 representing MSC according to the ISCT definition.

• Fetal and adult dermal cells are also capable of differentiating into chondrogenic, osteogenic and adipogenic cells using in-vitro assays.

Conclusions

•The use of epidermal adult cells and MSC offers opportunities for developing an autologous stem cell spray-Tx therapy in an “intra-operative setting” isolating and spraying keratinocytes and MSC immediately after the burn injury.

• These results allow us to advance the original concept from using autologous stem cells exclusively, to include fetal cells as a cell-banking product for clinical therapy on 2nd and 3rd degree burn injuries, potentially allowing new skin development.

1938

Precise Control of O_2 for Hypoxia Studies in Multi-well Cell Culture Plates.

M. Polinkovsky[1], E. Gutierrez[1], A. Groisman[1]; [1]Department of Physics, University of California - San Diego, La Jolla, CA

Hypoxic conditions, with the concentration of oxygen, [O_2], reduced below its normal physiological level, have been shown to significantly affect the expression of numerous genes and influence cellular behavior. In addition, to emulate native physiological conditions, it is preferable to culture cells at [O_2] = 7%, normally found in the human body, as opposed to [O_2] = 21% found in the atmosphere. However, physical limitations have made the precise control of [O_2] in cell cultures difficult. Diffusive transport of gas through the cell media is much slower than in the surrounding atmosphere, greatly increasing the equilibration time of [O_2] in the cellular environment with the incubator’s (or hypoxia chamber’s) atmosphere. Further, cell respiration may consume O_2 at a faster rate than diffusion through the media can replenish it, possibly resulting in significant differences between [O_2] in the incubator and around the cells. To overcome these problems, we have built and tested several systems to impose precise [O_2] in cell culture media in 24-well plates. The systems use a specially designed computer controlled, multi-channel gas mixer to generate mixtures of N_2 and O_2 (with 5% CO_2 in all mixtures), in which [O_2] is set anywhere between 0 and 21% with 0.1% accuracy. In the first system, six different N_2/O_2 mixtures are supplied to six rows of wells of a 24-well plate using flexible strips with micro-machined gas distribution networks and four silicone plugs in each strip (the plugs are inserted into the wells on the plate). Each plug is equipped with a tube, which is immersed in the medium and slowly bubbles gas through it, thus facilitating mixing and effective O_2 transport. In this fashion, we have the ability to study the response of cells to six different levels of [O_2] in parallel, with four separate wells for each [O_2]. We have tested this system by exposing mouse fibroblasts to hypoxic conditions and subsequently performing real-time PCR to study the effect on RNA expression of several hypoxia-activated genes. In addition, we found that without

bubbling, [O_2] around the cells rapidly drops far below [O_2] in the incubator once cell density reaches a high level, whereas with the bubbling, [O_2] around the cells closely matches the [O_2] in the incubator. We have also built two other multi-well plate systems that are equally efficient, but impose a uniform [O_2] upon all wells in the plate and are easier to use. The desired level of [O_2] in one of these systems can be effectively imposed by simply placing it into an [O_2]-controlled incubator. Our systems facilitate studies of cells under hypoxic conditions by enabling precise control of the oxygen content in the cell environment.

1939

Improved expansion of hematopoietic progenitors with osteogenically differentiated BM MSCs conditioned medium.

B. Celebi[1,2], Y. Boily[3], D. Mantovani[2], N. Pineault[3]; [1]Hema-Quebec Research & Development Dept, Department of Biochemistry, Microbiology, Laval University, Quebec, QC, Canada, [2]Laboratory for Biomaterials and Bioengineering, Laval University, Quebec, QC, Canada, [3]Hema-Quebec Research & Development Dept, Department of Biochemistry, Microbiology, Laval University, Canada

Objective: We recently reported that UCB hematopoietic stem cells co-cultured with irradiated mesenchymal stem cells (I MSCs) without contact increased cell and progenitor expansions due in part to the rapid differentiation of the MSCs into osteoblast-like cells following pre-irradiation treatment. The objective of this study was to determine whether expansion of hematopoietic cells and megakaryocyte progenitors would be recapitulated using medium conditioned with I-MSCs or osteogenically differentiated MSCs (OST).
Materials and Methods: Serum-free media were first conditioned for 7 days with I–MSCs (14 Gy) or OST cells. CD34+-enriched cells (>70%) were cultured in the conditioned media that were supplemented also with the cytokine cocktail OMPC (SCF, TPO, FL, from day 0-4) and BS1 (TPO, SCF, IL-6 and IL-9, from day 4-6), to favour progenitor expansion and megakaryocyte differentiation, respectively. Control cultures were supplemented solely with OMPC and BS1. At day-6, flow cytometry analyses and clonogenic progenitors (myeloid and megakaryocyte) assays were conducted.
Results: OST conditioned medium (CM) increased significantly the overall cell expansion achieved by CD34+ cell cultures at day-6 by 1.6-fold vs. control ($P< 0.01$) and 1.4-fold vs. I-MSC CM ($P< 0.07$). Expansions of CD34+ (1.8-fold, $P< 0.01$), CD34+41+ (megakaryocyte, 1.3-fold, $P< 0.01$) and CD235+ (erythroblast, 2.4-fold, $P< 0.05$) cells were also increased in OST CM compared to control. No significant differences in cell culture composition were observed in I MSC CM and control. Total myeloid (CFU-C) progenitors increased their expansions 1.3-fold while they were cultured in OST CM. Highest expansions (in CFU-C) were obtained for monocyte-granulocyte (CFU-G/M/GM) and granulocyte-monocyte-megakaryocyte progenitors (CFU-GEMM) such that 1.2 and 2.0-fold, non-significantly. Although I MSC CM had no impact on CFU-C, the rise expansion for CFU-G/M/GM progenitors was remarkable vs. control at day-6 (62±16 vs.45±20, $P< 0.05$). In contrast, the expansion of CD41+ cells and megakaryocyte progenitors (CFU-MK) were not promoted with I-MSCs and OST CM.
Conclusion: The present study demonstrated that OST conditioned medium increased total, CD235+, CD34+, CD34+ 41+ cell expansions and myeloid progenitors when used with our cytokine cocktail (OMPC and BS1). Future experiments will assess whether these growth advantages provided by conditioned medium translate into beneficiary in vivo reconstitution effects.

1940

Effect of Centrifugation on Viability of the Ciliated Protist, *Tetrahymena pyriformis.*

T. R. Carter[1], S. F. Revilla[2], R. E. Heard[1], J. M. Swann[3]; [1]Biology, Maryville College, Maryville, TN, [2]Biochemistry, Maryville College, Maryville, TN, [3]Maryville Coll, Maryville, TN

Because some labs report protocols that avoid centrifugation of suspension cultures, cell viabilities in cultures of *Tetrahymena pyriformis* were compared before and after centrifugation at different RPMs for varying amounts of time in order to determine if centrifugation resulted in lower cell viability. Trypan blue was utilized to indicate viability before and after centrifugation. There were no significant differences in viabilities before and after centrifugation when cells were centrifuged at 10K RPMs for 5 minutes (p=0.28; n=6), 10K RPMs for 10 minutes (p=0.067; n=12), 13.2K for 5 minutes (p=0.13; n=3), and 13.2K for 10 minutes (p=0.24; n=12). However, there were significant differences in before and after viabilities between cells that were 3 days old and cells that were 6 days old (p=0.003; n=6). It was concluded that, while centrifugation up to 13K RPMs for 10 minutes does not negatively affect the viability of 3-day old cultures, increasing age of the culture may result in a lower viability after centrifugation.

1941

New separation method of SDS-PAGE using inverse-gradient polyacrylamide gel.

