## ABSTRACT

**Objective:** We examined the association of different chronic physical and mental conditions, individually or comorbidly on health-related quality of life (QoL) in Chinese children aged  $\leq 14$  years in Hong Kong.

**Design:** Population-based cross-sectional survey.

**Participants:** Approximately 7500 Chinese children aged  $< 14$  years in Hong Kong.

**Interventions:** Nil.

**Primary and secondary outcome measures:**

Various health concepts of validated Chinese version of Child Health Questionnaire (CHQ), a health-related QoL questionnaire in children.

**Result:** There was significant association of physical and mental health conditions, either individually or comorbidly, on the various concepts of CHQ. Children with mental health problems were apparently more affected than those with physical health problems. Chronic renal disease and congenital malformation were the physical health conditions associated with the lowest scores in CHQ concepts in children aged 5–10 years and aged 10–14 years, respectively. Behavioural problem was the mental health condition associated with the lowest score in CHQ concepts in both age groups.

**Conclusions:** Our study shows important information concerning the prevalence of different health conditions and its association, either individually or comorbidly on the QoL in a representative sample of Chinese children in HK.

## INTRODUCTION

The WHO (1948) defines health as ‘a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity’. There has been an increasing use of health-related quality of life (HRQoL) assessment tools to assess the full impact of physical illness in both children and adults to guide the attainment of possible highest standard of health at individual, societal and population level. Data from representative population sample for comparison of the impact of various conditions and for

## ARTICLE SUMMARY

### Article focus

- To explore any association between chronic physical and mental health conditions and quality of life (QoL) in Chinese children aged  $\leq 14$  years.
- To compare the attributing effect of isolated physical health condition versus isolated mental health condition on various concepts of Child Health Questionnaire (CHQ), a validated QoL questionnaire commonly employed in children.
- To examine the effect of comorbid physical and mental health conditions on CHQ. Any effect on QoL in Chinese children aged  $\leq 14$  with comorbid health condition.

### Key messages

- There was significant association of physical and mental health conditions, either individually or comorbidly, on the various concepts of CHQ in a representative sample of Chinese children aged  $\leq 14$  years in Hong Kong.
- Children with mental health problems were apparently more affected than those with physical health problems.
- Chronic renal disease and congenital malformation were the physical conditions associated with the worst QoL in children aged 5–10 years and children aged 10–14 years, respectively, while behavioural problem was the mental health conditions associated with the worst QoL CHQ in both age groups.

measurement of the impact of having more than one condition on health and well-being are needed to provide surveillance framework for promotion and preventive health programmes of population health.<sup>1</sup> While there have been substantial studies that focused on a particular physical illness on QoL of individual patients, studies of the impact on QoL due to multiple conditions which occur more commonly in children<sup>1</sup> or older people<sup>2</sup> were scarce and furthermore there is no report on Chinese children. We therefore conducted a study to examine the association of different physical and mental

## ARTICLE SUMMARY

**Strengths and limitations of this study**

- One of the largest studies using a child self-report QoL measure in a population-based study.
- Use of both child self-report when age warranted and parent reported for younger ages within a study with fairly concurrent result is another substantial strength.
- Parental reports of physician diagnosed health conditions might underestimate the prevalence of various health conditions.
- Possibility of over-rating about certain health concepts like family activities, family cohesion as it was difficult to keep absolute confidentiality in children aged 10–14 years who reported CHQ themselves due to in general small household size in Hong Kong.
- Our study result may not be directly applicable to Chinese elsewhere as the living environment and standard, societal influence, social value, etc are different.

conditions, individually or comorbidly, on the general health (GH) and well-being of Chinese children in Hong Kong (HK).

**METHODS****Sampling strategy and sample size**

The Child Health Survey (CHS) was a population-based cross-sectional in-person household health survey of Chinese children aged  $\leq 14$  years in HK. The survey was carried out from September 2005 to August 2006. The target sample size was set to be approximately 7500 subjects. Details of sampling methodology are delineated in CHS Report 2005–2006, Department of Health, HK.<sup>3</sup> In brief, sampling units were selected using systematic replicated samples based on the frame of quarters maintained by the Census and Statistics Department at the first stage. At the second stage, households with children aged  $\leq 14$  residing were selected for the interview and all children aged  $\leq 14$  in the sampled households were included. The survey was approved by the Ethics Committee of Department of Health, HK. Written consent was obtained from parents.