M. Hashiguchi[1]; [1]Department of Physiology, Tokyo Medical University, Shinjuku, Japan

Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) is a widely used technique to separate a mixture of proteins based on their molecular size. Separation of proteins in SDS-PAGE relies on the gel concentration of acrylamide. Thus, suitable gel concentration must be chosen to separate target proteins.

I have been working on analyzing the regulatory mechanisms of tau phosphorylation catalyzed by tau kinases by Western blot analysis using phosphorylation dependent anti-tau antibodies. Phosphorylated tau proteins were separated on an acrylamide gel with similar migration distances and it is not easy to distinguish all the isoforms of phosphorylated proteins by immunoblotting because of sharing the immunoreactivity. Concerning this difficulty, better separation has been expected.

We are proposing the use of inverse-gradient acrylamide gel SDS-PAGE for the separation of the proteins with subtle differences in molecular size. This modified SDS-PAGE technique traps high molecular size proteins at the top of the gel, which contains high concentration of acrylamide. Electrophoresis of smaller size of proteins accelerates with decreasing acrylamide concentration of the bottom of the gel.

As a result, the method provided wider separation of proteins with certain molecular sizes below certain molecular weight. We found that 15-5% inverse-gradient gel is best suited for the reparation of the proteins smaller than 100 kDa. We will also demonstrate further improved method using inverse-gradient gel and the result will be discussed.

1942

A Novel System Enabling High Efficiency Low Toxicity Transfection of Cells in 3D Culture.

A. Lauer[1], D. Maltman[2], G. Talas[2], S. Przyborski[2], S. Hayes[1], L. Juckem[1]; [1]Mirus Bio, Madison, WI, [2]Reinnervate Ltd

Three-dimensional (3D) cell culture is an emerging trend in cell biology as it permits complex multicellular organization that more closely mimics the mechanical and biochemical cues present in native tissues as compared to routinely used two-dimensional (2D) cell culture. Transfection is an advantageous technique frequently used by cell biologists in 2D cell culture

and requires further development to be effectively expanded to 3D cell culture. In this study, we demonstrate a transfection system that implements the alvetex® polystyrene scaffold and a transfection formulation that enables high efficiency transfection of cells that have been adapted and grown in 3D culture. Unlike current 3D transfection protocols which require transfection of cells in suspension prior to plating in 3D matrices, we have established a system whereby cells are effectively transfected within the scaffold. To facilitate acclimation of cells to 3D culture, critical parameters such as cell density and post-seeding adaptation time were fine-tuned to obtain optimal transfection efficiencies. Thereafter, various transfection reagent formulations were tested for efficacy in terms of reporter output, e.g. luciferase and green fluorescent protein (GFP) expression, and absence of cytotoxicity in 3D culture. Transfection performance was further improved by titrating DNA dosage and reagent-to-DNA ratios. Optimization of cell growth conditions and transfection parameters has led to the development of a novel high efficiency low toxicity transfection system specific for 3D cell culture.

1943

Zinc-Finger Nucleases to "Chop" (Cop3) Chlamydomonas gens.

A. Greiner[1], I. Sizova[1], P. Hegemann[1]; [1]Experimental Biophysics, Humboldt-University Berlin, Berlin, Germany

The unicellular green algae *Chlamydomonas reinhardtii* is a promising model for fundamental and biotechnological research. A complete toolset for genetic manipulation has been developed for *Chlamydomonas* except site-specific gene targeting. By now we have developed a nuclear gene targeting system for *Chlamydomonas* which is based on the application of Zinc-Finger Nucleases (ZFNs) that function as artificial site-specific enzymes. ZFNs consist typically of 3 N-terminal ZF-modules each recognizing a DNA triplet. The C-terminal FokI domain works as a dimer and is able to induce DNA double strand breaks (DSB). Thus, two functional ZFN molecules must be created, both recognizing 9bp within the target sequence and separated by a small spacer (~6bp). DSBs stimulate homologous recombination that can be utilized to induce changes in the target sequence. However, engineering ZFNs for target sites that differ from the natural targets often results in low specificity and inefficient nuclease activity. The conclusion is that some target sites are better then others. Using available online tools the *Chlamydomonas* Channelrhodopsin1 (Cop3) genome sequence was searched for potentially good binding sites of available and evaluated ZF-modules. Although progress has been made in predicting the specificity of the assembled domains, *in vivo* testing is indispensable since unwanted off-target activity may result in cytotoxicity. Therefore we have constructed an easy-applicable model system for testing the sequence recognition of assembled ZF-modules in *Chlamydomonas*. We were able to optimize our system resulting in the successful generation of Cop3-specific Zinc-Finger Nucleases that targeted and finally deleted the non-selectable Channelrhodopsin1 gene in *C. reinhardtii*.

1944

Stabilization of Acetylcholinesterase Folding by Non-Catalytic Subunit N-Terminal Peptides Prevents Its ER Associated Degradation in Skeletal Muscle.

C. A. Ruiz[1], S. G. Rossi[2], R. L. Rotundo[2]; [1]Biology, Miami-Dade College, [2]Cell Biology and Anatomy (R-124), University of Miami Miller School of Medicine, Miami, FL

Acetylcholinesterase (AChE) terminates neurotransmission at cholinergic synapses in the peripheral and central nervous systems. The synaptic, or junctional, AChE in skeletal muscle derives from two separate gene products encoding the catalytic and the non-catalytic collagenic tail (ColQ) subunits, while a secreted tetrameric form is assembled from catalytic subunits either alone or with an N-terminal fragment of the non-catalytic subunit. However the vast majority of

newly synthesized AChE molecules do not assemble into catalytically active forms and are rapidly degraded by the endoplasmic reticulum associated protein degradation system. We have previously shown that AChE in skeletal muscle is regulated in part posttranslationally by the availability of ColQ subunits, and other laboratories have shown that the 17 amino acid N-terminal proline rich attachment domain (PRAD) of ColQ is sufficient to promote tetramerization of newly-synthesized AChE. Here we show that primary muscle cells or HEK cell lines expressing AChE catalytic subunits exposed to synthetic PRAD peptides containing an endoplasmic reticulum KDEL retrieval sequence take up and retrogradely transport them to the ER where they induce oligomerization and stabilization of AChE tetramers. The peptides rescue the newly-synthesized AChE molecules from ER degradation by enhancing AChE folding thereby stabilizing the tetrameric complex. This enhanced folding and stabilization of newly-synthesized AChE occurs in the presence of protein synthesis inhibitors indicating that it is post-translational. This in turn results in increased total cell associated AChE activity and increased secretion of active tetramers. These observations are supported by isotopically-labeled methionine pulse chase experiments showing that the newly synthesized AChE molecules are rescued from intracellular degradation. These studies provide a mechanistic explanation for the large intracellular pool of inactive AChE and intracellular degradation of 80% of AChE and suggest that simple peptides alone can increase the production and secretion of this critical synaptic enzyme in muscle tissue. Moreover, they suggest a novel therapeutic approach to treat organophosphate poisoning. These studies were supported by grants from the NIH to RLR and a Ruth Kirschstein National Research Service Award to CAR.

1945

Plasticity of the Asialoglycoprotein Receptor deciphered by ensemble FRET and Single-Molecule Counting PALM.

M. Renz[1], B. Daniels[1], I. Arias[1], J. Lippincott-Schwartz[1]; [1]National Institute of Child Health and Human Development, NIH, Bethesda, MD

The composition of many multi-subunited receptor complexes at the plasma membrane is still debated as well as the impact of changes in the receptor subunit composition. Receptor plasticity involving changes in stoichiometry and receptor function has been difficult to address. Here, we introduce new spectroscopic tools to dissect receptor subunit assembly of the Asialoglycoprotein Receptor (ASGPR). Using this highly tractable receptor model system we show that ASGPR can assemble into distinct oligomers at the plasma membrane and that differential subunit assembly dictates receptor specificity. With ensemble analyses of Fluorescence Resonance Energy Transfer (FRET) and analytical modeling, we quantified receptor subunit homo- and hetero-oligomerization in the living cell. Furthermore, we established single-molecule counting using Photoactivated Localization Microscopy (PALM), visualizing an asymmetric receptor subunit assembly on the single-molecule level. Our results define a probability hierarchy of ASGPR oligomerization driven by different molecular motifs that entails distinct co-existent receptor subunit assemblies. The Asialoglycoprotein Receptor is involved in the clearance of thrombogenic material [1,2]. The variety of potential ligands and the propensity of ASGPR subunits to form distinct oligomers may explain previous inconsistent results and underscore the importance of deciphering oligomerization in the single cell and on the single-molecule level.

1946

A specific,fast and gentle method of capturing cells expressing a protein of interest or exhibiting a specific promoter activity.

M. Haugwitz[1], O. Nourzaie[1], T. Garachtchenko[1], H. Sagawa[1]; [1]Clontech Laboratories, Mountain View, CA,

Existing cell capture technologies rely mainly on endogenous or exogenous protein markers that are unique to the cell type of interest. Specific T-cell populations, for example, have been isolated away from other blood cells in this manner using magnetic bead-based methods. Fluorescence activated cell sorting (FACS) is another widely used approach, however the harsh and unsterile sorting procedure itself is problematic for subsequent continuous culturing steps. However, capturing a sub-population of cells, distinguished from surrounding cells by the expression of a specific exogenous protein of interest or by exhibiting a specific promoter activity has not been addressed.
A novel cell capture system has been developed that addresses these limitations and allows for isolating homogeneous cell populations characterized by a specific promoter activity, or expressed protein. The CherryPicker™ system utilizes a chimeric membrane-anchored fluorescent protein with the dual purpose of providing both the monitoring and capturing moieties. Its red fluorescence can be monitored either via fluorescence microscopy or fluorometry, while the magnetic beads capture itself occurs via an antibody recognizing the chimeric protein. Importantly, the magnetic capture beads used in this system are unique in their remarkably low rate of non-specific binding.
The strength of this system is in its ability to isolate a homogeneous cell population. Of the entire population of transfected cells, only those with the desired gene or promoter activity express the chimeric membrane-anchored fluorescent protein, and are therefore prone to capture. This is achieved by expressing the chimera either with the protein of interest from a bicistronic mRNA, or its expression is driven by activation of a upstream promoter of interest. Since the capture method preserves cell integrity, the homogeneous cells can be re-cultured or further analyzed for marker identification purposes.
Here we present the distinct features of this magnetic bead-based cell capture system and how it can be used for re-culture purposes of captured cells. We show two studies where the methodology has been used to enrich for specific cells – the first for cells with an active NFkB response element, and the second, for cells expressing a constitutively active, cytosolic kinase mutant.

1947

Use of Fully Automated Cell Culture and Imaging Systems to Increase the Capacity and Consistency of Downstream Virology Assays.

J. M. Michelotti[1], D. Opishinski[1], K. Herman[1], N. Deiuliis[1], C. Jett[1]; [1]IRF, NIAID, contractor, Frederick, MD

The Cell Culture Laboratory at the NIAID Integrated Research facility is a newly designed core facility that is centralizing the production of tissue culture cells for translational virology research. The Cell Culture Lab supplies mammalian cells in flasks and plates to laboratories operating under standard Biosafety Level 2 (BSL-2) and high containment (BSL-3/4) conditions. In order to provide quality-controlled cell cultures to meet the needs of the Clinical Core Lab and molecular virologists, we are incorporating a tissue culture robot and automated imaging equipment into our workflow. The CompacT SelecT™ robot presently maintains multiple cells lines (e.g. VeroE6, BS-C-1, 293T) in T175 flasks in a controlled environment. The robot counts and checks cell viability before dispensing the cells into multi-well plates ready for downstream assays (e.g., plaque assays). Robotic plating is undergoing optimization by varying the viable

cell density, dispense volume and pattern, and incubation time. With such optimization, cell plating is completed in one quarter of the time required for manual plating. We are able to supply 2800 wells per week in confluent 6- or 24-well plates for downstream plaque assays. Comparative data from cowpox and simian hemorrhagic fever virus plaque assay show that the titers are analogous between cells plated by the robot and those plated manually. In addition, an Incucyte™ live-cell imager records cell growth properties and cell plating quality of selected plates to ensure consistency for multiple experiments. An in-house online system is under development that manages cell orders and generates valuable data about tropism of specific viruses for various cell lines. Automation of tissue culture provides both high quality cells and cost savings because of the centralization of tissue culture reagents and staff expertise.

1948

Detection of Mono-and Polyubiquitylated Proteins with Novel Ubiquitin Monoclonal Antibody.

S. Kumar[1], C. Richter-Landsberg[2], B. McLaughlin[3], V. Zhukareva[4,5]; [1]Progenra, Inc., Malvern, PA, [2]Molecular Neurobiology, Dept. of Biology, University of Oldenburg, Germany, [3]Dept. of Neurology, Vanderbilt University, Nashville, TN, [4]LifeSensors Inc., Malvern, PA, [5]Neurobiology and Anatomy, Drexel University, Philadelphia, PA

Work in the ubiquitin field is hampered by the lack of selective antibodies that recognize mono- and poly-ubiquitylated proteins. Many commercially available antibodies exhibit variable degrees of sensitivity and specificity against ubiquitin species in cell and tissue samples. Several ubiquitin antibodies available on the market detect predominantly polyubiquitin conjugates and have a low affinity to unconjugated ubiquitin limiting their usage in multiple applications. We have developed a panel of mouse monoclonal antibodies that recognize different configurations of ubiquitylated proteins. Here, we describe VU-1, a highly sensitive reagent for the identification of ubiquitin conjugates and free ubiquitin. The antibody was developed and tested in several applications in biochemistry and immunohistochemistry and can be used to address a wide spectrum of questions related to ubiquitin signaling. Here we demonstrate that VU-1 is a highly sensitive reagent for the identification of proteins with different degrees of ubiquitylation in cell and tissue lysates compared to other commercially available antibodies. Using tissue sections and different cell types in culture, we show that this antibody is a superior reagent for immunohistochemistry using both immunofluorescence and chromogenic substrates making it an indispensible tool for the Ubiquitome research.

1949

Improvement of Absorbance Measurements of Tetrahymena pyriformis Using the Vital Stain Acridine Orange/Ethidium Bromide.

S. F. Revilla[1], R. E. Heard[2], T. R. Carter[2], J. M. Swann[3]; [1]Biochemistry, Maryville College, Maryville, TN, [2]Biology, Maryville College, Maryville, TN, [3]Maryville Coll, Maryville, TN

Numerous published studies report absorbance values of unstained *Tetrahymena pyriformis* analyzed by a Spec20 spectrophotometer. Previous attempts by this lab to determine absorbances of unstained cultures from a microplate reader had yielded very low values. So, the goal of these experiments was to determine if the vital stain acridine orange/ethidium bromide improved absorbance readings from a microplate reader for *Tetrahymena pyriformis* cells in culture. Both stained and unstained samples of *T. pyriformis* were analyzed with a microplate reader using filters of differing wavelengths ranging from 340 nm to 655 nm. The highest absorbance from stained cells was achieved using a 495nm filter (mean OD = 0.160, n=18). The highest absorbances for unstained cells were obtained using filters at 340nm and 540nm wavelengths, each achieving a mean OD of 0.080 (n=6). The average absorbances for

stained and unstained cells at 90,000 cells/mL densities were significantly different (p=0.0238). Finally, cell cultures of increasing densities (20,000 to 100,000 cells/mL) were read by the microplate reader at 495nm, yielding a linear relationship (y = 0.0218x – 0.0152; r^2=0.0971, n=3). In conclusion, the microplate reader may be a useful method for estimating cell population counts of *Tetrahymena pyriformis* when the vital stain acridine orange/ethidium bromide is used.