**Survey instruments**

We obtained information from a parent as proxy respondent for children aged under 11, and both directly from the child and from a parent for those aged 11–14. We conducted face-to-face interview with parents of all participants to obtain household, family and personal demographic characteristics. We measured the GH status using the Child Health Questionnaire (CHQ). CHQ was developed in the USA for the measurement of physical and psychosocial well-being of children aged 5 and older.<sup>4</sup> Parents of children aged 5–10 completed the validated Chinese version of the CHQ-parent form CHQ-PF50 and children aged 11–14 completed the validated Chinese version of the CHQ-child form

CHQ-CF87, respectively, without the help of the interviewer.<sup>5</sup> The CHQ-PF50 and CHQ-CF87-consist of 50 and 87 items, based on which 14 multidimensional health concepts are measured. These concepts include: GH perceptions, physical functioning (PF), role functioning-emotional (RE), role functioning-behavioural (RB), role functioning-physical (RP), bodily pain (BP), general behavioural (BE), mental health (MH), self-esteem (SE), family activities (FA), family cohesion (FC), parental impact-emotional (PE), parental impact-time (PT) and change in health (CH). The two concepts, RE and RB are combined into one, namely role functioning-emotional and behavioural (REB) in the CHQ-PF50. Two concepts, PE and PT, are not applicable for CHQ-CF87 as the questionnaire is answered by the children themselves. These health concepts comprise multiple items or a single item. With the exception of the GH scale, the global behaviour item and the family cohesion item, the response to these items are based on a 4-week recall period. The response options of each item vary from 4–6 levels. For concepts with multiple items, the responses to the items are summed up and transformed to a scale that ranges from 0 (lowest possible score indicating the worst health) to 100 (highest possible score indicating the best health). Family cohesion, the only health concept comprising a single item in both CHQ-PF50 and CHQ-CF87, is also transformed to a 0–100 scale. We did not analyse CH in our study as this health concept was not validated in our previous Chinese version. We included questions on the prevalence of selected important chronic health conditions that had ever been diagnosed by a doctor, which included cardiorespiratory conditions, growth and endocrine conditions, neurological and developmental conditions, blood, oncology, immunology conditions, etc. The choices of these health conditions were based on local expert opinion, available local and overseas data on disease prevalence and CHSs of other countries.<sup>6</sup>

**Statistical methods and analysis**

We described the population characteristics with proportions and means and estimated the prevalence of chronic health conditions by age group of 5–10 years and 11–14 years. We used hierarchical linear regression<sup>1</sup> to explore the associations between chronic health conditions with each concept of the CHQ of the two age groups in two separate analysis. We put the physical and mental conditions as independent variables and as confounder. Each concept of the parent-reported or self-reported CHQ as dependent variables into the model with adjustment of potential confounders including child's gender and age, parents' marital status, parents' employment status and parents' education level. The size of the unstandardised regression coefficients indicated the mean difference between participants with that particular health condition and those without that health condition. The lower the score for CHQ concept, indicating worse health status as attained by the

participants with a particular health condition compared with those without it, the more negative value would be the regression coefficients. *p* Values of <0.05 were considered as significant. Analyses were conducted using SAS Software, V.9.1. (Cary, North Carolina, USA).

We used multiple analyses of variance (MANOVA) to evaluate the attributing effect of isolated physical health condition and that of isolated mental health condition on various concepts of the CHQ when compared with children without any health conditions. We also employed MANOVA to examine the effect of comorbid physical and mental health conditions on various concepts of CHQ. We categorised the participants into three groups: reported either one physical or one mental health condition; reported two comorbid physical and mental health conditions and reported three or more comorbid physical and mental health conditions. We adjusted the potential confounders including child's gender and age, parents' marital status, parents' employment status and parents' educational level. A *p* value of <0.01 was used in the post hoc tests following the MANOVA.

## RESULTS

The demographic characteristics of the sample are shown in table 1. There were 3223 children (1541 girls

and 1682 boys) aged 5–10 years (mean 7.8±1.7 years) and 2657 children (1268 girls and 1389 boys) aged 11–14 years (mean 12.5±1.2 years). There were slightly more parents had no or primary level of education for the younger age group than the older age group (7.9% vs 13.3%).