Biophysical Approaches to Cell Biology

1950

Subcellular distributions of traction forces in HUVECs under uniaxial stretch.

A. Tsukamoto[1], T. Ushida[2], S. Tada[3]; [1]National Defense Academy of Japan, Yokosuka, Japan, [2]University of Tokyo, [3]National Defense Academy of Japan

Cellular components maintain physical balances which are collapsed with applied external forces. This collapse of the physical balances induces new physical balances and mechanotransduction. In order to understand how the collapse of physical balances occur in cells under uniaxial stretch, subcellular distributions of traction forces were measured in HUVECs before and after uniaxial stretch. Furthermore, in order to understand involvement of actin stress fiber in the collapse of physical balances, GFP-actin was expressed in the HUVECs. As a result, 12% uniaxial stretch decreased traction force at edge regions in single HUVECs. In contrast, the stretch increased traction force at internal regions in single HUVECs. The decrease of traction force correlated with ablation of actin stress fibers. Thus, it was suggested that ablation of actin stress fiber largely contribute to collapse of physical balances in HUVECs under 12% uniaxial stretch.

1951

Designed 3D polymer scaffolds to study the migration of cancer cells with altered nuclear mechanics.

A. M. Goldyn Greiner[1], M. Jaeckel[1], B. Richter[2], C. M. Franz[1], M. Bastmeyer[1]; [1]Cell- and Neurobiology, Karlsruhe Institute of Technology, Karlsruhe, Germany, [2]Applied Physics, Karlsruhe Institute of Technology

During metastasis cancer cells migrate out of the primary tumor to form sister tumors in distant organs. This cancer cell migration and invasion is not only determined by biochemical but also by physical cues of the environment. In addition, the mechanics of the cell nucleus has an impact on cell motility. Nucleus stiffness is mainly determined by the intermediate filament proteins lamin A/C.

Here, we investigate the migration and invasion behavior of cancer cells using a novel 3D cell culture system. Woodpile-like 3D scaffolds with different mesh sizes (5-15 µm) are fabricated by direct laser writing (DLW) into biocompatible photoresists. The scaffolds are manufactured by scanning a photoresist relative to the focus of a femtosecond-laser beam. Thus, DLW can be thought of as a pencil of light in three dimensions. The resulting 3D scaffolds are geometrically well-defined, have a physiologically relevant stiffness, and are surface-functionalized with ECM proteins.

The human A549 cancer cell line is used to establish a siRNA-mediated lamin A/C knockdown (KD). KD cells have significantly softer cell nuclei compared to control cells as quantified by atomic force microscopy. Furthermore, morphology of the nucleus and the actin cytoskeleton is changed for KD cells compared to control cells on 2D substrates. Wound healing assays show that cell migration rate is reduced and cell polarization is disturbed in KD cells. Concerning 3D

woodpile scaffolds, we observe morphological differences of the nucleus and the cell body in both KD and control cells. With decreasing mesh size the nucleus is divided by the 3D scaffolds into separate small but still connected compartments and cells form more protrusions. We also observe a reduced proliferation rate of KD cells on the 3D substrates compared to control cells and 2D substrates. We are currently optimizing our 3D substrates to investigate cell motility by live cell imaging.
In summary, we describe a novel 3D cell culture system that allows for the precise control over physical environmental properties. This system will be supportive for the basic understanding of cell migration and nuclear mechanics in general and in cancer metastasis.

1952

A novel culture system provides high yields of non-fibrogenic primary dermal fibroblasts for grafting applications.

S. Chaudhry[1], H. Majd[2], G. Pietramaggiori[2], B. Alman[1], T. Quinn[3], B. Hinz[1]; [1]University of Toronto, Toronto, ON, Canada, [2]EPFL, [3]McGill University

Background: The expansion of primary autologous dermal fibroblasts in culture is a pivotal step to obtain sufficiently high numbers for applications where large surface area tissue destructions, e.g., occurring in burn/trauma injuries, exceed the body's repair capacity and demand grafting of regenerative cells. Stimulated by the stiff surface of conventional culture plastic, a substantial percentage of fibroblasts spontaneously differentiate into fibrotic myofibroblasts by producing excessive amounts of collagen, *de novo* expressing α-smooth muscle actin (α-SMA), and consequently developing high contractile force. Myofibroblasts cause pathological tissue contractures characteristic of hypertrophic scars and fibrosis. Hence, suppressing this phenotype during cell culture expansion is crucial for the success of subsequent grafting. We hypothesize that culture on highly elastic surfaces will deliver better quality fibroblasts by inhibiting myofibroblast development. **Objective:** To investigate the intracellular signalling mechanisms that control the transition from beneficial reparative cells to harmful fibrogenic cells under different mechanical conditions. **Method:** To rapidly produce high numbers of fibroblasts for cell therapy we implement a novel method combining dynamic enlargement of the culture surface with fibroblast growth on a highly compliant, and extendable, silicone rubber (HESR). **Results:** 1) Attachment and proliferation of human dermal fibroblasts on functionalized HESR is similar to conventional tissue culture plastic. 2) Repeated passaging on plastic augments the percentage of fibrogenic myofibroblasts. 3) Primary fibroblasts explanted and cultured on static and dynamically expanded HESR begin to express α-SMA at later passage numbers and always at lower levels when compared to plastic culture. 4) HESR fibroblast cultures show differential gene expression of putative markers for fibrosis. 5) The pro-fibrotic cytokine TGF-β1 fails to activate myofibroblast differentiation on HESR. 6) HESR polymer rheology and not polymer chemistry is responsible for the mechanically-induced gene expression changes. 7) Single stretch events of 1-10% do not induce α-SMA on HESR, and 8) HESR dynamic expansion culture generates a multi-fold increase in daily cell yield while retaining the anti-fibrotic properties of static HESR. **Conclusion:** The low elastic modulus of the HESR membrane provides mechanical cues to primary dermal fibroblasts which are anti-fibrotic while dynamic expansion culture serves to maintain a cell density optimal for proliferation. **Support:** This research is supported by the Collaborative Health Research Program CIHR/NSERC (CHRP).

1953

Patterning Cardiac Myocyte Micro-tissues for Force Analysis on Soft Poly(dimethylsiloxane) (PDMS)-Substrates Using a Lift-off Membrane.

T. Jonas[1], N. Hampe[2], N. Hersch[2], B. Hoffmann[1], R. Merkel[1]; [1]Research Center Jülich, Institute of Complex Systems, Biomechanics (ICS-7), Jülich, Germany, [2]Research Center Jülich, Institute of Complex Systems, Biomechanics (ICS-7), Bonn, Germany

Microcontact printing (µCP) has become a valuable tool in the field of biology, creating surfaces with defined patterns of complex molecules helping to control cell shape in culture. However, µCP in cell biology is normally performed on rigid substrates, e. g. Petri dishes, glass, or gold surfaces using elastomeric stamps with patterns of interest transferring biomolecules to the substrates. Despite the fact that those substrates can easily be patterned by µCP they display an artificial environment for cells effecting the cell´s morphology and behavior. In addition to that disadvantage cell force analysis, e. g. on cardiac myocytes, is impossible to perform. Using tunable elastomeric substrates, mimicking the cells natural environment reveals a more natural morphology and behavior of the cell and provides the opportunity of cell force analysis. Nevertheless, µCP on soft elastomeric substrates (cross-linked silicone rubber (PDMS)) is very difficult to perform.
Here we describe the patterning of extracellular matrix (ECM) proteins and cardiac myocytes onto soft cross-linked PDMS substrates with a Young´s modulus ranging from 15- 75 kPa using a newly established lift-off membrane. The membrane features two different geometric patterning designs of squares and rectangular holes with diverse width-to-height ratios varying from 50 µm to 100 µm for the square holes and from 15 µm x 200 µm to 50 µm x 200 µm for rectangular holes. Those geometrical shaped patterns create small defined myocyte micro-tissues for the cell force analysis

1954

Conduction Slowing with Stretch in Micropatterned Cardiomyocytes.

E. Pfeiffer[1], B. Murienne[1,2], A. Wright[1], A. McCulloch[1]; [1]Bioengineering, UCSD, La Jolla, CA, [2]Biotechnology and Bioengineering, Ecole Polytechnique Federale De Lausanne, Switzerland

An optical mapping system has been developed for study of electrical conduction during biaxial stretch in cultured cardiomyocytes.

The health and disease effects of mechano-electric feedback during cardiac loading are incompletely understood. Characterizing the several conflicting mechanisms by which tissue stretch may modulate conduction velocity and arrhythmogenicity is difficult in an in situ model, where changes in tissue geometry during the cardiac cycle may confound local measurements. In fact, published reports of the nature of the effect of stretch on conduction in the whole heart disagree.1 Optical mapping techniques for imaging cardiac electrophysiology have been adapted for assessment of conduction in a two-dimensional cell culture.2 This method utilizes high temporal and spatial resolution imaging of a transmembrane voltage-sensitive fluorescent dye and avoids the electrical disturbances of electrode measurements. This system also permits application of physiological anisotropic biaxial strain.

Neonatal mouse and rat ventricular cardiomyocytes are cultured on anisotropically patterned silicone elastomer substrates.3 Grooves are created in the PDMS using a micropatterned silicon wafer mold, ensuring physiological rod-like morphology and permitting electrical coupling with axial and lateral neighbors. Custom stretch devices apply homogeneous anisotropic biaxial strain across the substrate, such that the direction of the primary axis of strain may be varied relative to the axes of the aligned cardiomyocytes. Optical imaging of excitation is accomplished

using voltage-sensitive di-8-ANEPPS dye and a CMOS camera. Conduction velocity and duration of the action potential may be quantified.

Patterned cultures of mouse cardiomyocytes exhibit arrhythmogenic conduction velocity slowing, where the magnitude of slowing increases with magnitude of strain (directed either parallel or perpendicular to cell longitudinal axis), with little effect observed for stretches of 5% or smaller. Physiological strain on the order of 10% in the major stretch axis results in a reversible conduction velocity slowing on the order of 20%, comparable with in situ results.4

Motor-driven force fluctuations in suspended cells and in cytoskeletal model systems.

D. Mizuno[1], D. Head[2], F. C. MacKintosh[3], C. F. Schmidt[4]; [1]Organization for the Promotion of Advanced Research, Kyushu University, [2]School of Computing, University of Leeds, [3]Dept. Physics, Vrije Universiteit Amsterdam, [4]Dept. Physics, Georg-August-Universität Göttingen, Göttingen, Germany

Mechanical processes, such as cell division and growth or cell locomotion, are essential in cell life and are driven and controlled by the cytoskeleton. The polymeric components of the cytoskeleton are semiflexible polymers. The activity of motor proteins creates directed forces as well as random force fluctuations.

We have studied such force fluctuations and, at the same time, mechanical properties of cells and of in vitro model systems with microrheology techniques. We have used micron-sized probe particles, embedded in the medium to be studied or attached externally to cells, and laser optical traps to confine the particles, combined with laser interferometry to detect either their spontaneous fluctuations or the particles' response to a driving force with sub-nm accuracy and bandwidths up to 100 kHz. We have applied this technology to cytoskeletal model systems consisting of crosslinked actin and myosin 2 motors as well as to osteocytes and fibroblasts. We have universally found an intriguing spectral characteristic of the motor-generated fluctuations, resembling deceptively that of Brownian motion in a viscous fluid. We show that a simple model of slow build-up and sudden release of motor-generated tension in the elastic networks can explain this observation.

1956

Using Oscillating Magnetic Fields and Magnetic Nanoparticles To Improve Transfection Efficiency and Protein Expression.

A-J. Tyler[1], A. Fouriki[2], J. Lim[1], J. Dobson[3]; [1]Nanotherics Limited, Stoke-On-Trent, United Kingdom, [2]Institute for Science & Technology in Medicine, Keele University, Stoke-On-Trent, United Kingdom, [3]Department of Materials Science and Engineering, University of Florida, Gainesville, FL

OBJECTIVES: To evaluate the effectiveness of nanomangetic transfection combined with oscillating magnet arrays to improve gene uptake and protein expression.
METHODS: Magnetic nanoparticles complexed with either plasmid DNA or short interfering RNA (siRNA) were introduced to cells in culture and exposed to a high-field/high-gradient oscillating magnet array. For comparison, transfections were conducted on cells exposed to a static magnetic field, electroporation and cationic lipid transfection agents. Transfection efficiencies and protein yields were determined using fluorescence microscopy, flow cytometry or lucifierase assay.
RESULTS: Transfection efficiencies of 20-40% for primary hippocampal neurons and Mesenchymal Stem cells (MSCs) were achieved with GFP-nanoparticle complexes using the oscillating magnetic array, with >80% cell viability. Using a large (11kb) neuron-specific plasmid, mature neurons (>14 days *in vitro*, DIV) were successfully transfected with high cell viability. Delivery of siRNA against actin in the presence of an oscillating magnetic field was highly effective, with 75% knockdown observed in HeLa. Finally, Chinese Hamster Ovary (CHO) cells transfected with a Luciferase reporter plasmid demonstrated a six-fold increase in protein expression levels compared with conventional methods.
CONCLUSIONS: The use of oscillating magnetic fields in nanomagnetic transfection is very effective compared to other leading non-viral methods, even in hard-to-transfect cell types. High cell viabilities were maintained in all cases. This application exhibited the ability to 1) introduce large plasmids into mature primary hippocampal neurons; 2) improve protein production, and 3) silence an endogenous gene in an important cell line. The use of oscillating magnetic fields coupled with nucleic acid complexed with magnetic nanoparticles is a simple yet effective technique in gene delivery which will be an invaluable tool for cell biology research.

1957

Oxygen microscopy and high-throughput analysis of icO_2 by means of cell-penetrating phosphorescent dyes.