Table 2 shows the prevalence of health conditions tabulated by age group and gender. Mild-to-moderate vision problems (including short-sightedness, long-sightedness, astigmatism and colour-blindness), allergic rhinitis, eczema, food allergies and asthma were the top five health conditions reported in both age groups. Vision problems were more prevalent in women and in the older age group. Allergic rhinitis, food allergies and asthma were more prevalent in men in either age group. The prevalence of eczema was similar across either sex in children aged 5–10 years but more prevalent in women aged 11–14 years. Attention deficit hyperactivity disorder (ADHD) and then developmental delay were the commonest mental health conditions reported in both age groups with the conditions more prevalent in men than women.

Table 3 categorises the participants by age and by the number of reported health conditions: no physical or mental health condition; reported either one physical or one mental health condition; reported two comorbid physical and mental health conditions and reported

\*p<0.05; \*\*\*p<0.0001 different between sex in age 5–10 and 11–14 years; <sup>a</sup>p<0.0001 different between 5–10 and 11–14 years with  $\chi^2$  test.

three or more comorbid physical and mental health conditions. For children aged 5–10 years, around 70% of the parents reported that their children did not have any physical or mental health condition, 29% reported that their children had one physical health condition, 1% reported that their children had one mental health condition and 1.2% reported that their children had comorbid physical and mental health conditions. Fifty-two per cent of children aged 11–14 years reported no physical or mental health condition, 46% reported one physical health condition, 0.3% reported one mental health condition and 1.4% reported comorbid physical and mental health condition. Physical health

condition was more prevalent than mental health condition in either age group.

Table 4 shows that in children aged 5–10 years, 2 of 5 mental health conditions (40%) and 18 of 22 (82%) physical health conditions were found to have negative effect on various concepts of CHQ scores after adjusting for presence of other health conditions and potential confounders. The regression coefficients indicating the mean difference in CHQ scores between participants with a particular health condition and those without that health condition ranged from –1.1 to –53.7. The top three physical conditions with the most negative regression coefficients were chronic renal disease

**Table 3** Number (%) of children with physical, mental and both health conditions

Number of concerns	Number of children (%)
Children aged 5–10 years	
No physical or mental health condition	2081 (69.2)
One physical	858 (28.5)
One mental	26 (0.8)
Two conditions (one physical and mental)	16 (0.5)
Three or more conditions combination of physical and mental health condition	22 (0.7)
Children aged 11–14 years	
No physical or mental health condition	1252 (52.1)
One physical	1106 (46.0)
One mental	8 (0.3)
Two conditions (one physical and mental)	16 (0.6)
Three or more conditions combination of physical and mental health condition	20 (0.8)

(−53.7 on PE and −28 on PF); cancer (−28 on RP, −25 on RB, −21.5 on PF) and congenital malformations (−27 on FA and −20.2 on RB) while the mental health condition with the most negative regression coefficients were behavioural problems (−25.9 on PE, −24.7 on PT, −22 on FA, −19 on REB, −16.3 on BE, −15.6 on RP and −13.8 on MH). With regard to the extent of the effect, asthma, growth problem and speech problems were associated with negative effect on eight concepts of CHQ. Whereas behavioural problems, allergic rhinitis, cerebral palsy or other motor problems on seven and eczema on six of CHQ concepts.

As shown in table 5, children aged 11–14 years also reported were apparently less affected than younger children, with 3 of 5 mental health conditions (60%) and 11 of 22 (50%) physical health conditions having negative effect on various concepts of CHQ scores. The regression coefficients ranged from −1.3 to −40.5. The top three physical conditions with the most negative regression coefficients were congenital malformation (−40.5 on BP); diabetes (−34.3 on GH) and cardiac diseases (−23 on FA and −18.6 on MH). Behavioural problem was also the mental health condition having the most negative regression coefficient. For the extent of effect, growth problem was associated with negative effect on five concepts of CHQ, followed by mild vision problem and behavioural problems on four concepts.

Table 6 showed the different CHQ scores for health concepts in children of the two different age groups. For single health condition, children reported either one physical or one mental condition were compared with children reported neither physical nor mental

problem. For comorbid health conditions, children reported one physical and one mental health condition and children reported three or more comorbid physical and mental health conditions were compared with children reported either one physical or one mental condition.