R. I. Dmitriev[1], A. Fercher[1], A. V. Zhdanov[1], D. B. Papkovsky[1]; [1]Biochemistry, University College Cork, Cork, Ireland

The molecular oxygen (O_2) is one of the key parameters in analysis of mitochondrial function and cellular metabolism. In recent years new approaches based on the use of cell-penetrating phosphorescent O_2 sensitive probes were introduced. Among these, protein-, peptide- or nanoparticle-based probes show the potential for analysis of extra-, peri- and intracellular O_2 (icO_2).
Here, we report the development and evaluation of a number of cell-permeable intracellular phosphorescent O_2 probes which allow measurement of icO_2 in live cells: 1) the probes consisting of cell-penetrating peptide moiety (Arg- or Pro-rich) conjugated with PtCP dye which demonstrate various patterns of subcellular localization ranging from endosomal compartments to whole cell distribution and 2) PtTFPP dye embedded into positively charged nanoparticles which has increased brightness and photostability advantageous for microscopy imaging applications. The O_2-dependent luminescence of these probes can be measured on different

platforms such as TR-F microplate readers and fluorescence microscope (in intensity-based or FLIM-based modes).
Both classes of O_2 probes were tested on various cell lines in order to evaluate kinetics of cell staining, cell toxicity and possible cell-specificity specificity. A number of 'model' experiments have been performed including stimulation of mitochondrial respiration in adherent cells under different levels of external hypoxia. The cells produced the anticipated respiratory responses, with changes in probe signal and local (intracellular) O_2 concentrations reflecting dynamics of cellular respiration.
The usefulness of these new cell-permeable probes was demonstrated in physiological study of uncoupling effect of bafilomycin A1 (Baf) and ex vivo imaging applications. Altogether, the phosphorescence based cell penetrating O_2 probes represent a simple and efficient tool for analysis of icO_2 and cell bioenergetics.

BRET reports the subcellular localization and topology of membrane proteins with high spatial and temporal resolution.

T-H. Lan[1], Q. Liu[1], N. A. Lambert[1]; [1]Pharmacology and Toxicology, Georgia Health Sciences University, Augusta, GA

Many cellular functions require membrane proteins to be localized in a particular subcellular compartment or to move between compartments. Therefore, it is frequently necessary to determine the subcellular location of a membrane protein, or to track the movement of a protein between organelles. Here we demonstrate that bioluminescence resonance energy transfer (BRET) can report the subcellular location of membrane proteins in populations of live cells with high spatial and temporal resolution. In a typical experiment a membrane protein of interest is fused to a BRET donor (*Renilla* luciferase; Rluc8), and a membrane-bound compartment is labeled with a small targeting peptide fused to a BRET acceptor (venus fluorescent protein). A BRET signal is produced only if the membrane protein of interest is located in the acceptor-labeled compartment. For example, the temperature-sensitive vesicular stomatitis virus G protein tsO45 mutant fused to Rluc8 (VSVG-Rluc8) is retained in the endoplasmic reticulum (ER) at 40°C, and at this temperature produced BRET only with acceptors localized in the ER. After shifting to 32°C BRET between VSVG-Rluc8 and ER markers decreased, whereas BRET between VSVG-Rluc8 and markers of the golgi apparatus and plasma membrane increased. Similar results were observed when forward trafficking of misfolded G protein coupled receptors (GPCRs) was induced by pharmacological chaperones. BRET readily detected differences in the steady-state localization of the small G proteins H-Ras and K-Ras, and changes in H-Ras localization due to block of palmitoylation. BRET occured only when donor and acceptor moieties were located on the same side of a membrane bilayer, thus the method reported membrane topology, and resolved inner and outer mitochondrial membranes. The temporal resolution of BRET was sufficient to monitor translocation events that occurred in less than one second. The method yields semi-quantitative measures of membrane abundance without extensive data processing or user intervention, and can be scaled to medium-throughput with a simple plate reader. BRET is thus a versatile alternative to fluorescence microscopy and other methods to determine the subcellular location of membrane proteins. *Supported by NIH grants GM078317 and GM096762.*

1960

Use of a cell based screening device to decipher complex cell-microenvironment interactions.

J. Bingham[1], N. Serobyan[1], M. Zhang[1]; [1]MicroStem, San Diego, CA

Mammalian cells exist in unique micro-environments in vivo that affect their behavior (proliferation, differentiation, death, etc.) and function. When cells are cultured in vitro, it is necessary to recapitulate such microenvironment for physiologically relevant growth. Among many factors affecting cell behavior in vivo, extra cellular matrices (ECMs) play a significant role in determining cellular functions. Currently, finding the optimal ECM for cell culture is a trial and error process requiring large numbers of cells as well as a significant time and cost commitment.
MicroStem has developed a cell screening technology that deciphers and leverages optimal ECM combinations as a method for immobilizing live cells in a physiologically relevant state for high content immuno-fluorescent study of cellular function and behavior. The technology is especially powerful when studying rare cell populations like stem cells and human primary cells extracted during surgery. MicroStem has used this technology to study human primary cells such as cancer stem cells and human mesenchymal stem cells isolated from bone marrow. In each case, use of the technology led to a determination of an optimal ECM for which respective cells would attach and maintain proper cell function in vitro. This is the first technology of its kind that allows researchers to immediately study rare physiologically relevant cell behavior in vitro with out substantial scaling of cell populations.

1961

Optimal growth of cells in 3D culture relies on the appropriate shape and form of the supporting scaffold.

S. Przyborski[1]; [1]Reinnervate Limited, Sedgefield, United Kingdom

Cultured mammalian cells are important tools for providing predictions of drug activity, basic cell function, disease modeling, and toxicity in vivo. However, conventional cell culture environments are far removed from real-life tissues. In vivo, cells grown naturally in three dimensions (3D) and are supported by a complex extracellular matrix which facilitates cell-cell communication via direct contact and through the secretion of trophic factors. In contrast, cells grown in two dimensional (2D) culture are generally confined in flat monolayers. It is widely recognized that culturing cells in 3D radically enhances cell growth, differentiation and function. Authentic 3D cell cultures provide greater insight to how cells behave in the body in response to external challenges than is currently possible with existing 2D culture technologies. However, there is currently platform no technology that supports genuine 3D cell culture for routine use alongside conventional 2D cell culture methods.
Our research has resulted in the development of alvetex, a unique highly porous polystyrene scaffold that supports genuine 3D cell culture. Alvetex is developed for routine use following straightforward protocols and using conventional laboratory equipment and practices. Analysis of the resulting cultures is compatible with a broad range of standard molecular and cellular assays.
The shape and form of alvetex is an essential aspect to enable its optimal use and therefore much attention has been directed to the presentation of the scaffold and its application for 3D cell culture. For example, alvetex is engineered into a 200 micron thick membrane to enable cells to penetrate the material throughout and receive adequate nutrient and oxygen exchange. Different formats of the technology are presented for alternative uses, including a well insert for feeding cells from above and below the scaffold, and the option to include a large medium reservoir to support long term 3D cell cultures.

The 3D growth of many different cell types has been tested using alvetex technology. Cell types that are commonly used in industry such as CHO, HepG2, 3T3 fibroblasts, grow readily on alvetex. In addition, more extensive research has led to the development of customized 3D assays for liver toxicity and the development of skin equivalents. We will present evidence showing that cells grown in alvetex display enhanced cell viability, differentiation and function when compared to conventional 2D culture models.

1962

Quantifying the persistence of cell shape over time and through mitosis.

L. Case[1,2], A. Buchwalter[1,3], A. York[1,4], V. Hughes[1,5], Z. Santos[1,6], R. Khaliullin[1,7], C. Tropini[1,8], D. Cohen[1,9], H. Ishikawa[1,11], P. Avasthi[1,10], W. F. Marshall[1,10]; [1]Physiology Course, Marine Biological Laboratory, Woods Hole, MA, [2]NHLBI, Bethesda, MD, [3]Cell Biology, Washington University St. Louis, [4]NIH, [5]Biology, Indiana University, [6]Instituto Gulbenkian de Ciência, [7]Illinois Institute of Technology, [8]Stanford University, [9]UC Berkeley, [10]Department of Biochemistry and Biophysics, Univ California-San Francisco, San Francisco, CA

A major unanswered question in cell biology is what mechanisms determine the shape of cells. Because cell shape results from an interplay of dynamic processes, it is best viewed as a dynamical system, with biochemical regulatory pathways acting to "steer" the trajectory of the system towards an evolutionarily advantageous shape. In order to understand cell shape from a dynamical systems perspective, it is essential to know the time scale over which cell shape can persist. Here, we have addressed this question in two ways. First, we consider whether cell shape can be transmitted during mitosis. By comparing sister cells immediately after division, we ask whether sisters show increased similarity compared to non-sisters. We compared several different shape comparison metrics, including a chamfer matching based approach, an approach based on the Procrustes algorithm, and a non-rigid shape matching method. We found that for a set of data taken with fixed RPE1 cells, all methods showed strong evidence for similarity, whereas for live cell imaging of 3T3 cells, the first two methods did not show any evidence of similarity between sisters, while the non-rigid shape matching method did show a statistical bias for sisters to be more similar than non-sisters. We also tested whether there was a bias for or against mirror symmetry and found that the similarity between sisters did not have any bias for either type of symmetry for the live 3T3 cells, while for the fixed RPE1 cells there was a clear bias in favor of mirror symmetry. We also examined the shapes of mother cells immediately before division, and found that they tend to be bilaterally symmetric, which suggests a possible origin for a mirror symmetry bias in daughters, at least in some cell types. Finally, we directly analyzed the time scale of cell shape persistence using a principal components analysis in which we could reduce cell shape variation to a small number of modes, and then measure the relaxation time of those modes.

Prokaryotic Cell Biology

1963

A small molecule stabilizer of FtsZ inhibits cell division in Gram-negative bacteria.

Y-J. Eun[1], D. Kiekebusch[2,3], M. Foss[1], M. Thanbichler[2,3], D. Weibel[1,4]; [1]Biochemistry, University of Wisconsin-Madison, Madison, WI, [2]Max Planck Institute for Terrestrial Microbiology, Germany, [3]Department of Biology, Philipps University, Germany, [4]Department of Biomedical Engineering, University of Wisconsin-Madison

In bacteria, cytoskeletal proteins play a role in various processes including cell division and cell wall remodeling. FtsZ is a homolog of eukaryotic tubulin that polymerizes in the presence of GTP. In vivo, FtsZ polymers localize into a ring-like structure at the mid-cell to initiate cell division. The FtsZ ring provides a constricting force, and recruits other division proteins. The importance of chemical tools for studying eukaryotic cytoskeletons has fueled efforts to discover small molecule inhibitors of FtsZ. However, very few compounds have been demonstrated to target FtsZ specifically, and the best-characterized compound (PC190723) is effective only in Gram-positive organisms. Using a high-throughput in vitro screen, we identified a new FtsZ inhibitor and named it Divin (*DIV*ision *IN*hibitor). We found that the treatment with Divin caused incomplete constrictions in dividing cells of Gram-negative bacteria, including *Caulobacter crescentus* and *Escherichia coli*. The Divin-induced phenotype was similar to the morphology of FtsZ-overexpression strains, which led us to hypothesize that Divin stabilizes the division machinery in vivo. We tested this hypothesis by treating MipZ-overexpression and Δ*zapA* strains with Divin: MipZ and ZapA are antagonists and agonists of FtsZ polymerization, respectively. The presence of Divin suppressed the antagonistic effect of excess MipZ, and rescued the agonist-deficient cells. These results indicate that Divin inhibits cell division by stabilizing FtsZ. To measure a direct interaction between Divin and FtsZ, we performed a competitive binding assay using a fluorescent GTP analog. The apparent dissociation constant was 7 ± 6 μM for the Divin-FtsZ complex. In summary, we report a novel inhibitor, Divin, whose function is analogous to the stabilizing effect of Taxol on microtubules. We envision that this small molecule will be a valuable chemical tool for studying the function and structure of FtsZ, and can be potentially developed as a therapeutic agent against bacterial infections.

1964

In vivo time-lapse imaging reveals the mechanism of DNA segregation by the bacterial actin-like protein AlfA.

J. K. Polka[1,2], S. Arumugam[1,3], Z. Santos[1,4], A. Vander Heyden[1,5], R. D. Mullins[1,6]; [1]Physiology Course, MBL, San Francisco, CA, [2]Department of Biochemistry, UCSF, San Francisco, CA, [3]Department of Biophysics, Biotechnologisches Zentrum der TU Dresden, [4]Instituto Gulbenkian de Ciência, [5]Department of Cell Biology and Physiology, Washington University School of Medicine, [6]Department of Cellular and Molecular Pharmacology, UCSF

AlfA is an actin-like protein encoded by a plasmid from Bacillus subtilis. It forms filaments and promotes plasmid partitioning during vegetative growth and sporulation. The in vitro dynamics of AlfA filament assembly (lack of dynamic instability and anti-parallel bundling) are incompatible with proposed models of plasmid segregation driven by the actin-like protein ParM. To understand the mechanism of AlfA-dependent DNA segregation, we imaged AlfA polymers and plasmids by time-lapse fluorescence microscopy and used particle tracking to characterize DNA motions. We find that AlfA promotes two distinct plasmid motions, depending on cell growth conditions. In exponentially growing cells taken from liquid media, the alf operon positions plasmids at regular intervals along the long axis of the cell and reduces plasmid mobility. In

these cells, AlfA forms small, dynamic foci closely associated with plasmids. In cells taken from colonies grown on solid media, however, AlfA forms long-lived bundles composed of many short, dynamic filaments that promote plasmid movement. We postulate that the two modes enable the alf system to position plasmids equally between daughter cells during binary fission and increase the frequency of delivery to cell poles during sporulation. In contrast to the dynamic behavior of AlfA filaments observed in vivo, FRAP experiments performed in vitro reveal that purified AlfA filaments are much more stable. Our results both suggest a mechanism for DNA segregation AND indicate that unknown factors, provided by either the plasmid or the host cell, promote filament turnover.

1965

Structures of the RNA-guided surveillance complex from a bacterial immune system.

G. C. Lander[1], B. Wiedenheft[2], K. Zhou[2], M. M. Jore[3], S. J. Brouns[3], J. van der Oost[3], J. A. Doudna[2], E. Nogales[1]; [1]Life Sciences, Lawrence Berkeley National Lab, Berkeley, CA, [2]Mol and Cell Biology, UC Berkeley, [3]Wageningen University, Netherlands

Prokaryotes acquire resistance to viruses and plasmids by integrating short fragments of foreign DNA into clustered regularly interspaced short palindromic repeats (CRISPRs). The long CRISPR transcript is processed into a library of short CRISPR-derived RNAs (crRNAs) that each contain a unique sequence complementary to a foreign nucleic-acid challenger. In E. coli, crRNAs are incorporated into a multisubunit surveillance complex called Cascade, which is required for protection against bacteriophages. We used cryo-electron microscopy to determine the subnanometer structures of Cascade before and after binding to a target sequence. These structures reveal an architecture in which the crRNA is displayed along a helical arrangement of protein subunits that protect the crRNA from degradation, while maintaining its availability for base pairing. Cascade engages invading nucleic acids through high-affinity base-pairing interactions near the 5′ end of the crRNA. Base pairing extends along the crRNA, resulting in a series of short helical segments that trigger a concerted conformational change. This conformational rearrangement may serve as a signal that recruits a trans-acting nuclease (Cas3) for destruction of invading nucleic-acid sequences.

1966

Swarmer cells of Proteus mirabilis migrate faster than swimmer cells in viscous environments.