For children aged 5–10 years, MANOVA showed a significant effect of physical and mental health condition on different scores for CHQ concepts ( $F(24, 5746)=3.76, p<0.0001$ ). There was an apparent, yet statistically not significant trend that those with isolated mental health problem had the lowest scores across all concepts of CHQ among the three groups (table 7). Post hoc tests using a significance  $p<0.01$  demonstrated that children with isolated mental condition reported significantly lower scores in 2 (REB, BE) of 12 concepts than those with isolated physical condition and those without any reported health condition. Children with isolated physical condition reported significantly lower scores on 2 (BE and PT) of 12 concepts than those without any reported health condition. Significant impact of physical and mental health condition on scores for CHQ concepts was also observed in children aged 11–14 years ( $F(22, 4058)=3.45, p<0.0001$ ). Similar to the younger age group, there was an apparent but statistically non-significant trend that those with isolated mental health condition had the lowest scores across all concepts of CHQ except in RE (table 7). Compared with children without any health condition, children with isolated physical condition reported significantly lower scores on 5 (PE, BP, RE, BE and FA) of 11 concepts and children with isolated mental condition reported significantly lower score in RE ( $p<0.01$ ).

Table 8 showed the MANOVA and post hoc test results for the effect of comorbid physical and mental health conditions on scores of CHQ concepts in the children of the two different age groups. MANOVA showed a significant effect of comorbid physical and mental health conditions on scores of CHQ concepts in both children aged 5–10 years ( $F(241, 786)=2.85; p<0.0001$ ) and in children aged 11–14 years ( $F(221, 970)=1.67; p<0.02777$ ). For the younger age group, post hoc tests demonstrated that children with three more comorbid physical and mental health conditions reported significantly lower scores in 7 of 11 CHQ concepts (GH, PE, BP, REB, FA, PE and PT) than those with one physical or one mental health condition; and one (BP) of 11 CHQ concepts than those with two comorbid physical and mental health condition. For children age 11–14 years, those with three or more comorbid physical and mental health conditions reported significantly lower scores in 1 of 11 CHQ concepts (RE) than those with one physical or one mental health condition.

## DISCUSSION

To the best of our knowledge, this is the first study of the association of physical and mental health conditions,

either individually or comorbidly, on the GH and well-being of Chinese children in a representative population sample. We show that the QoL of the participants and their parents are affected in multiple concepts in the presence of significant health problems. Children with an isolated mental health problem are apparently more affected than those with an isolated physical health problem. Having more health problems concurrently is associated with worse QoL. As CHS included a fairly representative sample of the target population<sup>3</sup>; thus the result could be generalised to children aged 5–14 in HK.

Mild-to-moderate vision problems, allergic rhinitis, eczema, food allergies and asthma were the top five health conditions reported in both age groups. Our results supported a local study which showed that the prevalence and progression of myopia in HK school-aged children was much higher than children in Western countries.<sup>7</sup> While there is evidence supporting genetic influence, the rapid increase in prevalence of myopia in Chinese children over past few decades

suggested an important interplay of environmental factors.<sup>8–9</sup> Yet studies that tried to elucidate these environmental factors, such as accommodative demand associated with near-work tasks such as schoolwork, yielded mixed results.<sup>10</sup> More research in this area is warranted for disease prevention. We found that allergic rhinitis was highly prevalent in children in HK, being the second commonest chronic health condition. Previous ISAAC study showed that prevalence of allergic rhinitis in children aged 6–7 years in HK ranked the second highest among the participating cities or countries.<sup>11</sup> The high prevalence of allergic rhinitis was postulated to be related to outdoor environmental pollutants in our locality.<sup>12</sup>

ADHD was the most commonly reported mental health problem in both age groups. While our results concurred with recent studies from other countries such as Australia and the USA,<sup>13–14</sup> which also showed that ADHD was the most prevalent mental health problems based on parent-report, our prevalence was much lower

(ranged from 4.8% in Germany between 2003 and 2006 to 9.5% in the USA in 2007).<sup>15</sup> Whether the observed difference is due to cultural acceptance or genetic pre-disposition awaits further evaluation.

Our study showed that our child population has been enjoying fairly good health with low reported prevalence of many physical and mental diseases, which was not unexpected as in many developed countries or cities. Nowadays, the concepts of highest attainable standard of health is not limited to improved survival, free of disease, the ability to perform daily activities but to well-being and QoL. In children and adolescents, HRQoL is a multidimensional construct covering physical, emotional, mental, social and behavioural components of well-being as perceived by the children and adolescents or their parents. The definition of HRQoL used for adults thus cannot be directly applied to them. Although there were concern whether children and adolescents could reliably express their own opinions, attitudes and feelings about HRQoL in the past, QoL questionnaires in children and adolescents have been increasingly developed, validated and shown that children and adolescents are able to report on their