H. H. Tuson[1], M. Copeland[1], S. Trevino-Dopatka[1], R. Sacotte[1], D. Weibel[1,2]; [1]Biochemistry, University of Wisconsin - Madison, Madison, WI, [2]Biomedical Engineering, University of Wisconsin - Madison, Madison, WI

It has been repeatedly shown that slight increases in viscosity actually lead to increases in the swimming speeds of a wide variety of organisms, which is interesting given that many bacteria, especially pathogenic bacteria, commonly exist in viscous environments such as the mucosal lining of the gut. One such bacterium is *Proteus mirabilis*, an opportunistic human pathogen that can migrate through the urinary tract. It has been suggested that swarming, a type of surface motility that allows rapid migration, is involved in urinary tract colonization. During swarming, cells of *P. mirabilis* undergo a morphological change from ~5 μm long rods with 5-15 flagella to ~10-50 μm long rods with 50 to more than 100 flagella. Prior work has shown that increasing the number of flagella on a cell does not yield the expected increase in torque – i.e., a four-fold increase in the number of flagella yields less than a two-fold increase in torque. This result suggests that the dense flagellation of swarmer cells should not convey a motility advantage. However, mutant cells of *Bacillus pseudiformis* that express an increased number of flagella do swim faster than their wild-type counterparts in viscous solutions, and it has been proposed that

this increase in speed is due to altered flagellar bundling. We are examining whether this phenomenon also occurs with the different morphological forms of *P. mirabilis*. We harvest homogenous populations of four different cell morphologies: (1) long and hyperflagellated [swarmer], (2) short and normally flagellated [vegetative], (3) short and hyperflagellated [consolidated], and (4) long and normally flagellated [elongated vegetative]. We then use microscopy and MATLAB-based cell-tracking software to measure the swimming velocity of each of these different cell types in fluids containing different amounts of polyvinylpyrrolidone, a polymer that increases the viscosity of the solution. We have found that swarmer cells of wild-type *P. mirabilis* are significantly faster ($P<0.001$) than all other cell types in media with a viscosity of 9 - 1260 cP. In media with a viscosity of 8340 cP, swarmer cells are motile while all other cell types are amotile. These results suggest a possible role for the swarm cell morphology: allowing migration through viscous mucosal layers during infection. Furthermore, vegetative/swarmer cells of a strain that over-expresses FlhDC (a transcription factor responsible for an increase in flagellar synthesis) are not significantly faster than wild-type cells with the corresponding morphology, suggesting that an increase in flagellar density alone is insufficient to produce an increase in swimming velocity.

1967

Phylogenetically-Based Classification of Newly Sequenced Haloarchaeal Rhodopsins.

K. Shao[1,2], M. T. Facciotti[1]; [1]Biomedical Engineering, University of California at Davis, Davis, CA, [2]Davis Senior High School, Davis, CA

We present a broad phylogenetic analysis of 128 haloarchaeal opsins proteins encoded in the genomes of 65 newly and 14 previously sequenced species of halophilic archaea. Distinct branching within the bacteriorhodopsin (bR) and sensory rhodopsins (sR) clades suggests that greater functional segregation may be present within these two classes than has previously been appreciated. The sRs, for instance, cluster to form sub-clades beyond those of the well-known sR I and sR II. This finding lends additional support to a recent hypothesis, derived from biochemical characterizations of *Haloarcula marismortui's xop2*, which suggests a separate sR III functional group may exist. Interestingly, the sR III group is populated by at least three other sequences aside from *xop2,* making it nearly as well represented as the two previously known sR groups. Like sR, bR also diverges into multiple subgroups. We present spectroscopic data showing that the visible absorbance maximum of a secondary bR in *H.marismortui* is shifted ~20nm left of *Halobacterium salinarum's.* Mapping clade-specific amino acid substitutions onto the wild-type bR structure reveals that many of these residue substitutions occur on the interfaces between helices rather than within the cavity itself or the exterior surface. We hypothesize that these amino acid substitutions might be responsible for fine-tuning bR's spectral response curve. Finally, a novel clade of opsins has also been uncovered, whose members lack a structurally conserved lysine residue that typically functions as a covalent attachment site for a retinal chromophore. Further phylogenetic analysis performed in the context of a wider microbial opsin community, with 2000+ opsin sequences derived from non-redundant environmental samplings ("env_nr") and hypersaline metagenomes, suggests that these opsins are most closely related to fungal opsin-related proteins (ORPs), a group whose function, other than assistance in cell survival under stress, remains unknown. Cloning, expression and spectroscopic characterization of 3 of these novel haloarchaeal opsins, as well as of 23 additional bRs, is ongoing, and time permitting, may also be presented.

Assembly of a bacterial cell division machine.

E. D. Goley[1], Y-C. Yeh[2], H. McAdams[2], L. Shapiro[2]; [1]Biological Chemistry, Johns Hopkins University, Baltimore, MD, [2]Stanford University

Cytokinesis in Gram-negative bacteria is mediated by a multiprotein machine (the divisome) that assembles at midcell and serves to invaginate and remodel the inner membrane, peptidoglycan, and outer membrane. In the alpha-proteobacterium *Caulobacter crescentus*, the incipient division site also serves as a platform for localized peptidoglycan synthesis during elongation of the cell and recruitment of factors involved in the establishment of cell polarity. Understanding the order of assembly of proteins at midcell would inform models of the interactions among its components, their respective functions, and the mechanisms underlying integration of cytokinesis with other cell cycle events. We therefore leveraged the ability to isolate synchronous populations of *Caulobacter* cells to investigate assembly of proteins at the division site and place the arrival of each component into functional context. Additionally, we investigated the genetic dependency of localization among divisome proteins and the cell cycle regulation of their transcript and protein levels to gain insight into the control mechanisms underlying their assembly. Our results revealed a picture of assembly of proteins at midcell with unprecedented temporal resolution. Specifically, we observed 1) initial establishment of the division site, 2) recruitment of early FtsZ-binding proteins, 3) arrival of proteins involved in peptidoglycan remodeling, 4) arrival of FtsA, 5) assembly of core divisome components, 6) initiation of envelope invagination, 7) recruitment of polar markers and cytoplasmic compartmentalization, and 8) cell separation. Our analysis revealed differences in divisome assembly among Caulobacter and other bacteria that establish a framework for identifying aspects of bacterial cytokinesis that are widely conserved from those that are more variable.

Entropy-driven translocation of an unstructured protein through the Gram-positive cell wall.

D. K. Halladin[1], K. C. Huang[1], A. Gopinathan[2], J. A. Theriot[1]; [1]Stanford University, Stanford, CA, [2]UC Merced

Listeria monocytogenes is a Gram-positive, intracellular pathogen that recruits host factors to promote the polymerization of actin filaments at its surface. The only bacterial molecule that is required to initiate actin-based motility is the transmembrane protein ActA. Because ActA is a transmembrane protein, and thus effectively anchored to the membrane, it must find a way to extend beyond the thick, highly cross-linked Gram-positive cell wall in order to interact with host cytoskeletal factors. We offer a geometrical explanation for protein translocation through the Gram-positive cell wall that is dependent only on the energetics of the protein and the physical properties of the translocation barrier. The predictions from our hypothetical model suggest that the entropic constraint imposed by a small periplasmic space could drive the translocation of a large, unstructured protein (e.g. ActA) across a barrier with a thickness and porosity similar to that of the Gram-positive cell wall. We present three independent experimental results that support our proposed entropic model. First, we show that truncating the endogenous ActA protein below a critical length shifts the entropically beneficial state from an extended state to a periplasmic state. Second, we demonstrate that exogenous disordered proteins of sufficient size are able to translocate through the Listeria cell wall. Finally, we show that a sufficiently large, unstructured protein will translocate through the Bacillus cell wall, while a shorter unstructured protein will not. Further, bioinformatic analysis of disordered proteins in Gram-positive bacteria suggest an enrichment for large, disordered regions in surface proteins of host-associated bacteria.