well-being and functioning.<sup>16</sup> In fact, our study might be one of the largest studies using a child self-report QoL measure in a population based study and it supported the adoption of child self-report QoL questionnaire in addressing the issue of HRQoL in children and adolescents in the future. The use of both child self-report when age warranted and parent reported for younger ages within a study with fairly concurrent result is also a substantial strength of our study. There have been several studies showing the impact of individual health conditions on child health and well-being compared with healthy children using either a generic or specific type of QoL questionnaire.<sup>17–22</sup> A generic instrument allows comparison across children with different health conditions and healthy population samples while a disease-specific type can enhance sensitivity for concepts relevant to a particular health condition. However, studies comparing QoL across different health conditions were difficult to conduct. Most studies that adopted generic questionnaires such as CHQ or PedQL would thus examine patients of a specific health condition with healthy population samples in a single study and then compare other health conditions using the

existing database. Limitations included retrospective nature of comparison groups and failure to adjust or match the demographic characteristics across the groups. Our large population study partially reduced these limitations although caution needs to be exercised when interpreting the result of health conditions of very low prevalence. Our study showed that children with either mental or physical health conditions reported lower scores across more than one concept of CHQ that measure physical or psychosocial functioning. Chronic renal diseases, cancer and congenital malformation had the most significant negative effect on health-related QoL in children aged 5–10 years. The respective health conditions in children aged 11–14 years were congenital malformation, diabetes and cardiac diseases. Our study was similar to the findings of a recent cross-sectional, multicentre cohort study. It showed that children aged 2–18 years with renal dialysis had the lowest scores of all three concepts of PedQL when comparing with those with liver transplant, renal transplant, juvenile rheumatoid arthritis, type 1 diabetes, cancer in remission and cardiac disease.<sup>23</sup>

We found that children aged 5–10 years with an isolated mental health problem appeared to be more affected in their QoL when compared with either normal or children with an isolated physical health problem. In particular, the scores in concepts that measured general behaviour and role functioning in emotions and behaviour were significantly lower. Our result is consistent with previous studies in Western population.<sup>24</sup> Of interest, parents of children with isolated physical health conditions reported statistically significant lower scores in concept that measured parental impact on time but not for those parents with isolated mental health conditions. Such a trend was not observed in older children who reported CHQ scores by themselves.

Older children with an isolated physical health condition seemed to be more affected than those with an isolated mental health condition. The former had lower scores in concepts that measured physical health aspects, mental health aspects and family impact related to activities while the latter had lower score in concepts that measure role functioning—emotional only when compared with those without any. Unexpectedly, there were apparent higher scores in concepts that measured mental health, self-esteem and family impact on activities in those with isolated mental condition. We believe that the observation could be due to the small number of children with an isolated mental health problem that might have skewed the result rather than being a genuine effect.

Our study also supported other studies<sup>7–11</sup> which reported that having a greater number of health problems is associated with poorer QoL across different CHQ concepts. The effect was more prominent in our children aged 5–10 years. Those with three or more comorbid health conditions were significantly more affected than those with two health conditions in one

concept and those with only one health condition in seven concepts. In older children aged 11–14 years, those with three comorbid health conditions were significantly more affected than those with one health condition in one concept only.

There were limitations to our study which require attention regarding drawing conclusions: first, we used parental reports of physician diagnosed health conditions to estimate the prevalence. The findings may be different from the reported prevalence by physicians; however, parental reports have been widely adopted in population health study. Moreover, previous studies showed that self-report measures of health conditions are fairly accurate.<sup>25</sup> Our results also concurred favourably with previous local condition-specific prevalence studies.<sup>7–11</sup> We did not attempt to analyse individual health conditions. For some very low prevalent health conditions such as diabetes, rheumatic diseases, the results are based on a small sample size. Second, we could not ensure absolute confidentiality in children aged 10–14 years who reported CHQ themselves due to in general small household size in our local population. The possibility of over-rating certain health concepts such as family activities, family cohesion could not be completely ruled out. Lastly, while our study suggests that there may be possible cultural differences in disease acceptance and perception of QoL between our HK Chinese and Caucasians, it may not be directly applicable to Chinese elsewhere as the living environment and standards, societal influence, social values, etc are different.

## CONCLUSION

Our study shows important information concerning the prevalence of different health conditions and its association on the QoL in a representative sample of Chinese children in HK. The information may be used for comparing the impact of various conditions and for measurement of the impact of having more than one condition on health and well-being so as to provide a surveillance framework for promotion and preventive health programmes.
